Abstract
We study the STEINER TREE problem on unit disk graphs. Given a \( n \) vertex unit disk graph \( G \), a subset \( R \subseteq V(G) \) of \( t \) vertices and a positive integer \( k \), the objective is to decide if there exists a tree \( T \) in \( G \) that spans over all vertices of \( R \) and uses at most \( k \) vertices from \( V \setminus R \). The vertices of \( R \) are referred to as terminals and the vertices of \( V(G) \setminus R \) as Steiner vertices. First, we show that the problem is NP-hard. Next, we prove that the STEINER TREE problem on unit disk graphs can be solved in \( n^{O(\sqrt{t+k})} \) time. We also show that the STEINER TREE problem on unit disk graphs parameterized by \( k \) has an FPT algorithm with running time \( 2^{O(k)}n^{O(1)} \). In fact, the algorithms are designed for a more general class of graphs, called clique-grid graphs Fomin (Discret. Comput. Geometry 62(4):879–911, 2019). We mention that the algorithmic results can be made to work for STEINER TREE problem on disk graphs with bounded aspect ratio. Finally, we prove that STEINER TREE problem on disk graphs parameterized by \( k \), is W[1]-hard.

Keywords Unit Disk Graphs · FPT · Subexponential exact algorithms · NP-Hardness · W-Hardness

1 Introduction

Given a graph $G$ with a weight function $w : E(G) \to \mathbb{R}^+$ and a subset $R \subseteq V(G)$ of vertices, a Steiner tree is an acyclic subgraph of $G$ spanning all vertices of $R$. The vertices of $R$ are usually referred to as terminals and the vertices of $V(G) \setminus R$ as Steiner vertices. The Minimum Steiner Tree problem is to find a Steiner tree $T$ such that the total weight of $E(T)$ is minimized. In the Steiner Tree problem, given a graph $G$, a subset $R \subseteq V(G)$ of vertices and a positive integer $k$, the objective is to determine if there exists a Steiner tree $T$ in $G$ for the terminal set $R$ such that the number of Steiner vertices in $T$ is at most $k$. The Steiner Tree problem is one of Karp’s classic NP-complete problems [1]; moreover, that makes the optimization problem NP-hard.

A special case of the Minimum Steiner Tree problem is the Metric Steiner Tree problem. Given a complete graph $G = (V, E)$, each vertex corresponds to a point in a metric space, and for each edge $e \in E$ the weight $w(e)$ corresponds to the distances in the space. In other words, the edge weights satisfy the triangle inequality. It is well known that, given an instance of the non-metric Steiner tree problem, it is possible to transform it in polynomial time into an equivalent instance of the Metric Steiner Tree problem. Moreover, this transformation preserves the approximation factor [2]. The Euclidean Steiner Tree problem or Geometric Steiner Tree problem takes as input $n$ points in the plane. The objective is to connect them by lines of minimum total length in such a way that any two points may be interconnected by line segments either directly or via other points and line segments. The Minimum Steiner Tree problem is NP-hard even in Euclidean or Rectilinear metrics [3].

Arora [4] showed that the Euclidean Steiner Tree and Rectilinear Steiner Tree problems can be efficiently approximated arbitrarily close to the optimal. Several approximation schemes have been proposed over the years on Minimum Steiner Tree for graphs with arbitrary weights [5–8]. Although the Euclidean version admits a PTAS, it is known that the Metric Steiner Tree problem is APX-complete. There is a polynomial-time algorithm that approximates the minimum Steiner tree to within a factor of $\ln(4) + \epsilon \approx 1.386$ [9]; however, approximating within a factor $\frac{96}{95} \approx 1.0105$ is NP-hard [10].

The decision version, Steiner Tree is well-studied in parameterized complexity. A well-studied parameter for the Steiner Tree is the number of terminals $t = |R|$. It is known that the Steiner Tree is FPT for this parameter due to the classical result of Dreyfus and Wagner [11]. Fuchs et al. [12] and Nederlof [13] gave alternative algorithms for Steiner Tree parameterized by $t$ with running times that are not comparable with the Dreyfus and Wagner algorithm. On the other hand, Steiner Tree parameterized by the number of Steiner vertices $k$ is W[2]-hard [14]. Hence, the focus has been on designing parameterized algorithms for graph subclasses like planar graphs [15], $d$-degenerate graphs [16], etc. In [17], Dcořáč et al. designed an efficient parameterized approximation scheme (EPAS) for the Steiner Tree parameterized by $k$.1

In this paper, we study the **Steiner Tree** problem on unit disk graphs when the parameter is the number of Steiner vertices \( k \). Unit disk graphs are the geometric intersection graphs of unit circles in the plane. That is, given \( n \) unit circles in the plane, we have a graph \( G \) where each vertex corresponds to a circle such that there is an edge between two vertices when the corresponding circles intersect. Unit disk graphs have been widely studied in computational geometry and graph algorithms due to their usefulness in many real-world problems, e.g., optimal facility location [18], wireless and sensor networks; see [19, 20]. These led to the study of many NP-complete problems on unit disk graphs; see [21, 22].

There are some works on variants of **Minimum Steiner Tree** on unit disk graphs in the approximation paradigm. Li et al. [23] studied node-weighted Steiner trees on unit disk graphs, and presented a PTAS when the given set of vertices is \( c \)-local. Moreover, they used this to solve the node-weighted connected dominating set problem in unit disk graphs and obtained a \((5 + \varepsilon)\)-approximation algorithm. In [24], Biniaz et al. studied the **Full Steiner Tree** problem on unit disk graphs. They presented a 20-approximation algorithm for this problem, and for \( \lambda \)-precise graphs gave a \((10 + \frac{1}{2})\)-approximation algorithm where \( \lambda \) is the length of the longest edge. Although there have been a plethora of work on variants of the **Minimum Steiner Tree** problem on unit disk graphs in approximation algorithms, hardly anything is known in parameterized complexity for the decision version. In this regard, we refer to the work of Marx et al. [25] who investigated the parameterized complexity of the **Minimum Steiner Tree** problem on planar graphs, where the number of terminals \( t \) is regarded as the parameter. They have designed an \( n^{O(\sqrt{t})} \)-time exact algorithm, and showed that this problem on planar graphs cannot be solved in time \( 2^{o(t)} \cdot n^{O(1)} \), assuming ETH. However, these results do not directly apply on unit disk graphs as unit disk graphs can contain very large cliques, but, then planar graphs contains arbitrarily large stars. Recently, Berg et al. [26] showed that the **Steiner Tree** problem can be solved in \( 2^{O(t^{1-\frac{1}{d}})} \) time on intersection graphs of \( d \)-dimensional similarly-sized fat objects, for some \( d \in \mathbb{Z}^+ \).

More often than not, the geometric intersection graph families such as unit disk graphs, unit square intersection graphs, rectangle intersection graphs, provide additional geometric structure that helps to generate algorithms. In this paper, our objective is to understand parameterized tractability landscape of the **Steiner Tree** problem on unit disk graphs.

**Our Results.** First in Sect. 3, we show that **Steiner Tree** on unit disk graphs is NP-hard. Then, in Sect. 4, we design a subexponential time algorithm for the **Steiner Tree** problem on unit disk graphs parameterized by the number of terminals \( t \) and the number of Steiner vertices \( k \).

**Theorem 1** **Steiner Tree** on unit disk graphs can be solved in \( n^{O(\sqrt{t+k})} \) time.

The approach to design this subexponential time algorithm is very similar to that used in [27]. First, we apply a Baker-like shifting strategy to create a family \( \mathcal{F} \) of instances (of **Exact Steiner Tree**, which is a variant of **Steiner Tree**) such that

---

2 A full Steiner tree is a Steiner tree which has all the terminal vertices as its leaves.
if the input instance \((G, R, t, k)\) is a yes-instance then there is at least one constructed instance in \(\mathcal{F}\) that is a yes-instance of EXACT STEINER TREE. On the other hand, if \((G, R, t, k)\) is a no-instance of STEINER TREE, then no instance of \(\mathcal{F}\) is a yes-instance of EXACT STEINER TREE. With the knowledge that the answer is preserved in the family \(\mathcal{F}\), we design a dynamic programming subroutine to solve EXACT STEINER TREE on each of the constructed instances of \(\mathcal{F}\).

Next, in Sect. 5, we show that the STEINER TREE on unit disk graphs has an FPT algorithm when parameterized by \(k\).

**Theorem 2** STEINER TREE on unit disk graphs can be solved in \(2^{O(k)} n^{O(1)}\) time.

Here, we show that solving the STEINER TREE problem on an instance \((G, R, t, k)\) is equivalent to solving the problem on an instance \((G', R', t', k)\) where the graph \(G'\) is obtained by contracting all connected components of \(G[R]\). Although \(G'\) loses all geometric properties, we show that the number of terminals in \(R'\) is only dependent on \(k\). This essentially changes the problem to running the Dreyfus-Wagner algorithm on \((G', R', t', k)\).

Both the results in Theorem 1 and 2 are shown to work for a superclass of graphs, called clique-grid graphs. We would like to remark that the algorithms can also be made to work for disk graphs with constant aspect ratio.

Finally, in contrast, in Sect. 6 we prove that the STEINER TREE problem for disk graphs is \(W[1]\)-hard, parameterized by the number Steiner vertices \(k\). The STEINER TREE problem is known to be \(W[2]\)-hard on general graphs [14]. However, it is not clear how to use that reduction for disk graphs. We show a reduction of our problem from Grid Tiling with \(\geq\) [28], ruling out the possibility of a \(f(k) n^{\alpha(k)}\) time algorithm for any function \(f\), assuming ETH. The Grid Tiling with \(\geq\) problem is a generalization of the better known Grid Tiling Problem. Given an integer \(n\), a \(k \times k\) matrix for an integer \(k\) and a set of pairs \(S_{ij} \subseteq [n] \times [n]\) of each cell, the objective is to find, for each \(1 \leq i, j \leq k\), a value \(s_{ij} \in S_{ij}\) such that if \(s_{ij} = (a, b)\) and \(s_{i+1,j} = (a', b')\) then \(a \geq a'\); if \(s_{ij} = (a, b)\) and \(s_{i,j+1} = (a', b')\) then \(b \geq b'\).

**Theorem 3** The STEINER TREE problem on disk graphs is \(W[1]\)-hard, parameterized by the number of Steiner vertices \(k\).
Observation 4 A tree $T$ is a $k$-Steiner tree for an instance $(G, R, t, k)$ if and only if $T$ is an exact $k'$-Steiner tree for the instance $(G, R, t, k')$ of Exact Steiner Tree for some $k' \leq k$.

Definition 5 [27] A graph $G$ is a clique-grid graph if there is a pair $p, p' \in \mathbb{N}$ and a function $f : V(G) \rightarrow [p] \times [p']$ such that the following conditions hold:
1. For all $(i, j) \in [p] \times [p']$, $f^{-1}(i, j)$ is a clique in $G$.
2. For all $uv \in E(G)$, if $f(u) = (i, j)$ and $f(v) = (i', j')$ then $|i - i'| \leq 2$ and $|j - j'| \leq 2$.

Such a function $f$ is called a representation of the graph $G$.

Unit disk graphs are clique-grid graphs [27]. Next, we define a representation of a clique-grid graph called a cell graph.

Definition 6 [27] Given a clique-grid graph $G$ with representation $f : V(G) \rightarrow [p] \times [p']$, the cell graph $cell(G)$ is defined as follows:
- $V(cell(G)) = \{vi_j | i \in [p], j \in [p'], f^{-1}(i, j) \neq \emptyset\}$,
- $E(cell(G)) = \{vi_j v'i'j' | (i, j) \neq (i', j'), \exists u \in f^{-1}(i, j) \text{ and } \exists v \in f^{-1}(i', j') \text{ such that } uv \in E(G)\}$.

For each vertex $v_{ij} \in V(cell(G))$, the pair $(i, j)$ is also called a cell of $G$ and by definition corresponds to a non-empty clique of $G$. A vertex $v \in V(G)$ is said to be in the cell $(i, j)$ if $f(v) = (i, j)$. The set of neighbours of a cell $C = (i, j)$ in a cell $C' = (i', j') \neq C$ is the vertex subset $\{v \in V(G)| f(v) = (i', j')\}$.

Let $G$ be a graph. A path decomposition of a graph $G$ is a pair $T = (P, \beta : V(P) \rightarrow 2^{V(G)})$, where $P$ is a path where every node $p \in V(P)$ is assigned a subset $\beta(p) \subseteq V(G)$, called a bag, such that the following conditions hold: (i) $\bigcup_{p \in V(P)} \beta(p) = V(G)$, (ii) for every edge $xy \in E(G)$ there is a $p \in V(P)$ such that $\{x, y\} \subseteq \beta(p)$, and (iii) for any $v \in V(G)$ the subgraph of $P$ induced by the set $\{p | v \in \beta(p)\}$ is connected. A path decomposition will also be denoted as a sequence of bags $\{\beta(p_1), \beta(p_2), \ldots, \beta(p_q)\}$ where $P = p_1p_2\ldots p_q$. The width of a path decomposition is $\max_{p \in V(P)} |\beta(p)| - 1$. The pathwidth of $G$ is the minimum width over all path decompositions of $G$ and is denoted by $pw(G)$. Given a path decomposition of a graph $G$, we say it is rooted at exactly one of the two degree one vertices of the underlying path.

Definition 7 [27] A path decomposition $T = (P, \beta)$ of a clique-grid graph $G$ with representation $f : V(G) \rightarrow [p] \times [p']$ is a nice $\ell$-clique path decomposition ($\ell$-NCPD) if for the root $r$ of $P$, $\beta(r) = \emptyset$ and for each $v \in V(P)$ the following hold:
1. There are at most $\ell$ cells $\{(i_1, j_1), (i_2, j_2), \ldots, (i_\ell, j_\ell)\}$ such that $\beta(v) = \bigcup_{p=1}^{\ell} f^{-1}(i_p, j_p)$.
2. The node $v$ is one of the following types: (i) Leaf node where $\beta(v) = \emptyset$, (ii) Forget node where $v$ has exactly one child $u$ and there is a cell $(i, j) \in [p] \times [p']$ such that $f^{-1}(i, j) \subseteq \beta(u)$ and $\beta(v) = \beta(u) \setminus f^{-1}(i, j)$, (iii) Introduce node where $v$ has exactly one child $u$ and there is a cell $(i, j) \in [p] \times [p']$ such that $f^{-1}(i, j) \subseteq \beta(v)$ and $\beta(u) = \beta(v) \setminus f^{-1}(i, j)$.
See Fig. 1 for an example of an NCPD. A path decomposition for a clique-grid graph $G$ with representation $f$ where only property 1 of Definition 7 is true for a positive number $\ell$ is referred to as an $\ell$-CPD.

### 3 NP-Hardness of Steiner Tree on Unit Disk Graphs

In this section, we consider the Steiner Tree problem on unit disk graphs and prove that this problem is NP-hard. We show a reduction from Connected Vertex Cover in planar graphs with maximum degree 4. The reduction is very similar to that in [29].

**Theorem 8** The Steiner Tree problem on unit disk graphs is NP-hard.

**Proof** We show a reduction from the Connected Vertex Cover in planar graphs with maximum degree 4 problem, which is known to be NP-hard [3]. Given a planar graph $G$ with maximum degree 4 and an integer $k$, the Connected Vertex Cover problem asks to find if there exists a vertex cover $D$ for $G$ such that the subgraph induced by $D$ is connected and $|D| \leq k$. We adopt the proof of Abu-Affash [29], where it was shown that the $k$-Bottleneck Full Steiner Tree problem is NP-hard. We make this reduction compatible for unit disk graphs. Given a planar graph $G$ with maximum degree 4 and an integer $k$, we construct an unit disk graph $G_C$ where $V(G_C) = \mathcal{C}$ in polynomial time, where $V(G_C)$ is divided into two sets of unit disks $R$ and $S$, denoted by Steiner and terminals, respectively. Let $V(G) = \{v_1, v_2, \ldots, v_n\}$ and let $E(G) = \{e_1, e_2, \ldots, e_m\}$. Then, we compute an integer $k'$ such that $G$ has a connected vertex cover $D$ of size $k$ if and only if there exists a Steiner Tree with at most $k'$ Steiner vertices of $G_C$.

As an intermediate step we build a rectangular grid graph $G'$. First, we embed $G$ on a rectangular grid, with distance at least 8 between adjacent vertices. Each vertex $v_i \in V(G)$ corresponds to a grid vertex, and each edge $e = v_i v_j \in E(G)$ corresponds to a rectilinear path comprised of some horizontal and vertical grid segments with endpoints corresponding to $v_i$ and $v_j$. Let $V(G') = \{v'_1, \ldots, v'_n\}$ be the grid points corresponding to the vertices of $V(G)$, and let $E(G') = \{p_{e_1}, \ldots, p_{e_m}\}$ be the set of paths corresponding to the edges of $E(G)$. Moreover, these paths are pairwise disjoint; see Fig. 2b. This embedding can be done in $O(n)$ time and the size of the grid is at
most $n - 2$ by $n - 2$; see [30]. Next, we construct an unit disk graph $G_C$ from $G'$. First, we replace each grid vertex $v_i' \in V(G')$ by an unit disk. Let $C = \{c_1, \ldots, c_n\}$ be the set of unit disks centered at the grid points corresponding to the vertices of $V(G')$. For the sake of explanation we call these disks grid point disks. At this point, the unit disk graph is not connected due to the edge length which we have taken between any two adjacent vertices in the grid graph. In fact this length ensures that there are no undesirable paths other than the ones in $G$. Next, we place two sets of disks on each path $p_e_i \in E(G')$. Let $|p_e_i|$ be the total length of the grid segments of $p_e_i$. We place two Steiner disks on $p_e_i$, such that each one of them is adjacent to a grid point disk corresponding to $p_e_i$ and the distance between their centers is exactly 2. Next, we place $|p_e_i| - 6/2$ many terminals disks on $p_e_i$ such that the distance between any two adjacent centers is exactly 2. See Fig. 2c for detailed explanation. Let $s(e_i)$ be the set of Steiner disks and $t(e_i)$ be the set of terminal disks placed to $p_e_i$. The terminal set $R = \bigcup_{e_i \in E(G')} t(e_i)$; the Steiner set $S = C \cup \bigcup_{e_i \in E(G')} s(e_i)$. $V(G_C) = R \cup S$ and $G_C$ is the intersection graph induced by $V(G_C)$. Finally, we set $k' = m + 2k - 1$. Observe that, for any path $p_e_i$, the terminal set $t(e_i)$ itself form a Steiner tree without any Steiner disks. However, in order to make that tree connected we need at least one of Steiner disks from $s(e_i)$. This completes the construction.

In the forward direction, suppose $G$ has a connected vertex cover $D$ of size at most $k$. We construct a Steiner tree of $R$ in the following manner. For each edge $e_i$, we simply take the terminal path induced by $t(e_i)$. Now, let $T_S$ be any spanning tree of the subgraph of $G$ induced by $D$, containing $|D| - 1$ edges. The existence of such a spanning tree is ensured since $D$ is a connected vertex cover of $G$. For each edge $e = v_i v_j \in T_S$ we connect the corresponding disks $c_i, c_j$ by two Steiner red disks adjacent to them. Then, for each edge $e = v_i v_j \in G \setminus T_S$ we select one endpoint that is in $D$ (say $v_j$) and connect $c_i$ to the tree by its adjacent disk. The constructed tree is a Steiner tree of $R$ consisting $|D| + 2(|D| - 1) + (m - (|D| - 1))$ which is $m + 2k - 1$.

Conversely, let there exists a Steiner tree $T$ of $R$ with at most $k'$ Steiner disks. Let $D \subseteq C$ be the set of vertices that appear in $T$, and let $T'$ be the subtree of $T$. Fig. 2 (a) A planar graph $G$ of maximum degree 4, (b) the intermediate rectilinear embedding $G'$ of $G$, (c) the unit disk graph $G_C$; the black disks are corresponding to the grid vertices of $G'$, the red disks are Steiner disks and the blue disks are the terminal disks (Color figure online)
spanning over $D$. For each subset $t(e_i) \subseteq R$, let $T_{e_i}$ be the subtree of $T_{e_i}$ spanning the vertices in $t(e_i)$. By the above construction, $T_{e_i}$ does not require any Steiner disk. Moreover, it is easy to see that in any valid solution $T_{e_i}$ must be connected to at least one endpoint of $D$. This implies that the set of vertices in $G$ corresponding to the vertices in $D$ is a connected vertex cover of $G$. Moreover a tree $T_{e_i}$ which also a subtree of $T$ is connected to $D$ via two Steiner disks of $s(e_i)$. Therefore, $T_S$ contains $|D| + 2(|D| - 1) + (m - (|D| - 1))$ many Steiner disks. We started with the tree $T$ with at most $k' = m + 2k - 1$ many Steiner disks. This completes the proof. \qed

4 Subexponential Time Exact Algorithm for Steiner Tree on Unit Disk Graphs

In this section, we prove Theorem 1 by designing a subexponential time algorithm for the Steiner Tree problem on unit disk graphs parameterized by $t + k$, where $t$ is the number of terminals and $k$ is an upper bound on the number of Steiner vertices. In fact, our aim for this section is to design a subexponential time algorithm for Steiner Tree on clique-grid graphs and as unit disk graphs are clique-grid graphs [27], this would imply the algorithm proposed in Theorem 1.

**Lemma 9** The Steiner Tree problem on clique-grid graphs can be solved in $n^O(\sqrt{t+k})$ time.

For the rest of the section, we concentrate on proving Lemma 9. Informally, we first apply a Baker-like shifting strategy to create a family $\mathcal{F}$ of instances of Exact Steiner Tree that preserves the answer for the input instance $(G, R, t, k)$ of Steiner Tree: if $(G, R, t, k)$ is a yes-instance then there is at least one constructed instance in $\mathcal{F}$ that is a yes-instance of Exact Steiner Tree; if $(G, R, t, k)$ is a no-instance of Steiner Tree then all instances of $\mathcal{F}$ are no-instances of Exact Steiner Tree. As a second step, we design a dynamic programming subroutine to solve Exact Steiner Tree on each of the constructed instances of $\mathcal{F}$, which is enough to solve the Steiner Tree problem on $(G, R, t, k)$.

Before we describe the subexponential time algorithm, we state some properties of Steiner trees in clique-grid graphs.

**Observation 10** Consider a $k$-Steiner tree $T$ for a clique-grid graph $G$ with representation $f$, such that the set $\{uv \in E(T) | f(u) \neq f(v)\}$ is minimised over all $k$-Steiner trees for $G$. Let $C = (i, j)$ be a cell of $G$. Then there are at most 24 edges with one endpoint in $C$ and the other endpoint in another cell.

**Proof** We claim that in the $k$-Steiner tree where the set $\{uv \in E(T) | f(u) \neq f(v)\}$ is minimised, there can be at most one neighbour of $C$ in each cell $C' \neq C$. Suppose that $C'$ is a cell that contains at least two neighbours of $C$. Let two such neighbours be $u', v'$. Note that $u'v'$ is an edge in $E(G)$. Let $u, v$ (may be the same) be the neighbours of $u', v'$, respectively in $C$. Note that $uv$ is an edge in $E(G)$. Thus adding the edge $u'v'$ and removing the edge $uv$ results in a connected graph containing all the terminals. The spanning tree of this connected graph has strictly less number of edges with endpoints in different cells, which is a contradiction to the choice of $T$. \[ Springer \]
By the definition of clique-grid graphs, \(|i - i'|, |j - j'| \leq 2\). Thus, when we fix a cell \(C\) there are at most 24 cells that can have neighbours of vertices in \(C\). Putting everything together, for the \(k\)-Steiner tree \(T\) where the set \(\{uv \in E(T) \mid f(u) \neq f(v)\}\) is minimised, \(|\{v \mid f(v) \neq (i, j), \exists u \text{ such that } f(u) = (i, j), uv \in E(G)\}| \leq 24\). □

**Observation 11** Suppose there is a \(k\)-Steiner tree for a clique-grid graph \(G\), and let \(T\) be a \(k\)-Steiner tree where the set \(\{uv \in E(T) \mid f(u) \neq f(v)\}\) is minimised. Moreover, amongst \(k\)-Steiner trees where \(\{uv \in E(T) \mid f(u) \neq f(v)\}\) is minimised, \(T\) has minimum number of Steiner points. Then, in \(T\) the number of Steiner vertices per cell is at most 24.

**Proof** For the sake of contradiction, let \(C = (i, j)\) be a cell such that \(|f^{-1}(i, j) \cap V(T)| \geq 24 + 1\). Then by Observation 10, there is at least one Steiner vertex \(v \in f^{-1}(i, j) \cap V(T)\) such that it does not have any neighbours in \(T \setminus f^{-1}(i, j)\). Consider the subgraph \(T \setminus \{v\}\). Since the vertices of \(f^{-1}(i, j)\) induce a clique, \(T \setminus \{v\}\) is still a connected subgraph that contains all the terminals and strictly less number of Steiner vertices. Thus, a spanning tree of this connected subgraph contradicts the choice of \(T\). □

Consider a \(k\)-Steiner tree \(T\) for an instance \((G, R, t, k)\) of \textsc{Steiner Tree} where \(\{uv \in E(T) \mid f(u) \neq f(v)\}\) is minimised and then the number of Steiner vertices is minimised. By Observation 4, \(T\) is an exact \(k'\)-Steiner tree for the instance \((G, R, t, k')\) of \textsc{Exact Steiner Tree} for some \(k' \leq k\). Next, we define a good family of instances that preserve the answer for \((G, R, t, k)\) of \textsc{Steiner Tree}.

**Definition 12** For an instance \((G, R, t, k)\) of \textsc{Steiner Tree} on clique-grid graphs where \(G\) has representation \(f\), a good family of instances \(\mathcal{F}\) has the following properties:

1. For each instance \((H, R, t, k')\) in the family, the input graph \(H\) is an induced subgraph of \(G\) that contains all vertices in \(R\) and \(k' \leq k\). Note that \(H\) is also a clique-grid graph where \(f|_{V(H)}\) is a representation.
2. \((G, R, t, k)\) is a yes-instance of \textsc{Steiner Tree} if and only if there exists an instance \((H, R, t, k') \in \mathcal{F}\) which is a yes-instance of \textsc{Exact Steiner Tree}.
3. For any instance \((H, R, t, k') \in \mathcal{F}, H\) has a \(7\sqrt{t} + k\)-NCPD.

We show that given an instance \((G, R, t, k)\) of \textsc{Steiner Tree} on clique-grid graphs, a good family of instances can be enumerated in subexponential time.

**Lemma 13** Given an instance \((G, R, t, k)\) for \textsc{Steiner Tree} on clique-grid graphs with \(G\) represented by \(f\), a good family of instances \(\mathcal{F}\) can be computed in \(n^{O(\sqrt{t+k})}\) time.

**Proof** Let \(T\) be a \(k\)-Steiner tree for \(G\). In particular, \(T\) is an exact \(k'\)-Steiner tree for some \(k' \leq k\) and \(V(T) = t+k' \leq t+k\). First, we employ a Baker-like technique similar to [27] (please refer to Fig. 3). Note that if \(G\) has \(n\) vertices and has representation \(f : V(G) \to [p] \times [p'],\) then \(p, p' \leq n\). Thus, \(f\) represents \(G\) on the \(n \times n\) grid. First we define a column of the \(n \times n\) grid. For any \(j \in [n]\) the set of cells \(((i, j)|i \in [n])\) is
called a column. There are \( n \) columns for the \( n \times n \) grid. We partition the \( n \) columns of the \( n \times n \) grid with \( n/2 \) blocks of two consecutive columns and label them from the set of labels \( \{\sqrt{\ell + k}\} \). Formally, each set of consecutive columns \( \{2i - 1, 2i\} \), where \( i \in [n/2] \) is labelled with \( i \mod \sqrt{\ell + k} \). Thus, all the two consecutive columns \( \{2i - 1, 2i\} \) are labelled with \( i \mod \sqrt{\ell + k} \).

Recall that an exact \( k' \)-Steiner tree \( T \) has at most \( t + k \) vertices. Applying the pigeonhole principle, there is a label \( \ell \in \{1, 2, \ldots, \sqrt{t + k}\} \) such that the number of vertices from \( V(T) \) which are in columns labelled \( \ell \) is at most \( \sqrt{t + k} \). As we do not know this \( k' \)-Steiner tree \( T \), we guess the Steiner vertices of \( V(T) \) which are in the columns labelled \( \ell \). The number of potential guesses is bounded by \( n^O(\sqrt{t + k}) \).

Suppose \( Y' \) is the set of guessed Steiner vertices of \( V(T) \) which are in the columns labelled by \( \ell \). Then we delete all the non-terminal vertices in columns labelled \( \ell \), except the vertices of \( Y' \). Let \( S \) be the set of deleted non-terminal vertices. Let \( Y_R \) be the set of terminal vertices that are in columns labelled by \( \ell \). Let \( Y = Y' \cup Y_R \). Notice that by choice of label \( \ell \), \( |Y| \leq \sqrt{t + k} \). By Property 2 of clique-grid graphs, \( G \backslash (S \cup Y) \) is a disjoint union of clique-grid graphs each of which is represented by a function with at most \( 2\sqrt{t + k} \) columns. Formally, \( G_1 = G[\bigcup_{j=1}^{2(\ell - 1)} f^{-1}(\ast, j)] \) and \( G_{i+1} = G[\bigcup_{j=i+2}^{\min(i, 2\ell + 2\sqrt{t + k} - n)} f^{-1}(\ast, j)] \) for each \( i \in \{1, \ldots, n/\sqrt{t + k}\} \). Each \( G_i \) is a clique-grid graph with representation \( f_i : V(G_i) \to [n] \times [2\sqrt{t + k}] \) defined as, \( f_i(u) = (r, j) \), when \( f(u) = (r, (i - 1)2\ell + j) \). Thus, by Property 2 of Definition 5, \( G \backslash (S \cup Y) = G_1 \uplus \ldots \uplus G_{n/\sqrt{t + k}} \).

**Claim 14** The graph \( G \backslash S \) has a \( 7\sqrt{t + k} \)-NCPD.

**Proof** Suppose we are able to show that for each \( i \in \{1, \ldots, n/\sqrt{t + k}\} \) \( G_i \) has a \( 6\sqrt{t + k} \)-CPD. This results in a \( 6\sqrt{t + k} \)-CPD for \( G \backslash (S \cup Y) = G_1 \uplus \ldots \uplus G_{n/\sqrt{t + k}} \).

Finally, note that \( |Y| \leq \sqrt{t + k} \) and therefore the vertices of \( Y \) can belong to at most \( \sqrt{t + k} \) cells. We add \( Y \) to all the bags in the \( 6\sqrt{t + k} \)-CPD for \( G \backslash (S \cup Y) \) to obtain a \( 7\sqrt{t + k} \)-CPD for \( G \backslash S \). We convert the \( 7\sqrt{t + k} \)-CPD of \( G \backslash S \) into a NCPD using the known algorithm of [31]. Note that this results in a \( 7\sqrt{t + k} \)-NCPD.
What is left to show is that for each $G_i$ there is a $6\sqrt{i + k}$-CPD. First, for each $G_i$, we give a path decomposition with the following sequence of bags: $\{X_1, X_2, \ldots, X_{n-2}\}$. This is done by defining each $X_i = f^{-1}(i, *) \cup f^{-1}(i + 1, *) \cup f^{-1}(i + 2, *)$. It is easy to check that this is a path decomposition of $G_i$. Note that since $G_i$ has at most $2\sqrt{i + k}$ columns, the number of cells contained in each $X_j$, $j \in [n - 1]$ is at most $6\sqrt{i + k}$.

Finally, notice that from the definition of the constructed instances keeping in mind potential $k$-Steiner trees, $(G, R, t, k)$ is a yes-instance of STEINER TREE if and only if there is an instance $(H, R, t, k') \in \mathcal{F}$ such that it is a yes-instance of EXACT STEINER TREE. Thus, accounting for guessing a label $\ell \in [\sqrt{i + k}]$ and the set $Y$ of Steiner vertices and terminal vertices of a potential solution Steiner tree that belong to columns labelled $\ell$, we obtain a good family of $nO(\sqrt{i + k})$ instances for the given instance $(G, R, t, k)$.

For the ease of our algorithm design, we make a slight modification of the NCPD for a constructed instance $(H, R, t, k') \in \mathcal{F}$: Upon fixing the label $\ell$ and a set $Y$ of terminal vertices and potential Steiner vertices in the columns labelled by $\ell$, we add the set $Y$ in all the bags of the resulting NCPD for $G \setminus S$. Therefore, no bag is empty after this modification. In particular the first and the last bags of the modified path decomposition contain only the set $Y$. Also notice that as $|Y| \leq \sqrt{i + k}$, the new path decomposition of $H$ is still an $O(\sqrt{i + k})$-CPD. We call this new path decomposition of $H$ a modified NCPD. Now, we are ready to prove Lemma 9.

**Proof of Lemma 9** As a first step of the algorithm, by Lemma 13 in $nO(\sqrt{i + k})$ time we compute a good family of instances $\mathcal{F}$ for the given instance $(G, R, t, k)$ of STEINER TREE on clique-grid graphs. From Definition 12(2), $(G, R, t, k)$ is a yes-instance of STEINER TREE if and only if there is an instance $(H, R, t, k') \in \mathcal{F}$ that is a yes-instance of EXACT STEINER TREE. Deriving from Definition 12(3), Lemma 13 and the construction of a modified NCPD, for each instance $(H, R, t, k') \in \mathcal{F}$, there is a modified $O(\sqrt{i + k})$-NCPD for $H$, due to a guessed label $\ell$ and a guessed set $Y$ of non-terminal vertices from columns labelled by $\ell$ such that the following hold: (i) $|Y| \leq \sqrt{i + k}$, (ii) if $(H, R, t, k')$ is a yes-instance then there is an exact $k'$-Steiner tree $T$ such that all vertices of $Y$ are Steiner vertices in $T$. Let the modified NCPD using the set $Y$ have the sequence of bags $\{X_1, X_2, \ldots, X_q\}$. Recall that the definition of the modified NCPD ensures that $X_1 = X_q = Y$.

In the next step, our algorithm for STEINER TREE considers every instance $(H, R, t, k') \in \mathcal{F}$ and checks if it is a yes-instance of EXACT STEINER TREE. By Definition 12(2), this is sufficient to determine if $(G, R, t, k)$ is a yes-instance of STEINER TREE.

For the rest of the proof we design a dynamic programming subroutine algorithm $A$ for EXACT STEINER TREE that takes as input an instance $(H, R, t, k') \in \mathcal{F}$ and uses its modified $O(\sqrt{i + k})$-NCPD to determine whether it is a yes-instance of EXACT STEINER TREE. Suppose $(G, R, t, k)$ is a yes-instance and consider a $k$-Steiner tree $T$ for $(G, R, t, k)$ where $\{uv \in E(T)| f(u) \neq f(v)\}$ is minimised and then the number of Steiner vertices in $T$ is minimised. Using Observation 4, this is an exact $k'$-Steiner tree of $G$ for some $k' \leq k$. By the construction in Lemma 13 note that there is an
instance \((H, R, t, k') \in \mathcal{F}\) such that \(T\) is an exact \(k'\)-Steiner tree for \((H, R, t, k')\).

The aim of the dynamic programming algorithm is to correctly determine that this particular instance \((H, R, t, k')\) is a yes-instance. The algorithm \(A\) is designed in such a manner that for such a yes-instance \((H, R, t, k')\) the tree \(T\) will be the potential solution Steiner tree that behaves as a certificate of correctness.

The states of the dynamic programming algorithm store information required to represent the partial solution Steiner tree, which is the potential solution Steiner tree restricted to the graph seen so far. The states are of the form \(A[\ell, Q, Q = Q_1 \cup Q_2 \ldots \cup Q_b, P = P_1 \cup \ldots \cup P_b, k'']\) where:

- \(\ell \in [q]\) denotes the index of the bag \(X_{\ell}\) of the modified NCPD of \(H\).
- \(Q \subseteq X_{\ell} \setminus R\) is a set of at most \(24 \cdot 7\) non-terminal vertices. For each cell \(C = (i, j)\) that belongs to \(X_{\ell}\), \(|Q \cap f^{-1}(i, j)| \leq 24\).
- \(Q = Q_1 \cup Q_2 \ldots \cup Q_b\) is a partition of \(Q\) with the property that for each cell \(C = (i, j)\), \(Q \cap f^{-1}(i, j)\) is contained completely in exactly one part of \(Q\).
- The partition \(P\) is over the vertex set \(Q \cup (R \cap X_{\ell})\). Also for each cell \(C \in X_{\ell}\), \(C \cap (Q \cup R)\) is completely contained in exactly one part of \(P\).
- The value \(k''\) represents the total number of Steiner vertices used so far in this partial solution Steiner tree. \(|Q| \leq k''\) holds.

Essentially, let \(T\) be an exact \(k'\)-Steiner tree for \((H, R, t, k')\) if it is a yes-instance. For \(\ell \in [q]\), let \(T_{ptl}^{\ell}\) represent the partial solution Steiner tree when \(T\) is restricted to \(H[\bigcup_{j=1}^{\ell} X_j]\). The partition \(P\) represents the intersection of a component of \(T_{ptl}^{\ell}\) with \(X_{\ell}\). The set \(Q\) is the set of Steiner vertices of \(T_{ptl}^{\ell}\) in the bag \(X_{\ell}\) and \(Q\) is the partition of \(Q\) with respect to the components of \(T_{ptl}^{\ell}\). The number \(k''\) denotes the total number of Steiner vertices in \(T_{ptl}^{\ell}\).

In order to show the correctness of \(A\) we need to maintain the following invariant throughout the algorithm: (LHS) \(A[\ell, Q, Q = Q_1 \cup Q_2 \ldots \cup Q_b, P = P_1 \cup \ldots \cup P_b, k''] = 1\) if and only if (RHS) there is a forest \(T'\) as a subgraph of \(H[\bigcup_{j=1}^{\ell} X_j]\) with \(b\) connected components \(D_1, \ldots, D_b\); \(D_i \cap X_{\ell} = P_i, (D_i \setminus R) \cap X_{\ell} = Q_i\), the total number of non-terminal points in \(T'\) is \(k''\), for each cell \(C\) the number of nonterminal vertices in \(C \cap T'\) is at most 24, and \(R \cap (\bigcup_{j=1}^{\ell} X_j) \subseteq V(T')\).

Suppose the algorithm invariant is true. This means that if \(A[q, Y, Y, k'] = 1\) then there is an exact \(k'\)-Steiner tree for \((H, R, t, k')\). On the other hand, suppose \((G, R, t, k)\) is a yes-instance and has a \(k\)-Steiner tree \(T\) where \(\{uv \in E(T) | f(u) \neq f(v)\}\) is minimised and then the number of Steiner vertices in \(T\) is minimised. By Observation 11, the number of Steiner vertices of \(T\) in each cell of \(G\) is bounded by 24. By Observation 4 and the construction in Lemma 13 note that there is a subset \(Y\) and an instance \((H, R, t, k') \in \mathcal{F}\) such that \(T\) is an exact \(k'\)-Steiner tree for \((H, R, t, k')\) and \(Y \subseteq V(T)\). Suppose the invariant of the algorithm is true. This means that if \((G, R, t, k)\) is a yes-instance of STEINER TREE then there is a \((H, R, t, k')\) for which \(A[q, Y, Y, k'] = 1\).

Thus, proving the correctness of the algorithm \(A\) amounts to proving the correctness of the invariant of \(A\). We prove the correctness of the invariant by induction on \(\ell\). If \(\ell = 1\) then \(X_{\ell}\) must be a leaf bag. By definition of the modified NCPD, the bag contains \(Y\).
\[ \mathcal{A}[1, Q, Q, P, k''] = 1 \text{ if } Q = Y, \ Q \text{ is the partition of } Y \text{ into the connected components in } H[Y], \ P = Q, k'' = |Y|. \] In all other cases, \( \mathcal{A}[1, Q, Q, P, k''] = 0. \)

First, suppose \( \mathcal{A}[1, Q, Q, P, k''] = 1. \) Then as \( X_1 \) does not contain any terminal vertices, \( \text{(RHS)} \) trivially is true for the cases when \( \mathcal{A}[1, Q, Q, P, k''] = 1. \) On the other hand, suppose \( \text{(RHS)} \) is true for \( \ell = 1. \) Again considering the cases when \( \mathcal{A}[1, Q, Q, P, k''] = 1, \) \( \text{(LHS)} \) holds. So the invariant holds when \( \ell = 1. \)

Now, we assume that \( \ell > 1. \) Our induction hypothesis is that the invariant of the algorithm is true for all \( 1 \leq \ell' < \ell. \) We show that the invariant is true for \( \ell. \) There can be two cases:

**Case 1:** \( X_\ell \) is a forget bag with exactly one child \( X_{\ell-1}. \) Let \( C \) be the cell being forgotten in \( X_\ell. \) Consider \( \mathcal{A}[\ell, Q, Q = Q_1, \ldots, Q_b, P = P_1 \ldots P_b, k'']. \)

Let \( Q' \subseteq X_{\ell-1} \setminus R \) such that \( Q \subseteq Q' \) and \( Q' \setminus Q \) consists of a set of at most 24 non-terminal vertices from \( C. \) Let \( P' = P'_1 \ldots P'_b \) be a partition of \( (Q' \cup R) \cap X_{\ell-1} \) such for each cell \( C' \) in \( X_{\ell-1}, \) \( C' \cap (Q' \cup R) \) is completely contained in exactly one part. Also, \( P_i = P'_i \setminus C. \) Moreover, consider the part \( P'_i \) such that \( C \cap (Q' \cup R) \subseteq P'_i: \) \( P'_i \setminus (C \cap (Q' \cup R)) \neq \emptyset. \) Let \( Q' \) be the partition of \( Q' \) such that \( Q' \cap P'_i = Q'_i. \) If \( \mathcal{A}[\ell-1, Q', Q', P', k''] = 1 \) then \( \mathcal{A}[\ell, Q, Q, P, k''] = 1. \) Otherwise, \( \mathcal{A}[\ell, Q, Q, P, k''] = 0. \)

Suppose \( \text{(LHS)} \) of the invariant is true for \( \mathcal{A}[\ell, Q, Q, P, k''] : \) \( \mathcal{A}[\ell, Q, Q, P, k''] = 1. \) By definition, there is an \( \mathcal{A}[\ell-1, Q', Q', P', k''] = 1 \) for a \( Q', Q', P' \) as described above. By induction hypothesis, \( \text{(RHS)} \) corresponding to \( \mathcal{A}[\ell-1, Q', Q', P', k''] = 1 \) holds. Thus, there is a witness forest \( T' \) in \( H[\bigcup_{j=1}^{\ell} X_j] = H[\bigcup_{j=1}^{\ell} X_j] \) (By definition of a forget bag). By definition of \( Q, Q, P, T', \) \( X_j \) is also a witness forest in \( H[\bigcup_{j=1}^{\ell} X_j] \) and therefore \( \text{(RHS)} \) is true for \( \mathcal{A}[\ell, Q, Q, P, k''] \).

On the other hand, suppose \( \text{(RHS)} \) is true for \( \mathcal{A}[\ell, Q, Q, P, k''] \). Then there is a witness forest \( T' \) in \( H[\bigcup_{j=1}^{\ell} X_j] = H[\bigcup_{j=1}^{\ell} X_j] \). Moreover, \( T' \) has \( b \) connected components \( D_1, \ldots, D_b: D_i \cap X_\ell = P_i, (D_i \setminus R) \cap X_\ell = Q_i, \) the total number of non-terminal points in \( T' \) is \( k'' \) and \( R \cap (\bigcup_{j=1}^{\ell} X_j) \subseteq V(T'). \) Let \( D_i \cap X_{\ell-1} = P'_i, (D_i \setminus R) \cap X_{\ell-1} = Q'_i, \) \( = \bigcup_{j=1}^{b} Q'_i. \) Note that the total number of non-terminal points in \( T' \) is \( k'' \) and by definition of a forget node it is still true that \( R \cap (\bigcup_{j=1}^{\ell-1} X_j) \subseteq V(T'). \) By induction hypothesis, \( \text{(LHS)} \) is true for \( \mathcal{A}[\ell-1, Q', Q', P', k''] \) and \( \mathcal{A}[\ell-1, Q', Q', P', k''] = 1. \) By the description above, this implies that \( \mathcal{A}[\ell, Q, Q, P, k''] = 1. \) Therefore, \( \text{(LHS)} \) is true for \( \mathcal{A}[\ell, Q, Q, P, k''] \).

**Case 2:** \( X_\ell \) is an introduce bag with exactly one child \( X_{\ell-1}. \) Let \( C \) be the cell being introduced in \( X_\ell. \) Consider \( \mathcal{A}[\ell, Q, Q = Q_1, \ldots, Q_b, P = P_1 \ldots P_b, k'']. \) Without loss of generality, let \( P_0 \) contain all the vertices in \( C \cap (Q \cup R). \)

By definition of a state, \( |C \cap Q| \leq 24. \) Let \( S_t = C \cap Q \) and \( Q' = Q \setminus S_t. \) Let \( P' = P'_1 \cup P'_2 \cup \ldots \cup P'_d \) be a partition of \( Q' \cup (R \cap X_{\ell-1}) \) such that for \( j < b, P_j = P'_j, \) and \( P_b = C \cap (Q \cup R) \cup \bigcup_{j=b}^{d} P'_j. \) Moreover, \( C \cap (Q \cup R) \) has a neighbour in each \( P'_j, b \leq j \leq d. \) Let \( Q' \) be the partition of \( Q' \) such that \( Q' \cap P'_i = Q'_i. \) Let \( k^* = k'' - |S_t|. \) If \( \mathcal{A}[\ell-1, Q', Q', P', k^*] = 1 \) then \( \mathcal{A}[\ell, Q, Q, P, k''] = 1. \) Otherwise, \( \mathcal{A}[\ell, Q, Q, P, k''] = 0. \)

Suppose \( \text{(LHS)} \) of the invariant is true for \( \mathcal{A}[\ell, Q, Q, P, k''] : \) \( \mathcal{A}[\ell, Q, Q, P, k''] = 1. \) By definition, there is an \( \mathcal{A}[\ell-1, Q', Q', P', k^*] = 1 \) for a \( Q', Q', P' \) as described above. By induction hypothesis, \( \text{(RHS)} \) corresponding to \( \mathcal{A}[\ell-1, Q', Q', P', k^*] = 1 \)

\[ \mathcal{A}[\ell, Q, Q, P, k''] = 1. \]
holds. Thus, there is a witness forest $T'$ in $H[\bigcup_{j=1}^{\ell-1} X_j]$. By definition of $Q$, $Q$, $P$, $H[V(T') \cup (C \cap (Q \cup R))]$ is a connected graph. Consider a spanning tree of this connected graph. By definition of $k^*$, this spanning tree has all vertices of $R$ and exactly $k''$ non-terminal vertices. Therefore, this spanning tree is a witness forest in $H[\bigcup_{j=1}^{\ell-1} X_j]$ and therefore (RHS) is true for $A[\ell, Q, Q, P, k'']$.

On the other hand, suppose (RHS) is true for $A[\ell, Q, Q, P, k''']$. Then there is a witness forest $T'$ in $H[\bigcup_{j=1}^{\ell} X_j]$. Moreover, $T'$ has $b$ connected components $D_1, \ldots, D_b$: $D_i \cap X_i = P_i, (D_i \setminus R) \cap X_i = Q_i$, the total number of non-terminal points in $T'$ is $k''$ and $R \cap (\bigcup_{j=1}^{\ell} X_j) \subseteq V(T')$. Without loss of generality, let $D_b$ contain $T' \cap C$. Let $D_1', D_2', \ldots, D_b', \ldots, D_d'$ be the connected components of $T'$ restricted to $H[\bigcup_{j=1}^{\ell-1} X_j]$. Let $D_i' \cap X_{t-1} = P_i', (D_i' \setminus R) \cap X_{t-1} = Q_i', Q' = \bigcup_{j=1}^{d} Q_i'$. Note that the total number of non-terminal points in $T'$ is $k'' = k'' - |S|$, and by definition of an introduce node it is true that $R \cap (\bigcup_{j=1}^{\ell-1} X_j) \subseteq V(T') \cap (\bigcup_{j=1}^{\ell-1} X_j)$. By induction hypothesis, (LHS) is true for $A[\ell - 1, Q', Q', P', k''']$ and $A[\ell - 1, Q', Q', P', k'''] = 1$. By the description above, this implies that $A[\ell, Q, Q, P, k'''] = 1$. Therefore, (LHS) is true for $A[\ell, Q, Q, P, k''']$.

Finally, we analyze the time complexity of the algorithm. First, the good family $\mathcal{F}$ is computed in $n^{O(\sqrt{t+k})}$ time as per Lemma 13, and the number of instances in the good family $\mathcal{F}$ is $n^{O(\sqrt{t+k})}$. For one such instance $(H, R, t, k')$ the possible states for the algorithm $A$ are of the form $[\ell, Q, Q, P, k''']$. By definition, $\ell \leq n, k'' \leq k'$ and $Q = O(\sqrt{t+k})$. Again, by definition $P$ is upper bounded by the number of partitions of cells contained in a bag of the modified NCPD of $(H, R, t, k')$. Thus, the number of possibilities of $P$ is $\sqrt{t+k}^{O(\sqrt{t+k})}$. Also by definition, $Q$ is fixed once $Q$ and $P$ are fixed. Therefore, the number of possible states is $n^{O(\sqrt{t+k})}$. From the description of $A$, the computation of $A[\ell, Q, Q, P, k''']$ may look up the solution for $n^{O(\sqrt{t+k})}$ instances of the form $A[\ell - 1, Q', Q', P', k''']$ and therefore takes $n^{O(\sqrt{t+k})}$ time. Thus, the total time for the dynamic programming is $O(n^{\sqrt{t+k}})$. 

\section{FPT Algorithm for Steiner Tree on Unit Disk Graphs}

In this section, we prove Theorem 2. We consider the Steiner Tree problem on unit disk graphs and design an FPT algorithm parameterized by $k$, which is an upper bound on the number of Steiner vertices in the solution Steiner tree. Our algorithm is based on the idea that for an instance $(G, R, t, k)$, in order to determine the existence of a Steiner tree we can first find spanning trees for all components of $G[R]$ and extend these spanning trees to a required $k$-Steiner tree.

In fact, we prove our results for the superclass of clique-grid graphs. For an instance $(G, R, t, k)$ of Steiner Tree on clique-grid graphs, where $G$ has $n$ vertices and $R \subseteq V(G)$ is the set of terminals we prove the following result in this rest of this section.

\textbf{Lemma 15} Steiner Tree on clique-grid graphs has an FPT algorithm with running time $2^{O(k)} n^{O(1)}$. 

\textcopyright Springer
First, we prove some properties of Steiner trees for unit disk graphs. Consider the induced subgraph $G[R]$. Let $C_1, C_2, \ldots, C_q$ be the connected components in $G[R]$. For each $C_i, i \in [q]$, let $T_i$ be a spanning tree of $C_i$.

**Observation 16** Let $G$ be a clique-grid graph with the terminal set $R$. Let $C_1, C_2, \ldots, C_q$ be the connected components of $G[R]$, and for each $i \in [q]$ let $T_i$ be a spanning tree for each $C_i$. For any $k$, let $T'$ be a $k$-Steiner tree for $G$. Then there is a $k$-Steiner tree $T$ such that for each $i \in [q]$ $T_i$ is a subtree of $T$. Moreover, $q \leq 24k$.

**Proof** Consider the $k$-Steiner tree $T$ and let $S = V(T) \setminus R$ be the set of Steiner vertices of $T$. Note that in $G[R \cup S]$, $T$ is a spanning tree and therefore $G[R \cup S]$ is a connected graph. Similarly, for each $i \in [q]$, $T_i$ is a subgraph of $G[R \cup S]$. Consider the subgraph $H = T' \cup \bigcup_{i \in [q]} T_i$. As $T'$ is a spanning tree, $T' \cup \bigcup_{i \in [q]} T_i$ is a connected graph. We consider an arbitrary ordering $O$ of the edges in $E(H) \setminus \bigcup_{i \in [q]} E(T_i))$. In this order we iteratively throw away an edge $e_j \in E(H) \setminus \bigcup_{i \in [q]} E(T_i))$ if the resulting graph remains connected upon throwing $e_j$ away. Let $H'$ be the graph at the end of considering all the edges in the order $O$. We prove that $H'$ must be a tree. Suppose for the sake of contradiction, there is a cycle $C$ as a subgraph of $H'$. As for each $i \in [q]$, $T_i$ is a tree and for each $i \neq i' \in [q]$, $V(T_i) \cap V(T_{i'}) = \emptyset$, there must be an edge from $E(H) \setminus \bigcup_{i \in [q]} E(T_i))$ in $E(C)$. Consider the edge $e \in (E(H) \setminus \bigcup_{i \in [q]} E(T_i))) \cap E(C)$ with the largest index according to $O$. This edge was throwable as $C \setminus \{e\}$ ensured any connectivity due to $e$. Thus, there can be no cycle in $H'$ and it is a spanning tree of $V(H)$. This implies that $T = H'$ is a $k$-Steiner tree for $G$, $S$ being the set of at most $k$ Steiner vertices, such that for each $i \in [q], T_i$ is a subtree of $T$.

Finally, we show that if a $k$-Steiner tree $T$ exists then $q \leq 24k$. Let $f$ be a representation of the clique-grid graph $G$. Note that for any cell $(a, b)$ $f^{-1}(a, b)$ is a clique, Therefore, there can be at most one component $C_i$ intersecting with a cell $(a, b)$. By property (2) of Definition 5, there are at most 24 cells that can have neighbours of any vertex in $(a, b)$. Thus, for any Steiner vertex, there can be at most 24 components of $G[R]$ it can have neighbours in. Putting everything together, if there are at most $k$ Steiner vertices that are used to connect the $q$ connected components of $G[R]$ and each Steiner vertex can have neighbours in at most 24 components, then it must be that $q \leq 24k$. \hfill \Box

Henceforth, we wish to find a solution $k$-Steiner tree $T$ such that for each $i \in [q]$, $T_i$ is a subtree of $T$.

**Definition 17** Let $G$ be a clique-grid graph with the terminal set $R$. Let $C_1, C_2, \ldots, C_q$ be the connected components of $G[R]$, and for each $i \in [q]$ let $T_i$ be a spanning tree for each $C_i$. Let $G^*$ be the following graph: $V(G^*) = V(G \setminus R) \cup R^*$ where $R^* = \{c_i | i \in [q]\}$, $E(G^*) = \{v_1v_2 | v_1, v_2 \in V(G) \setminus R \cup \{c_i | v \in V(G) \setminus R, \exists u \in C_i \text{ s.t. } uu \in E(G)\}$. $G^*$ is called the component contracted graph of $G$ and $\{c_i | i \in [q]\}$ is the set of terminals for $G^*$ (See Fig. 4).

Note that $G^*$ may no longer be a clique-grid graph. From the definition of a component contracted graph and Observation 16, we have the following observation.
Observation 18 Let $G$ be a clique-grid graph with the terminal set $R$. Let $C_1, C_2, \ldots, C_q$ be the connected components of $G[R]$, and for each $i \in [q]$ let $T_i$ be a spanning tree for each $C_i$. Let $G^*$ be the component contracted graph of $G$ using the $T_i$’s. Then $(G, R, t, k)$ is a yes-instance of STEINER TREE if and only if $q \leq 24k$ and $(G^*, R^*, q, k)$ is a yes-instance of STEINER TREE.

Now we are ready to design our FPT algorithm for STEINER TREE on clique-grid graphs parameterized by $k$ and complete the proof of Lemma 15.

Proof of Lemma 15 Let $(G, R, t, k)$ be an input instance of $n$-vertex clique-grid graphs. Let $C_1, C_2, \ldots, C_q$ be the connected components of $G[R]$, and for each $i \in [q]$ let $T_i$ be a spanning tree for each $C_i$. Let $G^*$ be the component contracted graph of $G$ using the $T_i$’s. Let $R^* = \{c^i| i \in [q]\}$ be the terminal set of $G^*$. By, Observation 16, if $G$ is a yes-instance then it must be that $q \leq 24k$. If this is not the case, then we immediately output no.

From now on, we are in the case $q \leq 24k$. By Observation 18, it is enough to determine whether $(G^*, R^*, q, k)$ is a yes-instance of STEINER TREE. As noted earlier, $G^*$ may no longer be a clique-grid graph.

We run the Dreyfus-Wagner algorithm [11] which returns a minimum edge-weighted Steiner tree connecting $R^*$ in $G^*$. Since $G^*$ is unweighted, the returned solution Steiner tree $T$ has the minimum number of edges. Note that since $G^*$ is unweighted, a Steiner tree for $R^*$ minimizes the number of Steiner vertices if and only if it has minimum number of edges. The total number of Steiner vertices in $T$ is $|V(T)| - |R^*|$. If $|V(T)| - |R^*| \leq k$, then our algorithm returns that $(G^*, R^*, q, k)$ is a yes-instance of STEINER TREE, and otherwise it returns no.

The construction of $G^*$ is done in polynomial time. Since $q \leq 24k$, the Dreyfus-Wagner algorithm runs in $2^{O(k)}n^{O(1)}$. Thus, our algorithm also has running time $2^{O(k)}n^{O(1)}$. $\square$

6 W[1]-Hardness for STEINER TREE on Disk Graphs

In this section, we consider the STEINER TREE problem on disk graphs and prove that this problem is W[1]-hard parameterized by the number Steiner vertices $k$. 

Springer
Theorem 3. The Steiner Tree problem on disk graphs is W[1]-hard, parameterized by the number of Steiner vertices $k$.

Proof We prove Theorem 3 by giving a parameterized reduction from the Grid Tiling with $\geq$ problem which is known to be W[1]-hard\(^3\) [28]. In the Grid Tiling with $\geq$ problem, we are given an integer $n$, a $k \times k$ matrix for an integer $k$ and a set of pairs $S_{ij} \subseteq [n] \times [n]$ of each cell. The objective is to find, for each $1 \leq i, j \leq k$, a value $s_{ij} \in S_{ij}$ such that if $s_{ij} = (a, b)$ and $s_{i+1,j} = (a', b')$ then $a \geq a';$ if $s_{ij} = (a, b)$ and $s_{i,j+1} = (a', b')$ then $b \geq b'$.

Let $I = (n, k, S)$ be an instance of the Grid Tiling with $\geq$. We construct a set of disks $D$, that is divided into three sets of disks $D_1, D_2, D_3$; $D = D_1 \cup D_2 \cup D_3$. Each disk in $D_1, D_2, D_3$ is of radius 1, $\delta$ and $\kappa$, respectively. We will define the value of $\delta$ and $\kappa$ shortly. The construction of the set $D = D_1 \cup D_2 \cup D_3$ will ensure that $D$ contains a Steiner Tree with $k^2$ Steiner vertices if and only if $I$ is a yes instance of Grid Tiling with $\geq$. Let $\epsilon = 1/n^{10}$, and $\delta = \epsilon/4$. Here, we point out that the value of $\kappa, \epsilon$ are independent of each other. First, we move the cells away from each other, such that the horizontal (resp. vertical) distance between the left columns (resp. top rows) any two consecutive cell is $2 + \epsilon$. Let $100\delta$ be the side of length of each cell. Then, we introduce diagonal chains of terminal disks into $D_3$ of radius $\kappa = \sqrt{2(2 + \epsilon - 100\delta)}/1000$ to connect the cells diagonally; see Fig. 5a. For every $1 \leq x, y \leq k$, and every $(a, b) \in S(x, y) \subseteq [n] \times [n]$, we introduce into $D_1$ a disk of radius 1 centered at $(2x + \epsilon x + \epsilon a, 2y + \epsilon y + \epsilon b)$. Let $D[x, y] \subseteq D_1$ be the set of disks introduced for a fixed $x$ and $y$, and notice that they mutually intersect each other. Next, for $1 \leq x, y \leq k$, we introduce into $D_2$, disks of radius $\delta$ between consecutive cells of coordinate $(2x + 1 + \epsilon x + \epsilon a, 2y + \epsilon y)$ (placed horizontally); and $(2x + \epsilon x, 2y + 1 + \epsilon y + \epsilon b)$ (placed vertically). For every cell $S[x, y]$, we denote the top, bottom, left, right cluster of terminal disks of radius $\delta$ from $D_2$ by $L[x, y], R[x, y], T[x, y], B[x, y]$, respectively. Moreover, for each cell $S[x, y]$, we introduce a disk of radius $\delta$ at a coordinate that is completely inside the rectangle bounding the centres of disks in $D[x, y]$. This is to enforce that at least one disk is chosen form each $D[x, y]$. See Figure 5b for an illustration.

We proceed with the following observation. Consider a disk $p$ that is centered at $(2x + \epsilon x + \epsilon a, 2y + \epsilon y + \epsilon b)$ for some $(a, b) \in [n] \times [n]$. Now, consider a disk $q$ from $R[x, y]$ centered at $(2x + 1 + \epsilon x + \epsilon a, 2y + \epsilon y)$. The distance between their centers are $\sqrt{1 + \epsilon^2 b^2}$. We need to show that this is less than $(1 + \epsilon/4)$. This is true because $1 + \epsilon^2 b^2$ is less than $(1 + \epsilon/4)$ as the value of $b$ goes to $n$, $\epsilon = 1/n^{10}$ and the value of $n$ is large. Hence, $q$ is covered by the disk $p$ from $S[x, y]$ centered at $(a, b)$. Next, consider a disk $q'$ from $R[x, y]$ centered at $(2x + 1 + \epsilon x + \epsilon (a + 1), 2y + \epsilon y)$. The distance between their centers are $\sqrt{(1 + \epsilon)^2 + \epsilon^2 b^2}$. We show that this value is bigger than $(1 + \epsilon/4)$. This means $(1 + \epsilon)^2 + \epsilon^2 b^2$ is bigger than $(1 + \epsilon/4)^2$. As the value of $b$ goes to $n$, it is not hard to see the left side is bigger since $\epsilon = 1/n^{10}$ and the value of $n$ is large. Therefore, $q'$ is not covered by the disk $p$ from $S[x, y]$ centered at $(a, b)$. The same calculation holds for $L[x, y], T[x, y]$ and $B[x, y]$.

---

\(^3\) $k \times k$ Grid Tiling with $\geq$ problem is W[1]-hard, assuming ETH, cannot be solved in $f(k)n^{o(k)}$ for any function $f$. Spring
In the forward direction, let the pairs $s[x, y] \in S[x, y]$ form a solution for instance $I$, and let $s[x, y] = (a[x, y], b[x, y])$. For every $1 \leq x, y \leq k$, we select the disk $d[x, y]$ from $D_1$ of radius 1 centered at $(2x + \epsilon x + \epsilon a[x, y], 2y + \epsilon y + \epsilon b[x, y])$. We have seen in the previous paragraph that this disk cover any disk from $R[x, y]$ of center with $(2x + 1 + \epsilon x + \epsilon a[x, y], 2y + \epsilon y)$ but does not covers disks with coordinate $(2x + 1 + \epsilon x + \epsilon (a[x, y] + 1), 2y + \epsilon y)$. Similarly, this holds for $L[x, y], T[x, y], B[x, y]$. $s[x, y]$’s forms a solution of $I$, then we have $a[x, y] \geq a[x + 1, y]$. Therefore, the disks $d[x, y]$ and $d[x + 1, y]$ will cover all disks from $R[x, y]$. Similarly, we have $b[x, y] \geq b[x, y + 1]$ which implies that $d[x, y]$ and $d[x, y + 1]$ will cover $T[x, y]$ and form a component them. Now, the diagonals chains consisting of terminal disks of radius $\kappa$, we have taken to join the cells (see Fig. 5a) ensures that all cells are connected. Moreover, we have shown that if $s[x, y]$’s form a solution of instance $I$, then all terminals in $L[x, y], R[x, y], T[x, y], B[x, y]$ (for any $1 \leq x, y \leq k$) are covered. Therefore, this will form a connected Steiner tree with $k^2$ many Steiner disks.

In the reverse direction, let $D' \subseteq D_1$ be a set of $k^2$ Steiner disks that spans over all terminals in $D_2 \cup D_3$. This is true when for every $1 \leq x, y \leq k$, the set $D'$ contains a disk $d'[x, y] \in D[x, y]$ that is centered at $(2x + \epsilon x + \epsilon a[x, y], 2y + \epsilon y + \epsilon b[x, y])$ for some $(a[x, y], b[x, y]) \in [n] \times [n]$. Indeed, we are required to choose one disk from $D[x, y]$ due to the reason that there is a terminal disk lying inside the rectangle bounding the centres of disks in $D[x, y]$. The claim is that $s[x, y] = (a[x, y], b[x, y])$’s form a solution of $I$. First of all, $d[x, y] \in D[x, y]$ implies that $s[x, y] \in S[x, y]$. Consider a cell $S[x, y]$. We have observed that it covers disk $q$ from $R[x, y]$ centered at $(2x + 1 + \epsilon x + \epsilon a, 2y + \epsilon y)$, but a disk $q'$ from $R[x, y]$ centered at $(2x + 1 + \epsilon x + \epsilon (a + 1), 2y + \epsilon y)$ is not covered. This is true for $L[x, y], T[x, y], B[x, y]$. Hence, if all terminals points

![Figure 5](image-url)
from inside $S[x, y]$’s and $L[x, y]$, $R[x, y]$, $T[x, y]$, $B[x, y]$ are covered by $k^2$ many Steiner disks, it would imply that $a[x, y] \geq a[x + 1, y]$ and $b[x, y] \geq b[x, y + 1]$. Therefore, $s[x, y]$’s form the solution for GRID TILING with $\geq$ instance $I$. This completes the proof. $\square$

**Conclusion** In this paper we studied the parameterized complexity of STEINER TREE on unit disk graphs and disk graphs under the parameterizations of $k$ and $t + k$. In future, we wish to explore tight bounds for the algorithms we have obtained and to probe into kernelization questions under these parameters. It would also be interesting to consider the minimum weight of a solution $k$-Steiner tree as a parameter. A variant of STEINER TREE that usually is easier to study is FULL STEINER TREE. However, in the case of unit disk graphs this problem proved to be very resilient to all our algorithmic strategies. We wish to explore FULL STEINER TREE on unit disk graphs under natural and structural parameters in future works.
