ABSTRACT

We use three semi-analytical models (SAMs) of galaxy formation and evolution run on the same 1 h⁻¹ Gpc MultiDark Planck2 cosmological simulation to investigate the properties of [O II] emission line galaxies at redshift z ~ 1. We compare model predictions with different observational data sets, including DEEP2–FIREFLY galaxies with absolute magnitudes. We estimate the [O II] luminosity (L[O II]) of our model galaxies using the public code GET_EMLINES, which ideally assumes as input the instantaneous star formation rates (SFRs). This property is only available in one of the SAMs under consideration, while the others provide average SFRs, as most models do. We study the feasibility of inferring galaxies’ L[O II] from average SFRs in post-processing. We find that the result is accurate for model galaxies with dust attenuated L[O II] > 10^{42.2} erg s⁻¹ (≤ 5 per cent discrepancy). The galaxy properties that correlate the most with the model L[O II] are the SFR and the observed-frame u and g broad-band magnitudes. Such correlations have r-values above 0.64 and a dispersion that varies with L[O II]. We fit these correlations with simple linear relations and use them as proxies for L[O II], together with an observational conversion that depends on SFR and metallicity. These proxies result in [O II] luminosity functions and halo occupation distributions with shapes that vary depending on both the model and the method used to derive L[O II]. The amplitude of the clustering of model galaxies with L[O II] > 10^{41.4} erg s⁻¹ remains overall unchanged on scales above 1 h⁻¹ Mpc, independently of the L[O II] computation.

Key words: galaxies: distances and redshifts – galaxies: haloes – galaxies: statistics – large-scale structure of Universe – cosmology: observations – cosmology: theory.

1 INTRODUCTION

In the era of precision cosmology, surveys are starting to rely on star-forming galaxies to go further into early cosmic times, when dark energy is just starting to dominate the energy-matter budget of the Universe. Star-forming galaxies with strong nebular emission lines (ELGs) are among the preferred targets of the new generation of spectroscopic surveys as SDSS-IV/eBOSS (Dawson et al. 2016), DESI (Schlegel et al. 2015), 4MOST,WFIRST, Subaru-PFS, and Euclid (Laureijs et al. 2011; Sartoris et al. 2015), and will be

used to trace the baryon acoustic oscillation (BAO; Eisenstein et al. 2005) scale and the growth of structure by measuring redshift-space distortions in the observed clustering (Alam et al. 2015; Mohammad et al. 2018; Orsi & Angulo 2018). Star-forming galaxies will also be fundamental to inform halo occupation distribution (HOD; Berlind & Weinberg 2002; Cooray & Sheth 2002; Kravtsov et al. 2004; Zheng, Coil & Zehavi 2007) and (sub)halo abundance matching (SHAM; Conroy, Wechsler & Kravtsov 2006; Behroozi, Conroy & Wechsler 2010; Trujillo-Gomez et al. 2011; Nuza et al. 2013) models to generate fast mock galaxy catalogues useful for cosmological tests.

At $z \sim 1$ and for optical detectors, the samples of star-forming ELGs are dominated by [O II] emitters. Therefore, measuring and modelling the relations between redshift and the physical properties of these galaxies – such as [O II] luminosity with star formation rate (SFR) – is crucial for capitalizing on the science that can be addressed from [O II] data. In this work, we aim to do exactly this, ultimately allowing us to build robust galaxy clustering predictions for near-future [O II] data sets dominated by star-forming galaxies.

Modelling emission lines require, at least, a certain knowledge of both the gas and the star formation history of a given galaxy. [O II] emission is particularly difficult to predict, as it critically depends on local properties, such as dust attenuation, the structure of the H II regions and their ionization fields. For this reason, [O II] traces star formation and metallicity in a non-trivial way (e.g. Kewley, Geller & Jansen 2004; Dickey et al. 2016). Previous works on [O II] emitters have shown that semi-analytical models of galaxy formation (SAMs) are ideal laboratories for studying the physical properties of these galaxies, since they can reproduce the observed [O II] luminosity function (LF) at $z \sim 1$ (Orsi et al. 2014; Comparat et al. 2015, 2016; Hirschmann et al. 2017). Gonzalez-Perez et al. (2018) explored how [O II] emitters are distributed in the dark matter haloes. They found typical host halo masses in agreement with the results from Favole et al. (2016a), which were based on a modified SHAM technique combining observational data with the MultiDark Planck dark matter N-body simulation (MDPL; Klypin et al. 2016).

For this project, we use the MultiDark-Galaxies mock products, which are publicly available at https://www.cosmosim.org. These catalogues were produced using three different SAMs to populate the snapshots of the MultiDark2 (MDPL2; Klypin et al. 2016) dark matter cosmological simulation, over the redshift range $0 < z < 8$ (Knebe et al. 2018). MDPL2 is one of the largest dark matter simulation boxes with a volume of $1 \times 10^9 Mpc^3$ and $3048^3$ particles with mass resolution of $1.51 \times 10^7 M_\odot$. The models used in the production of these catalogues were: SAG (Gargiulo et al. 2015; Muñoz Arancibia et al. 2015; Cora et al. 2018), SAGE (Crocce et al. 2018), and GALACTICUS (Benson 2012).

In this work, we explore the limitations of estimating the [O II] luminosity in post-processing using different approaches, assessing how this quantity correlates with other galactic properties within the studied SAMs. The results from model galaxies are compared with observations from DEEP2 (Newman et al. 2013). The DEEP2 spectra have been fitted using FIREFLY (Comparat et al. 2017; Wilkinson et al. 2017) to extract physical properties for these galaxies. Our final DEEP2 data set and SAM galaxy catalogues including emission line properties are made publicly available (see Section 6). In this analysis, we assume a Planck Collaboration XIII (2015) cosmology with $\Omega_m = 0.6929$, $\Omega_\Lambda = 0.3071$, and $h = 0.6777$.

The paper is organized as follows: in Section 2, we describe the SAMs considered in our study, the DEEP2 observational data set and the FIREFLY code for spectral fitting. We compare the model SFR and stellar mass functions with current observations. In Section 3, we describe how we calculate the [O II] emission line luminosity in the SAMs using the publicly available code GET_EMLINES by Orsi et al. (2014) with instantaneous SFR and cold gas metallicity as inputs. We analyse the impact of using average rather instantaneous SFR in this calculation to be used in those SAMs that do not provide instantaneous quantities. We compare the derived [O II] LFs with current observations. In Section 4, we explore the correlations between $L$[O II] and several galactic properties to establish model proxies for the [O II] luminosity. We provide scaling relations among these quantities that can be used in models without an emission line estimate. We further test these proxies by checking the consistency of the evolution of their [O II] LFs and clustering signal with observations and direct predictions from SAMs. Section 5 summarizes our findings.

2 DATA

2.1 Semi-analytical models

SAMs of galaxy formation (White & Frenk 1991; Kauffmann, White & Guiderdoni 1993) encapsulate the key mechanisms that contribute to form galaxies in a set of coupled differential equations, allowing one to populate the dark matter haloes in cosmological N-body simulations with relative haste (see e.g. Baugh 2006; Benson 2010; Somerville & Davé 2015). In the last two decades, a huge effort has been made to improve these models and account for the physical processes that shape galaxy formation and evolution, such as gas cooling (e.g. De Lucia et al. 2010; Monaco et al. 2014; Hou, Lacy & French 2017), gas accretion (e.g. Guo et al. 2011; Henriques et al. 2013; Hirschmann, De Lucia & Fontanot 2016), star formation (e.g. Lagos et al. 2011), stellar winds (e.g. Lagos, Lacey & Baugh 2013), stellar evolution (e.g. Tonini et al. 2009; Henriques et al. 2011; Gonzalez-Perez et al. 2014), active galactic nucleus (AGN) feedback (e.g. Bower et al. 2006; Croton et al. 2006), or environmental processes (e.g. Weinmann et al. 2006; Font et al. 2008; Stevens & Brown 2017; Cora et al. 2018). Typically, SAMs do not attempt to resolve the scales on which these key astrophysical processes take place, but rather they describe their effects globally. Inevitably, this leads to free parameters in the models that require calibration; in essence, these compensate for the lack of understanding of certain processes and also for not resolving the relevant small scales.

In this study, we use the results from three SAMs of galaxy formation: SAG (Cora 2006; Gargiulo et al. 2015; Muñoz Arancibia et al. 2015; Cora et al. 2018), SAGE (Croton et al. 2006, 2016), and Galacticus (Benson 2012). The three SAMs considered have been run on the same MultiDark2 1 $h^{-1}$ Gpc cosmological simulation with Planck cosmology (Klypin et al. 2016) to produce mock galaxy catalogues.

The complete description of the first data release of the MultiDark-Galaxies products including SAG, SAGE, and GALACTICUS mock catalogues can be found in Knebe et al. (2018). All these catalogues lack [O II] luminosity estimates. A version of Galacticus does have an emission line calculation (Merson et al. 2018), but it has not been applied to the MultiDark models.

2.1.1 SAG

We consider a modified version of the semi-analytical galaxies (SAG; Cora 2006; Lagos, Cora & Padilla 2008; Gargiulo et al. 2015; Muñoz

6 publicly available at https://www.cosmosim.org and http://skiesanduniverses.org/.
Arancibia et al. 2015; Collacchioni et al. 2018; Cora et al. 2018) code, which involves a detailed chemical model and implements an improved treatment of environmental effects (ram pressure of both hot and cold gas phases and tidal stripping of gaseous and stellar components). It also includes the modelling of the strong galaxy emission lines in the optical and far-infrared range as described in Orsi et al. (2014). The free parameters of the model have been tuned by applying the particle swarm optimization technique (PSO; Ruiz et al. 2015) and using as constraints the stellar mass function at \( z = 0 \) and \( 2 \) (data compilations from Henriques et al. 2015), the SFR function at \( z = 0.14 \) (Gruppioni et al. 2015), the fraction of mass in cold gas as a function of stellar mass (Boselli et al. 2014), and the black hole–bulge mass relation (Kormendy & Ho 2013; McConnell & Ma 2013).

### 2.1.2 SAGE

The semi-analytical galaxy evolution\(^6\) code (SAGE; Croton et al. 2006, 2016) is a modular and customizable SAM. The updated physics includes gas accretion, ejection due to feedback, a new gas cooling–radio mode AGN heating cycle, AGN feedback in the quasar mode, galaxy mergers, disruption, and the build-up of intracluster stars.

SAGE was calibrated to reproduce several statistical features and scaling relations of galaxies at \( z = 0 \), including the stellar mass function, tightly matching the observational uncertainty range (Baldry, Glazebrook & Driver 2008), the black hole–bulge mass relation, the stellar mass–gas metallicity relation, and the Baryonic Tully–Fisher relation (Tully & Fisher 1977).

### 2.1.3 GALACTICUS

GALACTICUS\(^7\) (Benson 2012) has much in common with the previous two models, in terms of modularity, the range of physical processes included and the type of quantities that it can predict. Although this model has not been re-tuned to this simulation, the original calibration was performed using analytically built merger trees assuming a WMAP7 cosmology (Benson 2012). The original model reproduced reasonably well, the observed stellar mass function at \( z \sim 0.07 \) (Li & White 2009) and the H\textsc{i} mass function at \( z \sim 0 \) (Martin et al. 2010).

### 2.1.4 Model comparison

For a full comparison between the SAG, SAGE, and GALACTICUS SAMs adopted in this work, we refer the reader to Knebe et al. (2018). The main differences between them are: (i) the calibrations; (ii) the treatment of mergers; (iii) galaxies without a host halo, ‘orphans’, are not allowed in SAGE, while they can happen, due to mass stripping, within GALACTICUS and SAG; and (iv) the metal enrichment models, with GALACTICUS and SAGE assuming an instantaneous recycling approximation and SAG implementing a more complete chemical model (Cora 2006; Collacchioni et al. 2018).

Here, we also recall some results from Knebe et al. (2018) that are important for interpreting the outcomes of our analysis and a further study of global properties can be found in Appendix C. As we impose a minimum limit of \( M_\star > 10^{8.57} M_\odot \) and SFR \( > 0 \) yr\(^{-1} \) M\(_\odot\)\(^8\).

Fig. 1. Cosmic SFR density of SAG, SAGE, and GALACTICUS MultiDark-Galaxies as a function of redshift, compared to four independent compilations of data sets from Behroozi, Wechsler & Conroy (2013) [this was corrected to a Chabrier, Hennebelle & Charlot (2014) IMF by the same authors], Madau & Dickinson (2014), Driver et al. (2018), and Gruppioni et al. (2015). The error bars are the 1\( \sigma \) dispersion around each point. We show this result only up to \( z \sim 2 \), which is the maximum redshift of interest for our study.

The cuts above have been chosen taking into account the resolution limit of the MultiDark cosmological simulation (see Knebe et al. 2018). At \( z \sim 1 \), the limit on SFR excludes about 4 per cent of the entire SAG population, 17 per cent of galaxies in SAGE, and no galaxies from GALACTICUS.

Fig. 1 only extends to \( z \sim 2 \), as higher redshifts are not of interest for this study. All the SAMs agree with the observations within our redshift range of interest \( 0.6 < z < 1.2 \). Beyond \( z = 2 \), SAG and GALACTICUS model galaxies maintain a good agreement with the data out to \( z \sim 8.5 \), while SAGE overpredicts the SFR density at \( z \gtrsim 4 \) (see Knebe et al. 2018). In SAMs, galaxy properties are obtained by solving coupled differential equations in a certain number of steps in which the time interval between snapshots of the underlying DM simulation is divided. In this context, we define the ‘instantaneous SFR’ as the SFR computed using the mass of stars formed over the last step before the output. The ‘average SFR’ is instead the SFR obtained by considering the average contribution from all the steps. The SAG model subdivides the time between snapshots in 25. This time-scale typically corresponds to \( \approx 10–25 \) Myr at \( z \sim 1 \), which is the time-scale physically relevant for the [O\textsc{ii}] emission. SAGE and GALACTICUS split time in 10 steps.

Fig. 2 displays the average SFR functions of the MultiDark-Galaxies at different redshifts compared to the Herschel data from the PEP and HerMES surveys (Gruppioni et al. 2015). We find good agreement for SAG model galaxies over the whole SFR and \( z \) ranges considered. GALACTICUS is consistent with the measurements at \( \text{SFR} \lesssim 10^{2.5} \) yr\(^{-1} \) M\(_\odot\), while SAGE agrees with the data up to...
$10^2$ yr$^{-1}$ $M_{\odot}$. At higher SFRs, SAGE underpredicts the number of star-forming galaxies by $\sim 2$ dex.

In Fig. 3, we show the evolution of the MultiDark-Galaxies stellar mass function compared to, from top to bottom, the SDSS–GALEX observations at $z = 0.1$ (Moustakas et al. 2013), the PRIMUS measurements at $0.50 < z < 0.65$ (Moustakas et al. 2013), the BOSS CMASS observations at $0.5 < z < 0.6$ (Maraston et al. 2013), the DEEP2-FF data at $0.9 < z < 1.1$, and the ZFOURGE/CANDELS star-forming galaxies at $1.5 < z < 2.5$ (Tomczak et al. 2014). The BOSS CMASS mass function drops in the low-mass end due to the incompleteness effect generated by the CMASS colour cuts specifically designed to select luminous, red, massive galaxies (Maraston et al. 2013). Note that the stellar mass functions shown in Fig. 3 are not the same as those from Knebe et al. (2018) due to the SFR > 0 cut we apply to the SAMS. The systematic errors on DEEP2 observations at $z \sim 1$ are expected to differ from those of SDSS galaxies at lower redshifts.

It is not surprising that the agreement between SAG and ZFOURGE/CANDELS data is especially good because this model was calibrated against these observations. SAGE and GALACTICUS overpredict the number of galaxies with $\log(M_\star/[M_\odot]) \leq 11$, and this excess is enhanced at higher redshift (from $\sim 0.1$ dex at $z = 0.1$ to $\sim 0.4$ dex at $z = 2$). SAGE underestimates the number of galaxies more massive than $10^{11} M_\odot$ at all redshifts. We deem the MultiDark-Galaxies to be in sufficient agreement with observations in terms of their stellar mass and SFR evolution such that we can draw meaningful predictions from the models that rely on these properties.

**2.2 DEEP2 galaxies**

We are interested in exploring the relationship between $L[O\ II]$ and different galactic properties. For comparison, we use an observational data set, the DEEP2–FIREFLY (DEEP2-FF, hereafter) galaxy sample, which allows us to test whether the model galaxies cover similar ranges of parameters, once the adequate selection functions are implemented.

The DEEP2 survey obtained spectra of about 50 000 galaxies brighter than $R \sim 24.1$, in four separate fields covering $\sim 2.8$ deg$^2$ (Newman et al. 2013). The redshift measurement for each object in the DEEP2 DR4 data base was inspected by eye and assigned an integer quality code $-2 < Q < 4$ based on the determined accuracy.
of the redshift value.\(^8\) For this work, we consider galaxies with \(Q > 2\), corresponding to secure redshifts, within the range \(0.001 < z_{\text{best}} < 1.7\).

We adopt the DEEP2 flux-calibrated spectra generated by Comparat et al. (2016).\(^9\) We also use the extended photometric catalogues developed by Matthews et al. (2013),\(^10\) which supplement the DEEP2 photometric catalogues with (\(u, g, r, i, z\)) photometry from the Sloan Digital Sky Survey (SDSS). By applying the cuts specified above and taking into account the cross-match between the mentioned catalogues, the spectra of 33,838 galaxies from the original DEEP2 DR4 catalogue are used in this study. These spectra are fitted using stellar population models to extract quantities such as stellar masses, stellar metallicities, SFRs, and ages. In particular, the DEEP2 SFR values are computed by fitting stellar population models to the spectral continuum, where the emission lines are masked for the fit. Thus, this constitutes an independent estimate from an \([\text{O II}]\)-based SFR.

The spectral fit is performed using the FIREFLY\(^11\) code (Comparat et al. 2017; Wilkinson et al. 2017) in which no priors, other than the assumed model described immediately below, are applied. FIREFLY treats dust attenuation in a novel way, by rectifying the continuum before the fit; for full details see Wilkinson et al. (2017) and Comparat et al. (2017). The FIREFLY fit is performed for spectral templates with ages below 20 Gyr and metallicities in the range 0.001 \(< Z < 3\). The maximum age found for the DEEP2-FF sample is 10.18 Gyr. It is noteworthy to remark that FIREFLY does not interpolate between the ages of the templates used in the spectral fitting. For this study, we adopt spectral templates from Maraston & Strömbäck (2011), assuming a Chabrier (2003) initial mass function (IMF), same as in the MultiDark-Galaxies, and the ELODIE stellar library. This latter covers the wavelength range 3900–6800 Å with a 0.55 Å sampling at 5500 Å, i.e. at a resolution \(R = 10,000\) (Prugniel et al. 2007).

The DEEP2 survey used the DEIMOS spectrograph at Keck, which covers approximately the wavelength range 6500–9300 Å with a resolution \(\sim 6000\) (Faber et al. 2003). The discrepancy in wavelength coverage results in a lack of fits at low redshifts for this survey.

The FIREFLY fits to the DEEP2 spectra described above are available at http://www.icg.port.ac.uk/Firefly/ (340 MB). Another fit to the DEEP2 spectra has been performed by Comparat et al. (2017) assuming slightly different age and metallicity ranges, and using a previous version of FIREFLY that did not take into account the presence of mass-loss in the stellar population models. Here, we refer to ‘stellar mass’ as the sum of the mass of living stars and the mass locked in stellar remnants (i.e. white dwarfs, neutron star, and black holes).

2.2.1 Broad-band absolute magnitudes

The DEEP2-FF galaxy catalogue also provides SDSS (\(u, g, r, i, z\)) apparent magnitudes. In order to compare these observations with the MultiDark-Galaxies absolute magnitudes, we have \((k + e)\) corrected them (where ‘\(e\)’ stands for evolution). To this end, we have produced an evolving set of simple stellar populations (SSP; Maraston & Strömbäck 2011) with ages, metallicities, and redshifts matching those used for the FIREFLY runs described above. In particular, we produce a table of possible evolutionary paths that provides the observed-frame properties of the given SSPs in the SDSS filters and allows us to determine the \(k\)-correction in those filters without any approximation. Hereafter, we will call it ‘MS table’. This table calculates intrinsic magnitudes. The DEEP2 data have been corrected from interstellar dust attenuation by applying Calzetti et al. (2000) extinction law.

These SDSS observed-frame properties are computed by red-shifting the model SEDs to a fixed grid of redshifts from \(z = 3.5\) down to \(z = 0\), with \(\Delta z = 0.1\), and applying cosmological dimming using the Flexible-k-and-evolutionary-correction algorithm (FLAKE; Maraston in preparation). We interpolate between the redshifts when needed. Such a technique has been widely used in the literature (e.g. Maraston et al. 2013; Etherington et al. 2017) and can be generalized to any arbitrary set of filters.

From each SSP model in the MS table above, we extract the \((k + e)\) correction as
\[
(k + e)_j = M_j(z) - m_j = M_j(z) - M_j(z = 0),
\]
where \(M_j\) are the galaxy SDSS \(j = (u, g, r, i, z)\) absolute magnitudes at redshift \(z\) and \(m\) are the observed magnitudes, i.e. the absolute magnitudes at \(z = 0\).

The FIREFLY spectral fitting code finds the best fit to a galaxy by weighting different SSPs and adding them together. It turns out that the best FIREFLY fits to the DEEP2 galaxy sample have only two SSP components. Thus, the DEEP2-FF galaxy sample can be cross-matched with the components of the MS table, by using a linear combination of the two SSP components of each FIREFLY (FF) best fit:
\[
\text{SSP}_{\text{MS}} = w_0 \times \text{SSP}^{\text{FF}}_0 + w_1 \times \text{SSP}^{\text{FF}}_1,
\]
with \(w_0 + w_1 = 1\). Then, each DEEP2-FF galaxy is assigned a \((k + e)\) correction that is the weighted, linear combination of the corrections from each SSP component:
\[
(k + e)_j = (k + e)^0_j w_0 + (k + e)_j^1 w_1.
\]

2.2.2 The DEEP2–FIREFLY galaxy sample

For our analysis, we focus on DEEP2-FF galaxies within the redshift range \(0.9 < z < 1.1\). We consider the sum of the \([\text{O II}]\) 3727 Å and 3729 Å line fluxes as the \([\text{O II}]\) doublet. Here, we impose a flux limit of \(F[\text{O II}] > 5 \sigma_{[\text{O II}]}\) (where \(\sigma_{[\text{O II}]}\) is the flux error) to guarantee robust flux estimates, and a minimum stellar mass uncertainty of \(\log_{10}(M_{10}^{\text{up low}}) - \log_{10}(M_{10}^{\text{up low}})) < 0.4\). In the previous expression, \(M_{10}^{\text{up low}}\) represents the FIREFLY stellar mass within \(\pm 1\sigma\) from the mean value of the distribution.

After applying the cuts described above, our final sample includes 4478 emitters with minimum \([\text{O II}]\) flux of \(2.45 \times 10^{-19} \text{ erg s}^{-1} \text{ cm}^{-2}\), mean \(L[\text{O II}] \sim 10^{41.6} \text{ erg s}^{-1}\), \(M_\odot \sim 10^{10.3} \text{ M}_\odot\), age \(\sim 10^{2} \text{ yr}\), and mean cold gas metallicity \(Z_{\text{cold}} \sim 0.72\). Fig. 5 shows the distribution of \(L[\text{O II}]\) as a function of SFR. The observed sample only populates a narrow range of SFR, and this affects the comparison with the model galaxies, which have SFRs lower than the minimum value of the DEEP2-FF sample. Other properties from this data set can be seen in Fig. 8 and in Appendix C. We assume the dust attenuation of the nebular emission lines to be the same as for the continuum.

Thus, we also correct the \(L[\text{O II}]\) from interstellar dust attenuation by applying Calzetti et al. (2000) extinction law, as we have detailed above for the broad-band magnitudes.

For the analysis, we select both observed and models galaxies using a more conservative flux cut, \(F[\text{O II}] > 5 \times 10^{-18} \text{ erg s}^{-1} \text{ cm}^{-2}\).
Figure 4. Attenuated \(L_{\text{[O II]}}\) distribution of the original DEEP2 sample (black, empty dots) compared to the DEEP2-FF selection (black, filled dots), which we fit with a spline function. The area under the curves is normalized to unity. We compare these results with the SAG model galaxies selected with \(M_\star > 10^{8.87} M_\odot\) and \(SFR > 0\) yr \(^{-1}\) \(M_\odot\) (empty squares; see Section 2.1.4), and with the SAG galaxies randomly drawn from the DEEP2-FF spline distribution (filled squares). The \([\text{O II}]\) luminosity values in the model galaxies are calculated using the GET_EMLINES code, inputting either the instantaneous (purple) or average (salmon) SFR. All the details about these quantities and the calculations are given in Section 3.1.

Figure 5. Intrinsic \([\text{O II}]\) luminosity as a function of the SFR for the SAG model galaxies at \(z \sim 1\) (contours) and the DEEP2-FF observations at \(0.9 < z < 1.1\) (grey, shaded squares). The bar represents the number density of DEEP2-FF galaxies in each 2D bin normalized by the bin area in units of \([\text{dex}^{-2} \text{Mpc}^{-3}]\). We have imposed a minimum \([\text{O II}]\) flux of \(5 \times 10^{-18}\) erg s\(^{-1}\) cm\(^{-2}\) to both observations and models. The model \(L_{\text{[O II]}}\) values are calculated by assuming instantaneous (solid, purple contours) and average (dashed, salmon) SFR as input for the GET_EMLINES prescription. The innermost (outermost) model contours encompass 68 per cent (95 per cent) percent of the galaxy distributions. The diagonal lines represent the \(L_{\text{[O II]}}\)-SFR correlations, whose coefficients are given in Table 1.

Figure 6. Average (dashed, salmon) versus instantaneous (solid, purple) SFR functions for SAG model galaxies. The bottom panel shows the ratio between the two, and the yellow, shaded region highlights the 5 per cent region of agreement.

Figure 7. Intrinsic (thick lines) and attenuated (thin) \([\text{O II}]\) LFs based on SAG average (dashed, salmon) and instantaneous SFR (solid, purple). The bottom panel shows the ratios between the two and the yellow, shaded region highlights the 5 per cent region of agreement. We apply the mocks the same \([\text{O II}]\) flux limit of DEEP2-FF observations, \(5 \times 10^{-18}\) erg s\(^{-1}\) cm\(^{-2}\) (see Section 2.2.2).

This corresponds to \(L_{\text{[O II]}} \sim 10^{40.4}\) erg s\(^{-1}\) at \(z = 1\) in Planck cosmology (Planck Collaboration XIII 2015), and roughly mimics the observational limitations (see also Gonzalez-Perez et al. 2018). This cut reduces the sparse, faint tail of the observed distribution (there are only 4 DEEP2 galaxies with flux lower than \(5 \times 10^{-18}\) erg s\(^{-1}\) cm\(^{-2}\)) and allows us to obtain much narrower SAM constraints.

As shown in Fig. 4, most galaxies with \(L_{\text{[O II]}} < 10^{40.5}\) erg s\(^{-1}\) have been removed from the DEEP2-FF sample, compared to the original DEEP2 population. Despite this, the DEEP2-FF galaxy sample is statistically representative of the original DEEP2 population. In fact, the cumulative distribution functions of these two samples,
Figure 8. From top to bottom: intrinsic magnitudes, ages, and stellar masses as a function of SFR for SAG (contours) at $z \sim 1$ and DEEP2-FF observations at 0.9 < $z$ < 1.1 (grey, shaded squares). The colour bar shows the number density of DEEP2 galaxies per bin area in units of $[\text{dex}^{-2} \text{Mpc}^{-3}]$. The dashed, salmon (solid, purple) contours represent the average (instantaneous) SFRs. The innermost (outermost) contours encompass 68 per cent (95 per cent) of the distributions. The diagonal lines are the linear fits showing the significant correlations (i.e. $r \geq 0.6$), whose coefficients are reported in Table 2, together with the best-fitting parameters.

Approximated by splines, differ by less than 5 per cent, according to a Kolmogorov–Smirnov test.

Fig. 4 shows the distribution of the dust-attenuated $L$[O II] computed with GET_EMLINES (see Section 3.1) from instantaneous and average SFRs, for SAG model galaxies at $z = 0.94$ and with $M_*>10^{9.87}M_\odot$ and SFR $> 0 \text{yr}^{-1}M_\odot$ (see Section 2.1.4). These model $L$[O II] distributions are statistically different from the DEEP2-FF one. However, they have similar mean values: $\langle L[\text{O II}] \rangle \sim 10^{42} \text{erg s}^{-1}, \langle \text{age} \rangle \sim 10^{9.2} \text{yr}, \langle M_* \rangle \sim 10^{9.87}M_\odot$.

In order to draw a sample of model galaxies consistent with DEEP2-FF observations, we select SAG galaxies with a $L$[O II] distribution following the spline fit to the DEEP2-FF distribution, as shown in Fig. 4. We perform such a drawing for SAG [O II] luminosities computed both from instantaneous and average SFR. The $L$[O II] of these new selections have mean values consistent with those from the DEEP2-FF sample. Meanwhile, the ages, (age) $\sim 10^9$ yr, and the stellar masses, $\langle M_* \rangle \sim 10^{9.96}M_\odot$, are lower than the observed ones.

In Appendix A, the DEEP2-FF sample is directly compared to the SAG model galaxies selected following the DEEP2-FF $L$[O II] distribution. These SAG model subsets have brighter $L$[O II], $M_*$, and $M_e$ values, slightly lower ages, higher stellar masses, and span higher SFR values compared to the SAG selection at $z = 0.9$.

The main focus of this paper is to test the validity of different approaches for modelling emission lines in large galaxy samples with volumes comparable to the observable Universe. In this context, the comparison to the DEEP2-FF sample is meant to be a rough guide to the expected location of observed galaxies in different parameter spaces.

3 [O II] EMITTERS IN THE SAMS

The physics of [O II] emission lines is difficult to model, as it depends on local processes, such as dust extinction, and the inner structure and the ionizing fields of the H II nebula in which they are embedded. Different approaches have been used to model the [O II] emission line: (i) assume a relation between $L$[O II] and SFR and, possibly, metallicity as it happens in observations (Kennicutt 1998; Kewley et al. 2004; Moustakas, Kennicutt & Tremonti 2006; Jouve et al. 2009; Sobral et al. 2012; Talia et al. 2015; Valentino et al. 2017); (ii) assume an average H II region for a range of metallicities (Gonzalez-Perez et al. 2018); (iii) couple a photoionization model with a galaxy evolution one (Hirschmann et al. 2012; Orsi et al. 2014). We address method (i) in Section 4 and method (iii) here.

None of the MultiDark-Galaxies catalogues studied in this work provides direct $L$[O II] estimates. Therefore, we couple the SAMS with the GET_EMLINES model (Orsi et al. 2014), which encapsulates the results from the MAPPINGS-III photoionization code (Groves, Dopita & Sutherland 2004; Allen et al. 2008). Here, the ionization parameter of gas in galaxies is directly related to their cold gas metallicity, obtaining a reasonable agreement with the observed H α, [O II] $\lambda 3727$, [O III] $\lambda 5007$ LFs, and the Baldwin, Phillips & Terlevich (1981; BTP) diagram for local star-forming galaxies. Ideally, the GET_EMLINES methodology requires as input the cold gas metallicity and the instantaneous SFR. This latter quantity, however, is not usually output by SAMS. The instantaneous SFR is preferred to a time-averaged equivalent, as the latter can include contributions from stellar populations older than those responsible for generating the nebular emission in star-forming galaxies.

SAG is the only SAM providing both instantaneous and average SFR values, while SAGE and GALACTICUS only provide average SFRs. In the next section, we describe in detail the GET_EMLINES algorithm to be used in the $L$[O II] calculation for an SAM. Because SAMS do not usually output the instantaneous SFR, which is needed as default input for the GET_EMLINES code, we test the usage of the average SFR and how this affects different galactic properties.

3.1 The GET_EMLINES code

We now describe step by step how we have implemented the GET_EMLINES nebular emission code to obtain [O II] luminosities for the MultiDark-Galaxies. This methodology is based on the photoionization code MAPPINGS-III (Groves et al. 2004; Allen et al. 2008), which relates the ionization parameter of gas in galaxies, $q$, to their cold gas metallicity $Z_{\text{cold}}$ as

$$q(Z) = q_0 \left( \frac{Z_{\text{cold}}}{Z_0} \right)^{-\gamma},$$

where $q_0$ is the ionization parameter of a galaxy that has cold gas metallicity $Z_0$ and $\gamma$ is the exponent of the power law. Following Orsi et al. (2014), from the pre-computed H II region model grid of Levesque et al. (2010), we assume $q_0 = 2.8 \times 10^7 \text{ cm s}^{-1}$, $Z_0 = 0.012$, and $\gamma = 1.3$ for all the analysed galaxy models. This specific combination of values was presented in Orsi et al. (2014), and it has ionization parameter values that bracket the range spanned by the MAPPINGS-III grid for the bulk of the galaxy population studied in that work. The $q_0$ and $\gamma$ parameters above were found to produce model H α, [O II] $\lambda 3727$ (to indicate the doublet), [O III] $\lambda 5007$ LFs,
and a model BTP (Baldwin et al. 1981) diagram for local star-forming galaxies in good agreement with observations.

The GET EMILINES code has been calibrated to reproduce a range of LFs at different redshifts and local line ratios diagrams, and it has been tested against observations up to z = 5 (Orsi et al. 2014). A different combination of \( q_0 \) and \( \gamma \) changes the \( L[O \text{ II}] \) results in a complicated way. For instance, higher parameter values produce a lower number density of bright emitters, which translates into a substantial difference in the lower peak of the \( L[O \text{ II}] \)-SFR bimodality shown in Fig. 5. Changing the \( q_0 \) and \( \gamma \) parameters would require to recalibrate the GET EMILINES model, and this goes beyond the scope of this work.

The cold gas metallicity is defined as the ratio between the cold gas mass in metals and the cold gas mass (e.g. Yates 2014), considering both bulge and disc components, when available:

\[
Z_{\text{cold}} = \frac{M_{Z_{\text{cold}}}}{M_{\text{cold}}},
\]

Another fundamental quantity needed to derive the [O II] line luminosity is the hydrogen ionizing photon rate defined as

\[
Q_{\text{H}^+} = \frac{\int_0^{\lambda_0} n_\text{e} \lambda L_\lambda \, d\lambda}{hc},
\]

where \( L_\lambda \) is the galaxy composite SED in erg s\(^{-1}\) Å\(^{-1}\), \( \lambda_0 \) = 912 Å, \( c \) is the speed of light, and \( h \) is the Planck constant. \( Q_{\text{H}^+} \) is a unitless quantity calculated at each model snapshot just by solving the integral above. Assuming a Kroupa (2001) IMF, one can express the ionizing photon rate as a function of the instantaneous SFR as (Falcón-Barroso & Knapen 2013)

\[
Q_{\text{H}^+} = \log_{10}1.35 + \log_{10}(\text{SFR}/M_\odot \text{ yr}^{-1}) + 53.0.
\]

Combining equation (7) with the attenuation-corrected emission-line lists from Levesque et al. (2010), normalized to the H\( \alpha \) line flux, we compute the [O II] luminosity as

\[
L(\lambda_j) = 1.37 \times 10^{-12} Q_{\text{H}^+} F(\lambda_j, q, Z_{\text{cold}}) F(H\alpha, q, Z_{\text{cold}}),
\]

where \( F(\lambda_j, q, Z_{\text{cold}}) \) is the MAPPINGS-III prediction of the desired emission line flux at wavelength \( \lambda_j \) for a given set of \((q, Z_{\text{cold}})\) and \( F(H\alpha, q, Z_{\text{cold}}) \) is the \( H\alpha \) normalization flux.

The galaxy optical depth \( \tau_z \) that enters equation (10) is defined as (Devriendt, Guiderdoni & Sadat 1999; Hatton et al. 2003; De Lucia & Blaizot 2007)

\[
\tau_z = \left( \frac{A_\lambda}{A_V} \right) Z_{\odot} \left( \frac{Z_{\text{cold}}}{Z_{\odot}} \right)^s \left( \frac{N_{\text{HI}}}{2.1 \times 10^{21} \text{ atoms cm}^{-2}} \right),
\]

where the first two factors on the right-hand side represent the extinction curve. This depends on the cold gas metallicity \( Z_{\text{cold}} \) defined in equation (5) according to power-law interpolations based on the solar neighbourhood, the Small and the Large Magellanic Clouds. The exponent \( s = 1.6 \) (Guiderdoni & Rocca-Volmerange 1987) holds for the \( \lambda > 2000 \) Å regime, where the [O II] line is located. The \( (A_\lambda/A_V)_{Z_{\odot}} \) term is the extinction curve for solar metallicity, which we take to be that of the Milky Way, and \( (N_{\text{HI}}) \) the mean hydrogen column density. We adopt the values \( Z_{\odot} = 0.0134 \) (Asplund et al. 2009) for the solar metallicity.

Assuming the Cardelli et al. (1989) extinction law in 0.3 \( \mu \)m \( \leq \lambda < 0.9 \mu \)m (i.e. optical/NIR regime), one has:

\[
\left( \frac{A_\lambda}{A_V} \right) = a(x) + b(x)/R_V,
\]

where \( x = \lambda^{-1} \), \( R_V \equiv AV/E(B - V) = 3.1 \) is the ratio of total to selective extinction for the diffuse interstellar medium in the Milky Way.
Our implementation of the dust attenuation model is available at https://github.com/gfavole/dust.

3.3 Instantaneous versus average SFR

The GET EMLINES code described in Section 3.1 ideally requires as inputs the instantaneous SFR and cold gas metallicity of galaxies. The instantaneous SFR, which is defined on a smaller time-step compared to the average SFR (see Section 2.1.4), traces very recent or ongoing episodes of star formation, that are the relevant ones for nebular emission.

Fig. 5 shows, as a function of SFR, the intrinsic (i.e., corrected from dust attenuation) L[O II] that the coupling with GET EMLINES gives for both the instantaneous (solid contours) and average (dashed) SFR from SAG at \( z \sim 1 \). The innermost (outermost) contours enclose 68 per cent (95 per cent) of our model galaxies. The diagonal lines show the correlations between SFR and \( L[O\ II] \). These are tight correlations, whose best-fitting parameters are reported in Table 1.

Under laid are the DEEP2-FF observational data at 0.9 < \( z < 1.1 \). Overall, the model galaxy distributions presented in Fig. 5 are very similar for the \( L[O\ II] \) derived from either the instantaneous or the average SFRs. These distributions show a bimodality that can also be seen in the observations.

The instantaneous and average SFR derived distributions differ the most at \( SFR \lesssim 10^9\ yr^{-1}\ M_\odot \), with [O II] luminosities from average SFR being \( \sim 0.2 \) dex fainter than those from instantaneous SFR. At \( SFR \sim 10^{1.5}\ yr^{-1}\ M_\odot \), there are slightly less bright [O II] emitters from instantaneous SFR.

DEEP2-FF galaxies in the upper density peak of the observed bimodal distribution shown in Fig. 5 are older, more massive, more luminous and slightly more star forming (mean values: (age) \( \sim 10^{9.23}\ yr \), (\( M_\star \)) \( \sim 10^{9.42}\ M_\odot \), (\( L[O\ II] \)) \( \sim 10^{41.48}\ ergs^{-1} \), (SFR) \( \sim 10^{1.13}\ yr^{-1}\ M_\odot \)) compared to their counterparts in the lower density area (\( \sim 10^{10.17}\ yr \), \( \sim 10^{9.02}\ M_\odot \), \( \sim 10^{39.07}\ ergs^{-1} \), \( \sim 10^{08.38}\ yr^{-1}\ M_\odot \)). Overall, we find an opposite trend for model galaxies. In fact, the upper peak of the bimodality is composed of younger, less massive, slightly more luminous, less star-forming galaxies with mean values: (age) \( \sim 10^{9.16}\ yr \), (\( M_\star \)) \( \sim 10^{9.58}\ M_\odot \), (\( L[O\ II] \)) \( \sim 10^{41.26}\ ergs^{-1} \), (SFR) \( \sim 10^{9.21}\ yr^{-1}\ M_\odot \)); the lower peak has mean values: (age) \( \sim 10^{9.32}\ yr \), (\( M_\star \)) \( \sim 10^{9.06}\ M_\odot \), (\( L[O\ II] \)) \( \sim 10^{41.25}\ ergs^{-1} \), (SFR) \( \sim 10^{9.38}\ yr^{-1}\ M_\odot \).

At the end of this Section, we will discuss further the origin of the DEEP2-FF \( L[O\ II] \)-SFR bimodal trend in connection with other galactic properties shown in Fig. 8.

In the top panel of Fig. 6, we compare the average (dashed, salmon) and instantaneous (solid, purple) SAG SFR functions at \( z \sim 1 \), whose ratio is displayed in the bottom panel. The instantaneous and average SFR functions remain within 5 per cent of each other at \( SFR > 10^9\ yr^{-1}\ M_\odot \) (the 5 per cent region is highlighted by the yellow shade). There is a slightly larger fraction, within 20 per cent, of SAG galaxies having low average SFR, SFR < \( 10^9\ yr^{-1}\ M_\odot \), than instantaneous values. The main difference between average and instantaneous SFRs is found for galaxies with the highest specific SFR (i.e. SFR/\( M_\star \)) and stellar masses below \( 10^{11}\ M_\odot \).

The top panel in Fig. 7 presents the intrinsic (thick lines) and attenuated (thin) [O II] LFs derived from the average SFR (dashed, salmon line) and instantaneous SFR (solid, purple) from SAG. We impose on the SAG model galaxies the same [O II] flux limit of DEEP2-FF observations, \( 5 \times 10^{18}\ ergs^{-1} cm^{-2} \) (see Section 2.2.2), which corresponds to \( L[O\ II] \sim 10^{39.4}\ ergs^{-1} cm^{-2} \) at \( z = 1 \) in Planck cosmology (Planck Collaboration XIII 2015). The instantaneous-to-average amplitude ratios are displayed in the bottom panel of Fig. 7. The intrinsic (attenuated) \( L[O\ II] \) functions have differences below 5 per cent for luminosities in the range \( 10^{41} - 10^{43}\ ergs^{-1} \) (\( 10^{41} - 10^{42.2}\ ergs^{-1} \)), which are highlighted by the yellow shade. At lower (higher) luminosities, the discrepancies grow up to 20 per cent (30 per cent). For the brightest galaxies, the discrepancy remains within 50 per cent. The difference produced in \( L[O\ II] \) by assuming average instead of instantaneous SFR does not change significantly with redshift over the range \( 0.6 < z < 1.2 \) (see Appendix B for further details). Thus, the average and instantaneous SFR can be assumed interchangeably for average galaxies.

In Fig. 8, from top to bottom, we display the SAG broad-band \( u \) and \( g \) absolute magnitudes, ages, and stellar masses as a function of the average SFR (dashed, salmon contour) and instantaneous SFR (solid, purple). We compare them with the DEEP2-FF observations at \( 0.9 < z < 11 \) (grey, shaded squares). Except for the age, all these properties are tightly correlated with both SFRs. The lack of correlation between age and SFRs is clear for both the model and DEEP2-FF galaxies. We fit straight lines to the instantaneous and average contours and report the best-fitting parameters and correlation coefficients in Table 1. For the broad-band magnitudes, the slopes of the average SFR correlations are only \( \sim 0.07 \) shallower than the instantaneous ones;
for the stellar mass they are even closer. Overall, the width of the distributions as a function of both SFRs does not vary significantly. The average SFR contours extend down to slightly smaller values compared to the instantaneous contours.

The DEEP2-FF age and stellar mass distributions as a function of SFR in Fig. 8 show a bimodal trend, with an upper population of older, more massive, luminous, quiescent galaxies (⟨age⟩ ∼ 10^9.8 yr, ⟨M⋆⟩ ∼ 10^{10.82} M⊙, ⟨L[O II]⟩ ∼ 10^{40.55} erg s^{-1}, ⟨SFR⟩ ∼ 10^{0.05} yr^{-1} M⊙) and a lower tail of younger, less massive, luminous, more star-forming emitters (⟨age⟩ ∼ 10^{5.18} yr, ⟨M⋆⟩ ∼ 10^{7.2} M⊙, ⟨L[O II]⟩ ∼ 10^{40.45} erg s^{-1}, ⟨SFR⟩ ∼ 10^{2.14} yr^{-1} M⊙). We obtain the same mean galaxy properties splitting the DEEP2-FF sample with a cut in either the age-SFR or M⋆-SFR planes.

The mean DEEP2-FF values derived from splitting in age or stellar mass as a function of SFR are similar to those obtained by splitting in L[O II] versus SFR (see Fig. 5). The age/mass–SFR bimodal trend observed in DEEP2-FF galaxies is not reproduced by the SAG model galaxies, which instead look bimodal in the L[O II]–SFR plane (Fig. 5) because of the non-trivial dependence of L[O II] on metallicity through the parameters q0 and γ (see Section 3.1).

In this section, we have shown that using the SAG average SFRs as input for the GET_EMLINES code gives results within 5 percent from using the instantaneous value for galaxies with attenuated L[O II] in the range 10^{40.9–41.2} erg s^{-1}, and with intrinsic L[O II] between 10^{40.9} and 10^{41} erg s^{-1}. These are the ELGs with SFR within 10^{-0.2–1} yr^{-1} M⊙. At higher and lower SFRs, there is a larger discrepancy between the average and instantaneous values, which translates into a larger difference (< 60 percent) in the number of bright [O II] emitters. Thus, this effect is not significant for the average galaxy population.

### 3.4 Model [O II] luminosity functions

In the top panel of Fig. 9, we present the MultiDark-Galaxies dust attenuated [O II] LFs at z = 0.94 compared to a compilation of DEEP2 and VVDS data from Comparat et al. (2016). Note that similar results have been found within the redshift range 0.6 < z < 1.2, although they are not shown here. The SAM [O II] luminosities have been derived using the GET_EMLINES code described above coupled with instantaneous SFR for SAG model galaxies, and average SFR for SAGE and Galacticus, for which the instantaneous quantity is not available. The dust attenuation has been accounted for by correcting these luminosities applying equation (9) with Cardelli et al. (1989) extinction curve. There are varying degrees of agreement between the models and observational data across the ~3 decades in [O II] luminosity and redshift range considered. Nevertheless, the trends from all the data sources are consistent. This plot highlights that the shape and normalization of a predicted [O II] LF from an SAM are robust to both the precise prescriptions that govern galaxy evolution in the model, and the calculation of [O II] from either instantaneous or average SFR.

In the top panel of Fig. 9, we see a drop in the number of Galacticus [O II] emitters at intermediate luminosities that is independent of the stellar mass. This is mainly determined by the half-mass radii of the disc, R_{disc}^{1/2} that enter the dust attenuation correction (see equation 14). These radii in Galacticus are about 50 percent smaller than in SAG and SAGE. At L[O II] ∼ 10^{40.5} erg s^{-1} and z < 1.2, Galacticus predicts about 0.5 dex more [O II] emitters than the other two models.

In the bottom panel of Fig. 9, we display the ratios of the attenuated-to-intrinsic L[O II] functions. As expected, the largest effect of attenuation occurs at L[O II] ∼ 10^{42} erg s^{-1}, where more massive galaxies are located, while in the low-luminosity, low-mass regime, the observed and intrinsic signals tend to overlap. The ratio between the intrinsic and attenuated LFs is model dependent. In particular, the largest variations are due to the dust model, which depends on the metallicity, gas content, and size of each galaxy, as described in Section 3.2. For SAGE model galaxies, this ratio increases for brighter L[O II] galaxies. For SAG, the ratio also increases up to L[O II] ∼ 10^{41.5} erg s^{-1}, although with a steeper slope, and beyond this value it reaches a plateau. The ratio for Galacticus has a prominent bump in the luminosity range 10^{41.5–42.5} erg s^{-1}, where the effect of attenuation is more pronounced, and this feature corresponds to the drop seen at intermediate L[O II] in the upper panel. At higher luminosities, there is almost no difference between the intrinsic and dust attenuated Galacticus L[O II] functions.

### 4 [O II] LUMINOSITY PROXIES

Observational studies have shown tight correlations between the [O II] luminosity, SFR (Kennicutt 1998; Kewley et al. 2004; Moustakas et al. 2006; Sobral et al. 2012; Comparat et al. 2015), and the galaxy UV-emission (Comparat et al. 2015), without the need to introduce any dependence on metallicity (Moustakas et al. 2006). This has prompted authors of theoretical papers to treat star-forming galaxies as ELGs when making predictions for upcoming surveys (e.g. Orsi & Angulo 2018; Jiménez et al. 2019).

Here, we explore the possibility of using simple, linear relations to infer the [O II] luminosity from global galaxy properties that are commonly output in SAMs. For this purpose, we investigate both observationally motivated prescriptions (Section 4.1), and we derive model relations from the GET_EMLINES code coupled with the SAMs considered (Sections 4.2 and 4.3). For this last study, we quantify the correlation between the model L[O II] from GET_EMLINES with the average SFR, broad-band magnitudes, stellar masses, ages, and cold gas metallicities. Directly using the measured L[O II]–SFR linear relation is useful to understand when is adequate to consider ELGs equivalent to star-forming galaxies and when it is not.

We find that the stellar mass of the MultiDark-Galaxies are unaffected by the change in proxies for estimating their [O II] luminosities. As a consequence, the stellar-to-halo mass relation (SHMR) is also unchanged using different L[O II] proxies.

We remind the reader that, unless otherwise specified, we exclusively select emission line galaxies with fluxes above 5 × 10^{-19} erg s^{-1} cm^{-2} in both the DEEP2-FF observations and MultiDark-Galaxies. This flux limit corresponds to a L[O II] > 10^{40.4} erg s^{-1} at z = 1 in the Planck cosmology (Planck Collaboration XIII 2015). All the results in what follows have these minimum cuts applied.

### 4.1 The SFR–L[O II] relation

In this Section, we derive intrinsic L[O II] from the average SFR of the MultiDark-Galaxies using three different, published relations assuming a Kennicutt (1998) IMF. These are: the Moustakas et al. (2006) conversion (see also Comparat et al. 2015) calibrated at z = 0.1,

\[ L_{M}^{[O II]}(\text{erg s}^{-1}) = \frac{SFR(M_{\odot} \text{ yr}^{-1})}{2.18 \times 10^{-41}}, \tag{15} \]

the Sobral et al. (2012) formulation optimized at z = 1.47,

\[ L_{S}^{[O II]}(\text{erg s}^{-1}) = \frac{SFR(M_{\odot} \text{ yr}^{-1})}{1.4 \times 10^{-41}}, \tag{16} \]
where we assume \( Z_c = 0.0134 \) (Asplund et al. 2009), and \( [12 + \log_{10}(O/H)_{\text{cold}}] = 8.69 \) (Allende Prieto, Lambert & Asplund 2001).

As the above relations are for intrinsic luminosities, dust attenuated quantities are obtained following the description in Section 3.2.

For SAG and GALACTICUS, galaxies’ cold gas is broken into bulge and disc components (see their respective papers for their definitions of a ‘gas bulge’); we therefore take a mass-weighted average of these components’ metallicities to obtain \( Z_{\text{cold}} \). SAGE instead always treats cold gas as being in a disc. In addition, the SAG catalogues also output the \((O/H)_{\text{cold}}\) values, which are mass density ratios, that we use in the calculation of equation (17) for SAG model galaxies. In order to derive the correct abundances in terms of number densities, we need to rescale them by the oxygen-to-hydrogen atomic weight ratio, \( A_{\text{O}/\text{H}} \sim 15.87 \).

Fig. 10 displays the comparison between the gas-phase oxygen abundances of our SAM galaxies computed using equation (18) and the observed abundance of the SDSS [OII] ELGs at \( z \sim 0.1 \) from Favole et al. (2017). The SDSS metallicity values have been derived from the MPA-JHU DR7 catalogue of spectrum measurements and are built according to the works of Tremonti et al. (2004) and Brinchmann et al. (2004). Overall, we find that the gas-phase oxygen abundance in MultiDark-Galaxies increases with stellar mass up to \( M_\star \sim 10^{11} M_\odot \). Beyond this value it drops and reaches a plateau.

The SAG and SAGE model galaxies underpredict the gas-phase oxygen abundance by an average factor of \( \sim 0.02 \) dex. This systematic offset for SAGE is not predictive, but purely due to the fact that this model was calibrated by assuming a different value of \((O/H)_{\text{cold}}\), specifically \([12 + \log_{10}(O/H)] = [9 + \log_{10}(Z_{\text{cold}}/0.02)]\); for further details, see Knebe et al. (2018).

At \( M_\star < 10^{10.5} M_\odot \), GALACTICUS also underpredicts the gas-phase abundance by the same factor. However, this model exhibits a bump at \( M_\star \sim 10^{10.5} M_\odot \). This feature is related to the excess of galaxies around this stellar mass, which is seen in the galaxy stellar mass function (see Fig. 3). This excess was found to be produced by the depletion of gas due to the extreme AGN feedback mechanism implemented in GALACTICUS, where the galaxies have almost no inflow of pristine gas, and rapidly consume their gas supply (for further details, see Knebe et al. 2018).

We have investigated further this feature finding that, if we exclude galaxies with progressively higher cold gas fraction (CGF), which is defined as \( CGF = M_{\text{cold}}/M_\star \), the bump shrinks continuously. Fig. 10 is produced by combining two cuts: \( CGF > 0.1 \) and \( sSFR > 10^{-11} \text{ yr}^{-1} \). The first one eliminates about half of the GALACTICUS model galaxies, most of them with unrealistically small CGFs, possibly meaning that their metallicities are not reliable due to the precision used in evolving the relevant ordinary differential equations (Benson 2012). The second cut selects only very star-forming galaxies. The model completely disappears for CGF > 0.5, but in that case \( \sim 70 \) per cent of the galaxies are excluded from the sample.

Fig. 11 compares the intrinsic [OII] luminosity as a function of SFR for the three SAMs (coloured, filled contours) with the DEEP2-FF data at \( z \sim 1 \) (grey, shaded squares). We also show the results of the conversions given in equations (15)–(17) (diagonal, black and green lines). The model \( L\text{[OII]} \) is computed using the GET\_EMLINES code coupled with instantaneous SFR for SAG, and average SFR for the other SAMs. The distributions of SAG, SAGE, and GALACTICUS behave in a similar way, reproducing the bimodality observed in the data. The coloured lines (dashed, salmon; solid, yellow; dot–dashed, blue) are the linear fits to the model \( L\text{[OII]} \)–SFR correlations. The best-fitting parameters, correlation coefficients (r-values), and dispersions in both directions are reported in Table 2.

Fig. 11 shows that all the model galaxies considered overlap with the DEEP2-FF observations and extend further towards lower SFR values. All three SAMs cover the \( L\text{[OII]} \) observational range with their 2σ regions. SAGE and GALACTICUS get to the very bright domain of the parameter space, while SAG is limited to fainter \( L\text{[OII]} \) values.

All the SAMs are tightly correlated in the SFR–luminosity plane and such a trend is in reasonable agreement with the observationally derived relations from equations (15)–(17) (diagonal, black, and green lines).

In Fig. 11, the Kewley et al. (2004) parametrization (green line and contours in Fig. 11) appears above all the GET\_EMLINES derivations. These contours are obtained from equation (17), by inputting instantaneous (average) SFR and cold gas metallicity for SAG (SAGE, GALACTICUS) model galaxies. The green, straight lines are calculated by feeding the median metallicity values in bins of SFR into equation (17). Although both the Kewley et al. (2004) relation and the GET\_EMLINES code assume the same cold gas metallicity values as inputs, the obtained distributions are very different. The width of the distributions is model-dependent and the \( L\text{[OII]} \) obtained for galaxies in SAG and GALACTICUS present bimodal distributions. This bimodality comes from the MAPPINGS-III term \( F(l_j, q, Z_{\text{cold}}) \) in equation (8), that is a non-linear function of \( Z_{\text{cold}} \).
Figure 11. Intrinsic [O II] luminosity as a function of the SFR from the MultiDark-Galaxies at $z \sim 1$ (salmon, yellow and blue, filled contours), compared with the DEEP2-FF observations at $0.9 < z < 1.1$ (grey, shaded squares, colour coded with the density of emitters per 2D bin area). The innermost (outermost) contour represents 68 per cent (95 per cent) of the galaxy distributions. For SAG model galaxies, the [O II] luminosities have been computed from instantaneous SFRs, while for the other SAMs they are based on average SFRs. Both data and model ELGs are selected imposing a minimum [O II] flux of $5 \times 10^{-18}$ erg s$^{-1}$ cm$^{-2}$. The thick, coloured, diagonal lines are the linear fits to each SAM distribution, and their best-fitting parameters are reported in Table 2. The black dot–dashed and dashed, diagonal lines are the $L_{\text{[O II]}}$ predictions obtained from the SFR range of interest using equations (15) and (16), respectively. The green, empty contours are the Kewley et al. (2004) predictions obtained using equation (17) with SFR and cold gas metallicity as inputs. The green, solid lines are the same predictions assuming median metallicity values in bins of SFR.

Table 2. Best-fitting parameters of the linear scaling relations shown in Figs 11 and 12. All the [O II] luminosities here are intrinsic and computed using the GETEMLINES code with input the instantaneous SFR for SAGE and average SFR for SAGE and GALACTICUS.

4.2 $L_{\text{[O II]}}$ versus broad-band magnitudes

At a given redshift range, the broad-band magnitudes tracing the rest-frame UV emission of a galaxy are expected to be tightly correlated with the SFR and the production of emission line galaxies. The rest-frame UV slope (1000–3000 Å) at $z \sim 1$ is measured between the $u$ and the $g$ bands (∼2000 Å). As expected, these are the bands that correlate the most with both SFR and [O II] luminosity for the sample under study.

The correlations between the broad-band $u$ and $g$ absolute magnitudes and the intrinsic [O II] luminosity in MultiDark-Galaxies at $z \sim 1$ are displayed in the first two columns of panels in Fig. 12 together with DEEP2-FF observations. Data and all model galaxies show a good overlap in this parameter space.
EMLINES code with instantaneous SFR for SAG and average SFR for SAGE and GALACTICUS. The innermost and outermost model contours represent EMLINES code (see Section 3.1).

EMLINES code, EMLINES code is tightly related to EMLINES code (thick, coloured lines without the intrinsic $L$ between the intrinsic $[\text{O II}]$ luminosity and the stellar mass in as proxies for $L$ of the galaxy properties explored in this Section are good candidates $M_{\text{SFR}}$ and $M_{\text{stellar}}$.

The diagonal lines are the linear fits for strong correlations with $r > 0.6$, as reported in Table 2.

We also study the dependence of the $[\text{O II}]$ luminosity on galaxy properties. From top to bottom and from left to right: $\text{SAG}$, $\text{SAGE}$ and $\text{GALACTICUS}$.

In the third column of Fig. 12, we display the relationship between the intrinsic $[\text{O II}]$ luminosity and the stellar mass in both DEEP2-FF and our model galaxies. In $\text{SAGE}$, we identify a correlation, but none is found for $\text{SAG}$ and $\text{GALACTICUS}$ model galaxies. In DEEP2-FF, we identify a correlation, but none is found for $\text{SAG}$ and $\text{GALACTICUS}$ model galaxies. In $\text{SAGE}$, we identify a correlation with varying levels of success for each model and proxy, and thus they have the potential to be used as proxies for the $[\text{O II}]$ luminosity, using the relations presented in Table 2.

4.3 $[\text{O II}]$ versus age, metallicity, and stellar mass

We also study the dependence of the $[\text{O II}]$ luminosity on galaxy properties that are relevant to the $L[\text{O II]}$ and $(k + e)$ calculations: the age, metallicity, and stellar mass.

The right column of panels in Fig. 12 shows the relationship between the intrinsic $[\text{O II}]$ luminosity and the stellar mass in both DEEP2-FF and our model galaxies. In $\text{SAGE}$, we identify a correlation, but none is found for $\text{SAG}$ and $\text{GALACTICUS}$ model galaxies. The DEEP2-FF data do not exhibit any particular trend, and thus they have the potential to be used as proxies for the $[\text{O II}]$ luminosity, using the relations presented in Table 2.

4.4 From galaxy properties to $L[\text{O II}]$

The $L[\text{O II}]$ derived from the GET_EMLINES code is tightly related to the SFR by construction, but we found it to be also tightly related with the broad-band $u$ and $g$ magnitudes ($r \geq 0.64$, see Table 2). Here, we quantify the usability of the linear relations found as proxies to derive $L[\text{O II}]$ from average SFR and broad-band magnitudes. For this purpose, we compare the LFs and galaxy clustering signal for $[\text{O II}]$ emitters selected using the aforementioned linear relations and the relations from Section 4.1, with those obtained by coupling the SAMs with the GET_EMLINES code (see Section 3.1).

4.4.1 $[\text{O II}]$ luminosity functions

In the left column of Fig. 13, from top to bottom, we show the attenuated $[\text{O II}]$ LFs of the $\text{SAG}$, $\text{SAGE}$, and $\text{GALACTICUS}$ model galaxies at $z \sim 1$. We compare the $L[\text{O II}]$ predictions from coupling the models with the GET_EMLINES code (thick, coloured lines without error bars) with those from using the SFR (solid, black), $M_{\text{H}}$ (dashed, green), and $M_{\text{g}}$ (dot–dashed, orange) proxies established above and summarized in Table 2. The shaded regions represent the effect of the scatter $\sigma_y$ on the proxy–$L[\text{O II}]$ relation and are derived from LFs estimated from 100 Gaussian realizations $G(\sigma_y, \mu)$ with mean $\mu = (\text{SFR}, \text{M}_{\text{H}}, \text{M}_{\text{g}})$ and fixed scatter $\sigma_y = (\sigma_{\text{SFR}}, \sigma_{\text{M}_{\text{H}}}, \sigma_{\text{M}_{\text{g}}})$ from Table 2.

The $[\text{O II}]$ LFs derived from the proxies are strongly model dependent, with varying levels of success for each model and proxy, as can be seen in Fig. 13. In $\text{SAG}$, the $M_{\text{g}}$ proxy produces an LF which, in the $L[\text{O II}]$ range $10^{41.7}–10^{42.5}$ erg s$^{-1}$, is consistent with that derived from coupling the model with the GET_EMLINES code,
while the other two proxies are lower. In SAGE, the $M_\text{g}$ proxy returns an LF in very good agreement with the GET_EMLINES estimate on all luminosity scales. $M_\text{g}$ gives good agreement at $L[\text{O II}] \lesssim 10^{41.7} \text{erg s}^{-1}$, while beyond this value it slightly overestimates the number of [O II] emitters. The SFR proxy is consistent with the GET_EMLINES result at $L[\text{O II}] \lesssim 10^{41.7} \text{erg s}^{-1}$, while at higher $L[\text{O II}]$ values it overpredicts the LF by $\sim 1.5$ dex.

The $L[\text{O II}]$ function based on the SFR proxy from GALACTICUS is in reasonable agreement with that from coupling the model with GET_EMLINES, while the magnitude proxies produce a lack of emitters on all luminosity scales ($\sim 1.4$ dex at $\sim 10^{40.5}$ erg s$^{-1}$, $\sim 0.4$ dex at $\sim 10^{41.5}$ erg s$^{-1}$, and $\sim 1.8$ dex at $\sim 10^{42}$ erg s$^{-1}$). Fig. 12 shows that GALACTICUS magnitudes are below those from DEEP2-FF. This discrepancy is likely to be the cause of the lack of [O II] emitters.

In the right column of Fig. 13, we display the intrinsic $L[\text{O II}]$ functions colour coded as the left-hand panels. In SAG and SAGE model galaxies, the effect of dust attenuation is stronger at higher luminosities, while in GALACTICUS it is more significant at $L[\text{O II}] \lesssim 10^{42} \text{erg s}^{-1}$. We overplot, as dashed, blue lines, the $L[\text{O II}]$ LFs obtained by applying the Kewley et al. (2004) conversion (equation 17) to each one of the model catalogues. This lies below (above) the other results in the bright end for SAG and SAGE (GALACTICUS) model galaxies. The relation from Kewley et al. (2004) produces very different $L[\text{O II}]$ functions compared to the ones obtained from the SAM model galaxies coupled with the GET_EMLINES prescription. This result highlights that the dispersion in the model gas metallicities is not the only source of the variation seen in the LF in Fig. 13.

In this Section, we have investigated the impact of using the $L[\text{O II}]$ proxies established above. We find the $L[\text{O II}]$ proxies to be model-dependent and to overall result in either a lack or an excess of bright [OII] emitters. These outcomes emphasize the inappropriateness of using simple relations to derive the [O II] emission from global galaxy properties. In fact, besides introducing systematic uncertainties, they can also result in [O II] LFs with very different shapes depending which properties are used.

### 4.4.2 Galaxy clustering

We further check how the clustering of our model ELGs is sensitive to an [O II] luminosity selection, where $L[\text{O II}]$ is computed either from the GET_EMLINES code, or the proxies established above. We consider SAG, SAGE, and GALACTICUS model galaxies at $z \sim 1$ and...
impose on them a minimum luminosity threshold of $L[\text{O II}] > 10^{40.4}$ erg s$^{-1}$.

Fig. 14 shows the ratios between the projected two-point correlation functions obtained from the proxy- $L[\text{O II}]$ relations and those derived from $L[\text{O II}]$ computed using the GET_EMLINES code with instantaneous SFR, while SAGE and GALACTICUS using the average quantity. Galaxies have been selected to have $L[\text{O II}] > 10^{40.4}$ erg s$^{-1}$. The shaded regions represent the effect of the $\sigma_y$ scatter in the proxy– $L[\text{O II}]$ linear relations reported in Table 2. These regions are the $1\sigma$ uncertainties derived from the covariance of 100 Gaussian realizations with the $L[\text{O II}]$ proxy considered as mean and $\sigma_y$ as scatter. We over plot the Kewley et al. (2004) result as a dashed, blue line.

Figure 14. Proxy-to- $L[\text{O II}]$ ratios of the projected two-point correlation functions of, from top to bottom, SAG, SAGE, and GALACTICUS model galaxies at $z \sim 1$. The SAG $L[\text{O II}]$ is estimated using the GET_EMLINES code with instantaneous SFR, while SAGE and GALACTICUS using the average quantity. Galaxies have been selected to have $L[\text{O II}] > 10^{40.4}$ erg s$^{-1}$. The shaded regions represent the effect of the $\sigma_y$ scatter in the proxy– $L[\text{O II}]$ linear relations reported in Table 2. These regions are the $1\sigma$ uncertainties derived from the covariance of 100 Gaussian realizations with the $L[\text{O II}]$ proxy considered as mean and $\sigma_y$ as scatter. We over plot the Kewley et al. (2004) result as a dashed, blue line.

For the clustering, we adopt the Landy & Szalay (1993) estimator and the two-point function code from Favole et al. (2016b). The shaded regions present the effect of the $\sigma_y$ scatter given in Table 2 in the proxy– $L[\text{O II}]$ linear relations. The dispersion is computed from the covariance of 100 Gaussian realizations with the $L[\text{O II}]$ proxy considered as mean and $\sigma_y$ as scatter. We over plot the Kewley et al. (2004) result as a dashed, blue line.

Overall, we find that the MULTIDARK-GALAXIES clustering signal is model-dependent. The linear bias is mostly unchanged, however, differences are seen at small scales, below 1$h^{-1}$Mpc. The dispersion changes between the different proxies, with the SFR presenting the largest scatter, overall.

Our ELG clustering results show that simple $L[\text{O II}]$ estimates based on a linear relation with SFR are sufficient for modelling the large scale clustering of [O II] emitters, even if they are not accurate enough to predict the [O II] LF.

4.4.3 [O II] ELG halo occupation distribution

In Fig. 15, we show the MULTIDARK-GALAXIES mean HOD for model galaxies selected with $L[\text{O II}] > 10^{40.4}$ erg s$^{-1}$. Here, the model [O II] luminosities have been calculated using the GET_EMLINES code. We highlight contributions from central and satellite model galaxies. The shapes of the HODs are qualitatively consistent among the different models, with an asymmetric Gaussian for central galaxies, plus maybe a plateau, and a very shallow power law for satellite galaxies. A similar shape has been found using different models for either young or star-forming galaxies, selected in different ways (Zheng et al. 2005; Contreras et al. 2013; Cochrane &
less than 20 per cent for SAG at $M_{\text{halo}} \geq 10^{12} M_\odot$, while SAGE shows differences above a factor 1.5 in most cases. The $L[\text{O II}]$ proxies behave very similarly, with negligible differences between them, except for the GALACTICUS SFR proxy, which is slightly lower than the magnitude ones.

In summary, we find different levels of agreement with the GET_EMLINES results depending on the model considered. However, the HOD remains almost unchanged when different $L[\text{O II}]$ proxies are assumed.

5 SUMMARY AND CONCLUSIONS

In this work, we have explored how the $[\text{O II}]$ luminosity can be estimated for SAMs of galaxy formation and evolution using different methods: (i) by coupling the SAMs with the GET_EMLINES code (Section 3.1) and (ii) using simple relations between $L[\text{O II}]$ and global properties such as SFR, broad-band magnitudes and metallicity (Section 4.1).

We have studied the following models from the MULTIDARK-GALAXIES products (Knebe et al. 2018): SAG (Cora et al. 2018), SAGE (Croton et al. 2016), and GALACTICUS (Benson 2012). All these models are run on the MDPL2 cosmological simulation (Klypin et al. 2016). They were calibrated to a number of observations within $0 < z < 2$, and they produce SFR and stellar mass functions that evolve similarly to what is observed in this redshift range.

Throughout this study, we have compared our model results with different observational data sets, including DEEP2-FF galaxies with absolute magnitudes (see Section 2.2).

The GET_EMLINES code to calculate nebular emission lines is publicly available and ideally uses instantaneous SFR as input. However, usually SAMs only output SFRs that are averaged over long time intervals, corresponding to the outputs of the underlying dark matter simulation. From the SAMs under study, only SAG provides instantaneous SFRs. We have coupled the GET_EMLINES code with the SAG model using both instantaneous and average SFRs to study the impact that this choice has on the $L[\text{O II}]$ calculation in post-processing. Assuming as input for the GET_EMLINES code either the instantaneous or the average SFR, we see a variation below 5 per cent for the dust attenuated $[\text{O II}]$ LFs in the range $10^{41} - 10^{42.2}$ erg s$^{-1}$, and in the range $10^{41} - 10^{42}$ erg s$^{-1}$ for the intrinsic $[\text{O II}]$ LFs. These ranges correspond to model ELGs with $< 5 < SFR$ (yr$^{-1} M_\odot$) $< 10^{-13}$. At higher and lower SFRs, there is a larger discrepancy, $< 50$ per cent, in the LFs, when using either the average or the instantaneous SFR. Thus, we find that using average SFRs as inputs for GET_EMLINES is a good approach when studying average galaxy populations.

The LFs of the MULTIDARK-GALAXIES with $L[\text{O II}]$ computed using the GET_EMLINES algorithm are in good agreement with the DEEP2 and VVDS observations over the redshift range $0.6 < z < 1.2$. The $[\text{O II}]$ luminosity, SFR, and stellar mass functions of the SAMs all consistently predict a smaller number of massive, star-forming galaxies.

The GALFORM SAMs are computationally expensive, and for this reason, we have chosen to use the GET_EMLINES code in conjunction with the DEEP2 and VVDS observations. However, we note that other SAMs, such as SAG and SAGE, may be able to reproduce the characteristics of the observed DEEP2 $[\text{O II}]$ emitters. These selections return different levels of agreement in the explored parameter spaces, as shown in Figs 8, 12, A2, and C1. A remarkable result from this study is that our model galaxies span the same regions as the observed ones, in all the parameter spaces under study, with
overall consistent trends. This suggests that our modelling approach captures the most important physical processes that shape the DEEP2 galaxy sample.

We have also investigated the viability of obtaining \( L[\text{O II}] \) from simple relations with global galactic properties that are usually outputted by galaxy formation models. For this purpose, we use observationally derived relations (Kewley et al. 2004) and linear relations derived for each model. In particular, we explore the \( L[\text{O II}] \) derived using the \textit{GET,EMLINES} code as a function of SFR, broad-band magnitudes, age, and stellar mass. The SFR, both instantaneous and average, is the physical quantity that, by construction, is most correlated with \( [\text{O II}] \) luminosity (with correlation coefficients \( r \geq 0.80 \) for all the SAMs). Such a tight correlation is well described by a linear scaling law with an associated scatter \( \sigma_{\log\text{SFR}} \) that varies with \( L[\text{O II}] \) (see Table 2). Other valuable proxies to derive \( L[\text{O II}] \) are the observed-frame \( u \) and \( g \) broad-band magnitudes, \( M_u \) and \( M_g \), which trace the rest-frame UV emission in our redshift range of interest.

We test how feasible it is to use these correlations as proxies for \( L[\text{O II}] \) by studying the evolution of the derived \( [\text{O II}] \) LFs, mean HOD and the galaxy clustering signal in \( L[\text{O II}] \) thresholds.

The different methods explored to calculate \( L[\text{O II}] \) result in a range of \( [\text{O II}] \) LFs. Taking into account the effect of the scatter in the SAG \( L[\text{O II}] \)–proxy relations, the LFs from the proxies (including the Kewley et al. 2004 relation from equation 17) are in reasonable agreement with the direct \textit{GET,EMLINES} estimates. The differences are larger for the relations derived from \( M_u \) and SFR in SAG at all luminosities, for SFR in \( L[\text{O II}] \) at \( \log L > 10^{42} \) erg s\(^{-1}\), and for the magnitude proxies in \textit{GALACTICUS}. At high luminosities, \( L[\text{O II}] \) derived with most linear proxies result in a lack of bright emitters that increases with luminosity, but remains approximately constant with redshift. The Kewley et al. (2004) relation (equation 17) results in a lower number of bright \( [\text{O II}] \) emitters compared to all the other methods to obtain \( L[\text{O II}] \) in SAG and \( L[\text{O II}] \), and in a higher number in \textit{GALACTICUS}.

We find a large variation between the derived \( [\text{O II}] \) LFs among both the SAMs and the methods used to obtain \( L[\text{O II}] \). Thus, it is important to highlight that, despite the model SFR density evolution being in reasonable agreement with observations, simple relations based on global galaxy properties are not robust estimators for \( L[\text{O II}] \).

We further test the use of simple relations to obtain \( L[\text{O II}] \) for SAMs by measuring the galaxy two-point autocorrelation function for \( [\text{O II}] \) emitters selected above a given \( L[\text{O II}] \) threshold. We compare the clustering measured from the \( [\text{O II}] \) proxies with direct predictions from the SAMs coupled with the \textit{GET,EMLINES} code and with the Kewley et al. (2004) relationship. The results vary from model to model and the largest fluctuations are seen below \( 1h^{-1}\)Mpc. However, if we account for the effect of the scatter in the proxy–\( L[\text{O II}] \) relation, the discrepancies reconcile with direct luminosity predictions. The large scale bias remains similar for all the models.

By increasing the \( L[\text{O II}] \) threshold, the galaxy number density drops considerably resulting in a noisier clustering signal, which makes the comparison difficult. Despite this increased noise, we find that model galaxies with \( L[\text{O II}] > 10^{41} \) erg s\(^{-1}\) can be more clustered when \( L[\text{O II}] \) is derived from proxies (this depends both on the model and the proxy used). This possible dependence with \( L[\text{O II}] \) should be taken into account when using proxies to create fast galaxy catalogues for a particular survey.

There is no direct correspondence between a proxy resulting in a good LF and providing a similar outcome for the clustering.

We also test how the mean HOD of \( \text{[O II]} \) emitters changes when assuming different proxies compared to the \textit{GET,EMLINES} code in the \( L[\text{O II}] \) calculation of our SAMs. We find that the shape of the HOD is consistent with that expected for a star-forming population of galaxies. Quantitatively, the HOD is strongly model-dependent, and we find different levels of agreement between the proxies and the \textit{GET,EMLINES} results, in particular at \( M_{\text{halo}} > 10^{12} \) M\(_\odot\). However, the distributions remain substantially unchanged from one proxy to another for all the models under study.

Our results show that ELGs are different from SFR-selected samples and that the \( L[\text{O II}] \) estimation needs more complex modelling than assuming a linear relation with SFR. Simple \( L[\text{O II}] \) estimates are not accurate enough to predict direct statistics of \( L[\text{O II}] \), as the LF, but they are sufficient for modelling the large scale clustering of \( [\text{O II}] \) emitters.

New-generation optical and infrared surveys will provide enormous data sets with unprecedented spectroscopic precision and imaging quality. These observations, together with models of galaxy formation and evolution, will enable us to reach a complete and consistent understanding of both the Universe large-scale structure, and the galaxy formation and evolution processes within dark matter haloes. In this context, simple derivations of \( L[\text{O II}] \) might be adequate for the clustering above \( 1h^{-1}\)Mpc, although at least two simple approximations might be needed to determine the uncertainties.

AK is supported by the MINECO and the Fondo Europeo de Desarrollo Regional (FEDER, UE) in Spain through grant AYA2015-63810-P as well as by the MICIU/FEDER through grant number PGC2018-094975-C21. He further acknowledges support from the Spanish Red Consolider MultiDark FPA2017-90566-RED and thanks Christopher Cross for useful comments. The analysis of DEEP2 data using the \textit{FIREFLY} code was done on the Sciama High Performance Compute cluster which is supported by the ICG, SEPNNet and the University of Portsmouth (UK). The CosmoSim database used in this paper is a service by the Leibniz-Institute for Astrophysics Potsdam (AIP). The MultiDark database was developed in cooperation with the Spanish MultiDark Consolider Project CSD2009-00064. The authors gratefully acknowledge the Gauss Centre for
Supercomputing e.V. (www.gauss-centre.eu) and the Partnership for Advanced Supercomputing in Europe (PRACE, www.prace-ri.eu) for funding the MultiDark simulation project by providing computing time on the GCS Supercomputer SuperMUC at Leibniz Supercomputing Centre (LRZ, www.lrz.de). The authors thank New Mexico State University (USA) and Instituto de Astrofísica de Andalucía CSIC (Spain) for hosting the SKIES & UNIVERSES database for cosmological simulation products. This work has benefited from the publicly available software tools and packages: MATPLOTLIB\textsuperscript{14} 1990-2017, version 2.7., PYTHONBREW\textsuperscript{16}; we use whenever possible in this work a colour-blind friendly colour palette\textsuperscript{17} for our plots.

**DATA AVAILABILITY**

The data produced for this article are available at http://popia.ft.uam.es/MultiDarkEmissionLines/. Here, we provide the DEEP2-FIREFLY observations, both with and without dust attenuation, and the galaxy properties from the SAG, SAGE, and GALACTICUS models. For the latter, besides the \([\text{O II]}\) emission line, we also include the \(H\alpha\), \(H\beta\), and \([\text{O III]}\) luminosities.

APPENDIX A: SAG MODEL GALAXIES SELECTED FROM DEEP2-FF SPLINE

We study the properties of a subset of SAG model galaxies selected to reproduce the $L$[O II] distribution of the DEEP2-FF data approximated by a spline fit in Fig. 4. We compare these model properties with the observational ones from DEEP2-FF.

Fig. A1 displays the SAG non-attenuated [O ii] luminosities computed from average and instantaneous SFRs as a function of SFR. The bimodality observed in Fig. 5, where the model galaxies are selected by cutting at SFR > 0 and log(M*/M⊙) > 8.87, has now disappeared, but the discrepancy between the two sets of contours is larger, with the instantaneous correlation much shallower than the average one. At SFR> 10^1 yr^-1 M⊙, the instantaneous SFR returns

Figure A1. Non-attenuated [O ii] luminosity as a function of SFR for the SAG model galaxies at z ~ 1 (contours) and the DEEP2-FF observations at 0.9 < z < 1.1 (grey, shaded squares). The colour bar represents the observed galaxy number density in each 2D bin normalised by the bin area in units of [dex^{-2} Mpc^{-3}]. Here the SAG model galaxies are selected following the spline fit to the observed DEEP2-FF. [O ii] luminosity is shown in Fig. 4. The model [O ii] values are calculated by assuming instantaneous (solid, purple contours) and average (dashed, salmon) SFR as input for the GET, EMLINES prescription. The innermost (outermost) model contours encompass 68 per cent (95 per cent) per cent of the galaxy distributions. The diagonal lines represent the $L$[O II]–SFR correlations, whose coefficients are reported in Table A1.

Table A1. Best-fitting parameters of the linear scaling relations found for SAG model galaxies at z = 1 and shown in Fig. A2. The parameter r is the correlation coefficient and σy is the scatter in the y-axis. SAG galaxies have been selected in $L$[O II] randomly drawn from the DEEP2-FF spline fit shown in Fig. 4.

| $y = A x + B$ | A | B | $σ_y$ | r |
|----------------|----|----|--------|----|
| $y = \log_{10}(L[O II])$ | 0.741 \pm 0.002 | 41.24 \pm 0.01 | 0.41 | 0.92 |
| $x = \log_{10}(\text{SFR}_{\text{avg}})$ | 0.574 \pm 0.003 | 41.15 \pm 0.01 | 0.38 | 0.77 |
| $y = M_\odot$ | $-2.021 \pm 0.006$ | $-18.04 \pm 0.01$ | 1.16 | 0.88 |
| $x = \log_{10}(\text{SFR}_{\text{inst}})$ | $-2.084 \pm 0.005$ | $-17.88 \pm 0.01$ | 1.17 | 0.90 |
| $y = M_\odot$ | $-2.006 \pm 0.005$ | $-18.96 \pm 0.01$ | 1.11 | 0.92 |
| $x = \log_{10}(\text{SFR}_{\text{inst}})$ | $-2.032 \pm 0.005$ | $-18.84 \pm 0.01$ | 1.11 | 0.93 |
| $y = M_\odot$ | $0.859 \pm 0.002$ | 9.15 \pm 0.01 | 0.47 | 0.92 |
| $x = \log_{10}(\text{SFR}_{\text{inst}})$ | $0.846 \pm 0.002$ | 9.11 \pm 0.01 | 0.47 | 0.90 |
higher $L_{\text{[O II]}}$ values compared to the average SFR. Instead, at SFR $\lesssim 10^9\text{yr}^{-1}M_\odot$, the average contours reach fainter luminosities. Compared to the SAG results based on simple SFR and stellar mass cuts (see Fig. 5), here both sets of contours span a higher range of $L_{\text{[O II]}}$ and SFR values. The $L_{\text{[O II]}}$–SFR correlation based on average (instantaneous) SFR is stronger (less strong) and with a steeper (shallower) slope compared to that for galaxies selected with simple cuts (see Tables 1 and A1), while the scatter is the same.

The DEEP2-FF observations in Fig. A1 seem to span a narrower range in SFR and to go fainter in $L_{\text{[O II]}}$ compared to the model galaxy contours. However, we highlight that the low-luminosity observational tail has a very low-density of emitters ($\sim 10^{-7}$ in Fig. A1).

In Fig. A2, from top to bottom, we display the intrinsic $u$- and $g$-band absolute magnitudes, the age and stellar mass of the SAG model galaxies selected from the DEEP2-FF spline fit as a function of the average and instantaneous SFRs. Compared to the results based on simple cuts at SFR $> 0\text{yr}^{-1}M_\odot$ and $M_* > 10^8.87\text{M}_\odot$ (see Fig. 8), here the correlations between SFR and magnitudes are steeper and $M_*$ shows a wider scatter in the $y$-axis. On the contrary, the correlation between SFR and stellar mass is shallower for SAG galaxies drawn from the DEEP2-FF spline fit and with less scatter in the $y$-axis. The specific values of the correlation parameters and coefficients are reported in Table A1. Overall, SAG galaxies selected from the spline fit reach brighter values of $u$- and $g$-band magnitudes compared to their counterparts based on simple SFR and stellar mass cuts (see Fig. 8), which also extend down to fainter magnitudes and smaller stellar masses. As already noticed in Fig. 8, model galaxies have lower ages and stellar masses and they extend into larger SFR values, compared to the DEEP2-FF sample.

APPENDIX B: EVOLUTION OF $L_{\text{[O II]}}$ FROM INSTANTANEOUS AND AVERAGE SFR

We investigate further the redshift evolution of the small discrepancy generated in $L_{\text{[O II]}}$ by assuming average instead of instantaneous SFR as input for the GET EMLINES code. In Section 3.3, we have studied what happens at $z \sim 1$, now we look over the redshift range $0.6 < z < 1.2$ to see if there is some evolution.

Fig. B1 compares the ratios of the intrinsic (thick, blue lines) and attenuated (thin, green) $[\text{O II}]$ LFs obtained from average and instantaneous SFR at different redshifts. We have explored the entire range $0.6 < z < 1.2$ finding that, as the redshift increases, the instantaneous and average $L_{\text{[O II]}}$ results tend to agree on a larger luminosity domain. Specifically, the 5 per cent agreement threshold (yellow, shaded region in the plot) is reached for the first time at $z = 0.6, 1.2$ by galaxies with attenuated $L_{\text{[O II]}} = 10^{41.9}, 10^{42.3}\text{ erg s}^{-1}$ and with intrinsic $L_{\text{[O II]}} = 10^{42.6}, 10^{42.9}\text{ erg s}^{-1}$, respectively. This result is independent on the presence of attenuation in the $[\text{O II}]$ luminosity. At $z \sim 1.2$, we observe a larger discrepancy in both ratios in the faint region due to the larger effect of incompleteness.
APPENDIX C: GLOBAL PROPERTIES OF MULTIDARK-GALAXIES

We compare pair properties in MULTIDARK-GALAXIES and DEEP2-FF observations to better understand their mutual correlations. We then fit these dependences using linear scaling relations. Fig. C1 displays, from top to bottom, the correlations between broad-band magnitudes, age and stellar mass as a function of SFR and stellar mass of the DEEP2-FF galaxies (grey, shaded squares, colour coded according to their galaxy number density normalized by the 2D bin area) compared to the MULTIDARK-GALAXIES (contours indicating the 68 per cent and 95 per cent of each distribution). Data and models overlap covering the brighter, more massive and more star-forming region of the parameter space. In particular, the MULTIDARK-GALAXIES only cover the SFR range above the knee shown in Fig. 2.

For such a small observational sample, it is difficult to establish and fit clear correlations among these quantities and between these quantities and \( L_{\text{[O II]}} \) (see also Fig. 12). In order to do this properly, one should account for all the DEEP2-FF incompleteness effects, which goes beyond the scope of our work. Here, we show the comparison between the DEEP2-FF emitters and the MULTIDARK-GALAXIES only to verify that our models cover the parameter space of the observational data set.

From the model point of view, we do find clear correlation among most of the physical quantities presented in Fig. C1. Each set of panels shows the results for one model: from top to bottom we display SAG, SAGE and GALACTICUS model galaxies. The relevant correlations (\( r \geq 0.6 \)) are represented as linear fits and the optimal parameters are reported in Table C1, together with their correlation coefficient (\( r \)) and the associated scatter in the \( y \)-axis (\( \sigma_y \)).

As expected, tight correlation is observed between the SFR and the broad-band \( u \) and \( g \) magnitudes that trace the rest-frame UV emission of a galaxy (see also Section 4.2). Tight correlation is observed also between the magnitudes and the stellar mass in all our model galaxies, except for GALACTICUS. Overall, the DEEP2-FF observations and the MULTIDARK-GALAXIES show a good overlap in the brighter, more star-forming and massive portion of any parameter space. All the model galaxies then extend further down in SFR, stellar mass and magnitudes.

Age does not correlate with SFR neither in the observations, nor in SAG and SAGE mocks. In GALACTICUS, we observe an anticorrelation between age and SFR, meaning that older galaxies are more star-forming, as expected. Age does seem to correlate with stellar mass in DEEP2-FF; however this feature is not reproduced by any of our model galaxies. DEEP2-FF galaxies show a bimodal distribution in age and stellar mass, with an older, less star-forming, very massive population (\( \text{age} \gtrsim 10^{9.3} \text{yr}; \ M_\star \gtrsim 10^{10.3} \text{M}_\odot \)) and a younger, more star-forming distribution with less massive galaxies. None of the model galaxies seem to reproduce this bimodality.

SAG and SAGE stellar masses are tightly correlated with their SFRs, but no dependence is observed in GALACTICUS. While the DEEP2-FF quenched population is too sparse to identify any dependence in the stellar mass–SFR plane, the star-forming selection might show some correlation in the higher mass end of the distribution. However, as already mentioned above, in order to correctly quantify this correlation, we should take into account the incompleteness effects in the data set, but this calculation goes beyond the aim of our analysis. We do not to show the dependence of the above quantities on metallicity since they do not correlate significantly in any of the model galaxies considered.

Figure C1. Comparison of pairs of properties for MULTIDARK-GALAXIES at \( z = 1 \) (contours) and DEEP2-FF observations at \( 0.9 < z < 1.1 \) (grey, shaded squares). The colour bars show the number density of DEEP2 galaxies in each square. From top to bottom, we display SAG, SAGE, and GALACTICUS results. A minimum \([\text{O II] flux cut of } 5 \times 10^{-18} \text{ erg s}^{-1} \text{cm}^{-2}\] has been applied to both data and model galaxies. In each set of panels, from top to bottom, we compare broad-band \( u \) and \( g \) absolute magnitudes, age and stellar mass as a function of, from left to right, average SFR and stellar mass. The model contours, from inner to outer, represent 68 per cent and 95 per cent of the distributions. The diagonal lines are the linear fits showing the significant correlations, whose coefficients are given in Table 2.
Table C1. Best-fitting parameters of the linear scaling relations found in MULTI-DARK-GALAXIES at $z \sim 1$ and shown in Fig. C1. The parameter $r$ is the correlation coefficient and $\sigma_y$ is the scatter in the $y$-axis. The SFR values are instantaneous for SAG and average for SAGE and GALACTICUS. We highlight that we do not quantify the correlation in the DEEP2-FF sample, since this calculation would require accounting for all the observational incompleteness effects, which goes beyond the aim of this work.
