ABSTRACT

We discuss free-free radio emission from ionized gas in the intergalactic medium. Because the emissivity is proportional to the square of the electron density, the mean background is strongly sensitive to the spatial clumping of free electrons. Using several existing models for the clumping of ionized gas, we find that the expected free-free distortion to the cosmic microwave background blackbody spectrum is at a level detectable with upcoming experiments such as the Absolute Radiometer for Cosmology, Astrophysics, and Diffuse Emission experiment. However, the dominant contribution to the distortion comes from clumpy gas at \( z \leq 3 \), and the integrated signal does not strongly constrain the epoch of reionization. In addition to the mean emission, we consider spatial fluctuations in the free-free background and the extent to which these anisotropies confuse the search for fluctuations in 21 cm line emission from neutral hydrogen during and prior to reionization. This background is smooth in frequency space and hence can be removed through frequency differentiating, but only so long as the 21 cm signal and the free-free emission are uncorrelated. We show that because the free-free background is generated primarily at low redshifts, the cross-correlation between the two fields is smaller than a few percent. Thus, multifrequency cleaning should be an effective way to eliminate the free-free confusion.

Subject headings: cosmic microwave background — diffuse radiation — large-scale structure of universe

1. INTRODUCTION

Plans for upcoming low-frequency radio experiments able to measure the 21 cm background associated with neutral hydrogen during, and prior to, reionization (e.g., Scott & Rees 1990; Madau et al. 1997; Zaldarriaga et al. 2003; Morales & Hewitt 2003) have motivated study of the foregrounds that may contaminate such measurements. Synchrotron emission from the Milky Way, low-frequency radio sources (Di Matteo et al. 2002), and free-free emission from free electrons in the intergalactic medium (Oh & Mack 2003) are now thought to be the chief sources of confusion.

While the free-free background contaminates 21 cm studies, the emission itself captures important physics of the ionized component of the intergalactic medium (IGM). In particular, because the emissivity is proportional to the square of the electron number density, free-free emission is strongly sensitive to whether electrons are spatially clumped or distributed smoothly in the IGM. Initial estimates of the free-free background suggest that gas clumping boosts the specific intensity by a factor from order unity at \( z \sim 20 \) to over 100 at \( z \leq 3 \) (Oh 1999).

Here, we consider the direct detection of free-free emission through the distortion that it creates in the cosmic microwave background (CMB) blackbody spectrum at low radio frequencies (Loeb 1996; Oh 1999). We calculate the mean distortion temperature and suggest that it is at a level detectable with the planned Absolute Radiometer for Cosmology, Astrophysics, and Diffuse Emission (ARCADE; Kogut 2000) experiment. A detection of the distortion could help to discriminate between existing clumping models and to constrain the integrated ionization history of the universe. We also show that ionized halos at \( z \leq 3 \) dominate the background, with only a relatively insignificant contribution from the reionization era.

In addition to the mean background, we estimate the magnitude of spatial fluctuations in the free-free intensity. We find that the fluctuations are comparable to or greater than those from the 21 cm signal on the relevant scales. Fortunately, as shown by Zaldarriaga, Furlanetto, & Hernquist (2004), the smoothness of the free-free background in frequency space should allow one to clean these sources in 21 cm maps (see also Morales & Hewitt 2003); the cleaning is quite efficient but relies on the foreground and 21 cm signals being uncorrelated. In fact the two should be anticorrelated, because the free-free emission comes from ionized halos while the 21 cm signal comes from neutral regions. Here we show that because nearly all of the free-free background arises at \( z \leq 3 \), the anticorrelation is at the level of a few percent, suggesting that adequate cleaning is possible.

The discussion is organized as follows: in § 2, we briefly discuss free-free emission from ionized halos and its potential detectability as a distortion to the CMB. In § 3, we discuss the detectability of spatial fluctuations in the free-free background and the extent to which free-free emission contaminates 21 cm measurements. Throughout the Letter, we make use of the Wilkinson Microwave Anisotropy Probe–favored \( \Lambda \) cold dark matter cosmological model (Spergel et al. 2003).

2. THE MEAN FREE-FREE SIGNAL

First, we write the free-free emission coefficient as

\[
\epsilon_{e} = 5.4 \times 10^{-39} n_e^2 T_e^{-1/2} g_{ee}(v, T_e)e^{-\Delta E/kT_e}
\]  

(in units of ergs cm\(^{-3}\) s\(^{-1}\) Hz\(^{-1}\) sr\(^{-1}\)), where the Gaunt factor can be approximated in the radio regime as \( g_{ee}(v, T_e) \approx 11.96 T_e^{4/3} v^{-4/3} \) (Lang 1999). The cumulative specific intensity is simply \( I_e = \int d\chi \epsilon_e(z) x_e(z) C(z)/(1 + z)^4 \), where \( x_e(z) \) is the conformal time and \( \nu(z) = \nu_{\text{obs}}(1 + z) \) with \( \nu_{\text{obs}} \) the observed frequency. The electron fraction \( x_e(z) \) captures the ionization history of the IGM. In our calculations, unless specified as part of the clumping description, we take a model for reionization based on the UV radiation from star formation (e.g., Haiman & Holder 2003; Chen et al. 2003), with a cumulative optical depth to electron scattering of \( \sim 0.14 \) (consistent with the recent measurements from CMB polarization data; Kogut et al. 2003).
We quote results in terms of the brightness temperature $T_\text{b} = c^2 I / 2 \kappa_{\text{rad}} k_B$ (valid for the Rayleigh-Jeans part of the spectrum).

In equation (1), we have introduced $C(z) = \langle n_e^3 \rangle / \langle n_e \rangle^3$, the clumping factor of the electron density field. Instead of choosing a specific prescription, we make use of a variety of published models for $C(z)$. One approach is to estimate the clumping from the large-scale matter distribution by, for example, assuming that ionized electrons reside in virialized dark matter halos. Several such models are shown in Figure 1a, including estimates based on analytic (Haiman et al. 2001), semianalytic (Benson et al. 2001), and numerical (Gnedin & Ostriker 1997) techniques. These clumping models differ in detail, especially around $z \sim 10$, because they include different aspects of the reionization process. In general, these methods yield a minimal estimate for $C(z)$, because the models do not include recombinations within galaxies (where most ionizing photons are probably absorbed) or the biased distribution of ionizing sources. Gnedin (2000) has shown that these two factors strongly affect the effective clumping factor early in the reionization process, when ionizing photons are confined to the dense regions around galaxies.

The second approach, taken by Oh (1999), is to construct a model for the production rate of ionizing photons $\dot{n}_{\text{ion}}$ and assume that, throughout the universe, ionization equilibrium is a good approximation. The quantity $x_e C(z)$ is then fixed through the relation

$$\dot{n}_{\text{ion}} = x_e^2(z) n_e(z)(z) \alpha_{\text{rec}},$$

where $\alpha_{\text{rec}}$ is the recombination coefficient. We show the clumping factor estimated by Oh (1999) in Figure 1a as a dotted line; at high redshifts it assumes that the ionizing photon production rate is proportional to the mass in halos with virial temperatures $T_v > 10^4$ K (with $\sim 400$ ionizing photons per collapsed baryon, appropriate for a standard initial mass function (IMF)). We also show a similar estimate using the analytical model of Hernquist & Springel (2003) for the star formation history of the universe, again assuming Population II stars with a standard IMF. While the star formation history is model dependent at high redshifts, this model fits observational measurements at $z \lesssim 3$ (e.g., Somerville, Primack, & Faber 2001) reasonably well. The Oh (1999) approach predicts stronger clumping than models based on models of the IGM gas do, because it includes recombinations inside galaxies. These dominate the clumping as long as the escape fraction of ionizing photons is small, which causes the divergence between the two models at both low and high redshift. However, this method depends on the assumed (and uncertain) ionizing photon production rate. It also does not include collisional ionization in massive halos at low redshift, although this is a small effect.

As shown in Figure 1b, $dT_v/dz$ closely traces the redshift evolution of $C(z)$. In a smooth IGM, with $C(z) = 1$, a wide range of redshifts contribute approximately equally to the free-free background, decreasing only around reionization ($z \sim 15$ in our model). Clumping increases the contribution to the free-free background by a factor $C(z)$ at each redshift: because of the sharp increase in the clumping factor at $z \sim 3$, most of the free-free background arises at these low redshifts. Unfortunately, since one measures only the integrated background, the redshift evolution of the clumping factor is not directly observable.

Note that the models considered here give predictions that vary by a factor of a few. This suggests that these measurements may provide a discriminant between some of these models, especially between the two different approaches to clumping calculations. We also see that independent of the detailed modeling, the predicted distortion to the CMB spectrum is at a level that can be detected with ongoing experiments. While such a detection would not allow us to extract with confidence a specific model for $C(z)$ or to constrain the reionization history independently, a detection or upper limit of $\sim 10^{-3}$ K at a frequency of 2 GHz would place useful limits on current models of the ionized gas distribution.

In these calculations, we have assumed $T_e = 2 \times 10^4$ K, consistent with measurements of the Ly$\alpha$ forest at $z \sim 2.4$–3.9 (Zaldarriaga et al. 2001). The free-free emission does not depend strongly on $T_e$, $T_e \propto T_e^{-0.35}$, including the Gaunt factor, allowing the temperature to vary as a function of density, halo mass, or redshift only leads to a reduction in the mean brightness by a few tens of percent or less.

### 3. Angular Fluctuations from Free-Free Emission

We now consider the observability of spatial fluctuations in the free-free intensity. In general, fluctuations in the brightness temperature of the free-free background arise from fluctuations in the electron density field. We define the angular power spectrum of the free-free background to be $\langle T_{\ell}(l) T_{\ell'}(l') \rangle = (2\pi)^2 \delta(l + l') C_\ell$, where $T_{\ell}(l)$ is the Fourier transform of free-

---

**Fig. 1.**—(a) Clumping factor of electrons in the IGM as a function of redshift. These clumping factors come from Haiman et al. (2001; long-dashed line: reionization model that includes minihalos as well as star-forming halos with $T_v > 10^4$ K), Benson et al. (2001; dashed line: semianalytic model including cool neutral gas in ionized halos), and Gnedin & Ostriker (1997; dotted-dashed line: a direct measurement in numerical simulations). The dotted line is the clumping factor presented in Oh (1999), while the solid line is a similar calculation described in the text based on the star formation history of the universe. (b) Mean brightness temperature of free-free emission at an observed frequency of 2 GHz. Here, we show both the differential (thin lines) and cumulative brightness temperatures (thick lines) as a function of the redshift. The curves refer to the clumping models in the top panel. For reference, we show the case in which $C(z) = 1$ and the ionized gas distribution is taken to be spatially smooth. We also show the current limit on the free-free distortion of the CMB (top line with $T_{\ell} = T_{\ell} T_{\text{cmb}} / h(kT_{\text{cmb}})^{1/2} < 1.9 \times 10^{-3}$ K; Bersanelli et al. 1996) and the expected constraint from the ARCADE experiment (Kogut 2003).
free brightness temperature. Using the Limber approximation (Limber 1954), we can write the brightness temperature anisotropy power spectrum, observed at a frequency $\nu$, as

$$C_l = \frac{c^4}{4\pi^2k_\nu^2} \frac{d}{d \chi} \left( \frac{\epsilon_\nu(x) x^2}{(1 + z)^4} \right)^2 P_{\nu} \left( k = \frac{l}{d_\chi(x)} \right),$$

where $d_\chi$ is the comoving angular diameter distance and $P_{\nu}(k)$ is the three-dimensional power spectrum of the electron field.

To calculate this quantity we make use of the halo approach to large-scale structure (Cooray & Sheth 2002). We assume that on the scales of interest (from degrees to arcminutes), we can describe fluctuations in the density field through the 2 halo part of the power spectrum, which includes the clustering of different ionized halos. Thus we write $P_{\nu}(k) = b^2_{ee} P_{\text{lin}}(k)$ in terms of the linear power spectrum. We assume that the ionized patches exist in all halos with a minimum mass, $M_{\text{min}}(z)$, that corresponds to $T_e = 10^4$ K and calculate the bias factor of these halos with respect to the linear density field. Thus,

$$b_{ee}(z) = \frac{\int_{M_{\text{min}}}^M M^2 b_{\text{halo}}(M, z) dM}{\int_{M_{\text{min}}}^M M^2 dM},$$

where $b_{\text{halo}}(M, z)$ is the bias factor of the dark matter halos (Mo, Jing, & White 1997). Note the additional $M^2$ weighting, which takes into account the fact that the relevant bias factor is that of $n_e^2$. Essentially, we assume that the free electrons are in the form of ionized clumps in each dark matter halo, and we assign a halo occupation number proportional to the dark matter halo mass (in analogy to the halo approach for galaxy biasing). With this weighting, $b_{ee}$ exceeds the dark matter bias, although the difference is minor at redshifts of a few.

The angular fluctuations are summarized in Figure 2a. The typical level is $\lesssim 10^{-4}$ K at 2 GHz, a few percent of the mean brightness. This is consistent with a mildly biased field that traces the large-scale dark matter field and has its dominant contribution at redshifts of a few. Again the Oh (1999) model predicts substantially larger fluctuations than other models for clumping. For comparison, we show the noise power for anisotropy measurements with the planned Square Kilometer Array (SKA). In calculating the SKA noise, we follow the approach of Zaldarriaga et al. (2004) and assume a system temperature $T_{\text{sys}} = 50$ K at 2 GHz, a bandwidth of 10 MHz, and continuous observations over 4 weeks. We also show the anisotropy power spectrum of primordial CMB fluctuations. While the CMB fluctuations may swamp those expected from the free-free background, the CMB contamination can be reduced through two methods: (1) because free-free fluctuations are dominated by pointlike clumped regions in the IGM, one can filter the large-scale fluctuations of CMB and concentrate on the remaining pointlike emission, or (2) one can use existing cosmic variance–limited CMB maps at higher frequencies to clean the CMB contamination. We see that SKA can in principle detect free-free fluctuations on scales $l \lesssim 3000$. The main source of confusion will be the uncertain contribution from extragalactic radio sources, such as radio galaxies (Di Matteo et al. 2002). Because these sources are also pointlike, separating them from free-free fluctuations will require frequency information.

Because the integrated signal is dominated by low-$z$ sources, a large fraction of the fluctuations comes from relatively bright point sources that can be cleaned from maps. We make a simple estimate of the effect of such cleaning following the model of Oh (1999; see his § 4.2). We compute the number counts of sources at a given flux by assigning each dark matter halo an ionizing flux and assuming that all of the ionizations occur within the host halo in a single unresolved point source. The effective clumping factor of the halo (and hence its free-free luminosity) is then determined through equation (2). This simple estimate neglects the detailed distribution of matter within each halo and the variation of star formation rate with halo mass but gives an approximate upper limit to the effectiveness of point-source removal.

Figure 2a shows the signal after removing all point sources with fluxes $S > S_{\text{lim}} = 20$ mJy (the approximate sensitivity of the SKA). The integrated signal and the fluctuations decrease by about an order of magnitude but are still dominated by faint
sources at $z \sim 3$. In order for sources at $z \sim 10$ to dominate, point sources must be removed down to a few nanojanskys. Given the required integration time of several years, it is thus unlikely that fluctuations from the reionization era can be isolated even with the SKA. Using the number counts, we can also calculate the shot noise component of the free-free background through $C_{\text{sv}} = \int_0^{l_{\text{max}}} \frac{d\nu}{dS} S^2$. This term with and without point-source removal is also shown in Figure 2a. Without cleaning, shot noise can dominate on small scales because of nearby bright sources. However, because the Poisson noise component goes as $S^2$, it is strongly weighted toward the brightest halos. Thus, removing point sources has a dramatic effect on shot noise, essentially rendering it unimportant relative to clustering.

To estimate the background for 21 cm measurements, we consider free-free fluctuations at $f_{\text{obs}} = 140$ MHz, corresponding to line emission from neutral hydrogen at $z \approx 10$. We summarize our results in Figure 2b. Here we again show the SKA noise power spectrum, with $T_{\text{sys}} = 200$ K and a bandwidth of 0.2 MHz (corresponding to the desired narrow redshift slices for this experiment). The free-free fluctuations are comparable to or greater than the rms fluctuations in the 21 cm background, as estimated by Zaldarriaga et al. (2004), while contamination by the CMB is negligible.

As noted by Oh & Mack (2003), free-free fluctuations still present a substantial foreground; however, the free-free spectrum is smooth in frequency space, while the 21 cm signal varies strongly over ~0.2 MHz. Thus multifrequency differencing can efficiently remove the smooth background (Zaldarriaga et al. 2004) but only so long as the two signals are uncorrelated. We expect this to be the case with free-free emission: halos with ionized gas will emit free-free radiation but not 21 cm radiation, so the two fields are strongly anticorrelated.

To test how important this effect is, we show the free-free emission from halos in the same redshift slice as the 21 cm signal (a window of 0.2 MHz about $z = 10$) with the dotted line. To construct this curve we have used the Oh (1999) clumping model. Note that $\Delta T_{\text{rms}} \propto z^2 C(z)$ and can thus be easily scaled for different clumping scenarios. We then estimate the cross–power spectrum between the free-free and 21 cm signals by assuming that they are perfectly anticorrelated on large scales; the absolute value of the result is shown by the long-dashed line in the figure. This curve is thus our estimate for the maximally cleaned 21 cm map; it shows that the two are correlated only on the percent level. Because it is smaller than the noise power spectrum for SKA observations, the free-free signal can be efficiently removed with multifrequency data.

4. CONCLUSIONS

To summarize, using a variety of existing models for the clumping of ionized gas and its redshift evolution, we find that the expected free-free distortion to the CMB blackbody spectrum, at frequencies of the order of a few gigahertz and below, is within the reach of upcoming experiments such as ARCADE. The dominant contribution to the background is from ionized gas at $z \leq 3$, because the clumping factor is generally large below this redshift. The free-free background varies across the sky at the level of a few to at most 10%. These fluctuations can be detected with experiments such as the SKA, although a careful separation of CMB anisotropies and other low-frequency radio point sources will be required. At $\nu \leq 200$ MHz, where observations of 21 cm radiation from neutral hydrogen during and before the epoch of reionization are planned, angular fluctuations from free-free emission could become a significant source of confusion. However, we have shown that the cross-correlation between the 21 cm and free-free signals is small, suggesting that the free-free foreground can be removed to good accuracy.

This work is supported by the Sherman Fairchild foundation and DOE DE-FG 03-92-ER40701 (A. C.). We thank A. Benson and Z. Haiman for information related to their clumping models, S. P. Oh for useful comments on the manuscript, and A. Kogut for ARCADE specifications.
