Sampling Requirements for Stable Autoregressive Estimation

Abbas Kazemipour, Student Member, IEEE, Sina Miran, Student Member, IEEE, Piya Pal, Member, IEEE, Behtash Babadi, Member, IEEE, and Min Wu, Fellow, IEEE

Abstract—We consider the problem of estimating the parameters of a linear autoregressive model with sub-Gaussian innovations from a limited sequence of consecutive observations. Assuming that the parameters are compressible, we analyze the performance of the $\ell_1$-regularized least squares as well as a greedy estimator of the parameters and characterize the sampling trade-offs required for stable recovery in the non-asymptotic regime. Our results extend those of compressed sensing for linear models where the covariates are i.i.d. and independent of the observation history to autoregressive processes with highly interdependent covariates. We also derive sufficient conditions on the sparsity level that guarantee the minimax optimality of the $\ell_1$-regularized least squares estimate. Applying these techniques to simulated data as well as real-world datasets from crude oil prices and traffic speed data confirm our predicted theoretical performance gains in terms of estimation accuracy and model selection.

Index Terms—linear autoregressive processes, sparse estimation, compressive sensing, sampling.

I. INTRODUCTION

Autoregressive (AR) models are among the most fundamental tools in analyzing time series applications. Applications include financial time series analysis [2] and traffic modeling [3]–[8]. Due to their well-known approximation property, these models are commonly used to represent stationary processes in a parametric fashion and thereby preserve the underlying structure of these processes [9]. In order to leverage the approximation property of AR models, often times parameter sets of very large order are required [10]. For instance, any autoregressive moving average (ARMA) process can be represented by an AR process of infinite order. Statistical inference using these models is usually performed through fitting a long-order AR model to the data, which can be viewed as a truncation of the infinite-order representation [11]–[14]. In general, the ubiquitous long-range dependencies in real-world time series, such as financial data, results in AR model fits with large orders [2].

In various applications of interest, the AR parameters fit to the data exhibit sparsity, that is, only a small number of the parameters are non-zero. Examples include autoregressive communication channel models, quasi-oscillatory data tuned around specific frequencies and financial time series [8], [15]. The non-zero AR parameters in these models correspond to significant time lags at which the underlying dynamics operate. Traditional model selection procedures based on criteria such as Final Prediction Error (FPE) [17], Akaike Information Criterion (AIC) [18] and Bayesian Information Criterion (BIC) [19] are not efficient in order selection of sparse AR processes, as the ambient dimension of the parameters can be much larger than the sparsity. Also, these criteria pertain to the asymptotic regimes and their finite sample behavior is not well understood.

In recent years, the theory of compressed (CS) has become the standard framework for measuring and estimating sparse statistical models [20]–[22]. The theoretical guarantees of CS imply that when the number of incoherent measurements are roughly proportional to the sparsity level, then stable recovery of these models is possible. A key underlying assumption in most of the existing theoretical analyses of linear models is the independence and identical distribution (i.i.d.) of the covariates. Exceptions include measurement constructions based on correlated designs, and Toeplitz matrices where the design is extrinsic, fixed in advance and independent of the underlying sparse signal [23], [24]. Such assumptions do not hold for AR processes, as the intrinsic history of the process plays the role of the covariates. Hence the underlying interdependence in the model hinders a straightforward application of existing CS results to AR modeling.

In this paper, we address this issue by extending the analyses of CS theory to the estimation of compressible AR processes, and relaxing the assumptions of i.i.d. covariates. In particular, we will consider an AR process with sparse parameters and will analyze the performance of a LASSO-type estimator (corresponding to $\ell_1$-regularized Least Squares (LS) estimation) as well as a greedy solution. We will present theoretical guarantees that extend those of CS theory and characterize fundamental trade-offs between the number of measurements, compressibility, and estimation error of AR processes in the non-asymptotic regime. Our results reveal that when the number of measurements scale sub-linearly with the product of the ambient dimension and the sparsity level, then stable recovery of the underlying models is possible, even though the covariates solely depend on the history of the process. This is a significant improvement over existing results for stable AR estimation which require the number of measurements to scale quadratically with the ambient dimension [25]. We further establish sufficient conditions on the sparsity level which result in the minimax optimality of the $\ell_1$-regularized LS estimator.

Finally, we provide simulation results as well as application to
oil price and traffic data which reveal that the sparse estimates significantly outperform traditional techniques such as the Yule-Walker based estimators [26].

The rest of the paper is organized as follows. In Section II we will introduce the notations and problem formulation. In Section III we will state the main problem of interest and the estimation methods for the parameters of an AR process. We will also present the main theoretical results of this paper on robust estimation of AR parameters. In section III-D we establish the minimax optimality of the $\ell_1$-regularized LS estimator. Section IV includes our simulation results on simulated data as well as the real-world financial and traffic data.

II. Notations and Problem Formulation

Throughout the paper we will use the following notations. We will use the notation $x_i$ to denote the vector $[x_1, \ldots, x_j]^T$. We will denote the estimated values by $\hat{x}$ and the biased estimates with the superscript $(\cdot)$. Throughout the proofs, $c_i$’s express absolute constant which may change from line to line where there is no ambiguity. By $c_0$ we mean an absolute constant which only depends on a positive constant $\eta$.

Consider an AR($p$) process defined by

$$x_k = \theta_1 x_{k-1} + \theta_2 x_{k-2} + \cdots + \theta_p x_{k-p} + w_k = \theta^T x_{k-p} + w_k,$$

where $\{w_k\}_{k=-\infty}^{\infty}$ is an i.i.d sub-Gaussian innovation sequence with zero mean and variance $\sigma_w^2$. This process can be considered as the output of an LTI system with transfer function

$$H(z) = \frac{\sigma_w^2}{1 - \sum_{\ell=1}^{p} \theta_\ell z^{-\ell}}.$$  \hspace{1cm} (2)

Throughout the paper we will assume $||\theta||_1 \leq 1 - \eta < 1$ to enforce the stability of the filter. We will refer to this assumption as the sufficient stability assumption, since an AR process with poles within the unit circle does not necessarily satisfy $||\theta||_1 < 1$. However, beyond second-order AR processes, it is not straightforward to state the stability of the process in terms of its parameters in a closed algebraic form, which in turn makes both the analysis and optimization procedures intractable. The AR($p$) process given by $\{x_k\}_{k=-\infty}^{\infty}$ in (1) is stationary in the strict sense. Also by (2) the power spectral density of the process equals

$$S(\omega) = \frac{\sigma_w^2}{|1 - \sum_{\ell=1}^{p} \theta_\ell e^{-j\omega\ell}|^2}. \hspace{1cm} (3)$$

The sufficient stability assumption implies boundedness of the spectral spread of the process defined as

$$\rho = \sup_{\omega} S(\omega) / \inf_{\omega} S(\omega).$$

We will discuss how this assumption can be further relaxed in Appendix A-B. The spectral spread of stationary processes in general is a measure of how quickly the process reaches its ergodic state [25]. An important property that we will use later in this paper is that the spectral spread is an upper bound on the eigenvalue spread of the covariance matrix of the process of arbitrary size [27].

We will also assume that the parameter vector $\theta$ is compressible (to be defined more precisely later), and can be well approximated by an $s$-sparse vector where $s \ll p$. We observe $n$ consecutive snapshots of length $p$ (a total of $n + p - 1$ samples) from this process given by $\{x_k\}_{k=-p+1}^{n}$ and aim to estimate $\theta$ by exploiting its sparsity; to this end, we aim at addressing the following questions:

- Are the conventional LASSO-type and greedy techniques suitable for estimating $\theta$?
- What are the sufficient conditions on $n$ in terms of $p$ and $s$, to guarantee stable recovery?
- Given these sufficient conditions, how do these estimators perform compared to conventional AR estimation techniques?

Traditionally, the Yule-Walker (YW) equations or least squares formulations are used to fit AR models. Since these methods do not utilize the sparse structure of the parameters, they usually require $n \gg p$ samples in order to achieve satisfactory performance. The YW equations can be expressed as

$$R \theta = r_{-p}^{-1}, \hspace{1cm} r_0 = \theta^T r_{-p}^{-1} + \sigma_w^2,$$  \hspace{1cm} (4)

where $R := R_{p \times p} = E[x_k x_{k}^T]$ is the $p \times p$ covariance matrix of the process and $r_k = E[x_k x_{k+k}]$ is the autocorrelation of the process at lag $k$. The covariance matrix $R$ and autocorrelation vector $r_{-p}$ are typically replaced by their sample counterparts. Estimation of the AR($p$) parameters from the YW equations can be efficiently carried out using the Burg’s method [28]. Other estimation techniques include LS regression and maximum likelihood (ML) estimation. In this paper, we will consider the Burg’s method and LS solutions as comparison benchmarks. When $n$ is comparable to $p$, these two methods are known to exhibit substantial performance differences [29].

When fitted to the real-world data, the parameter vector $\theta$ usually exhibits a degree of sparsity. That is, only certain lags in the history have a significant contribution in determining the statistics of the process. These lags can be thought of as the intrinsic delays in the underlying dynamics. To be more precise, for a sparsity level $s \ll p$, we denote by $S \subset \{1, 2, \ldots, p\}$ the support of the $s$ largest elements of $\theta$ in absolute value, and by $\theta_S$ the best $s$-term approximation to $\theta$. We also define

$$\sigma_s(\theta) := ||\theta - \theta_S||_1$$  \hspace{1cm} (5)

and

$$\varsigma_s(\theta) := ||\theta - \theta_S||_2$$  \hspace{1cm} (6)

which capture the compressibility of the parameter vector $\theta$ in the $\ell_1$ and $\ell_2$ sense, respectively. Note that by definition $\varsigma_s(\theta) \leq \sigma_s(\theta)$. For a fixed $\xi \in (0, 1)$, we say that $\theta$ is $(s, \xi)$-compressible if $\sigma_s(\theta) = O(s^{1-\xi})$ and $(s, \xi, 2)$-compressible if $\varsigma_s(\theta) = O(s^{1-2\xi})$. Note that $(s, \xi, 2)$-compressibility is a weaker condition than $(s, \xi)$-compressibility and when $\xi = 0$, the parameter vector $\theta$ is exactly $s$-sparse.

Finally, in this paper, we are concerned with the compressed sensing regime where $n \ll p$, i.e., the observed data has
a much smaller length than the ambient dimension of the parameter vector. The main estimation problem of this paper can be summarized as follows: given observations $x^n_{p+1}$ from an AR process with sub-Gaussian innovations and bounded spectral spread, the goal is to estimate the unknown $p$-dimensional $(s, \xi, 2)$-compressible AR parameter vector $\theta$ in a stable fashion (where the estimation error is controlled) when $n \ll p$.

III. THEORETICAL RESULTS

In this section, we will describe the estimation procedures and present the main theoretical results of this paper.

A. $\ell_1$-regularized least squares estimation

Given the sequence of observations $x^n_{p+1}$ and an estimate $\hat{\theta}$, the normalized estimation error can be expressed as:

$$\mathcal{L}(\hat{\theta}) := \frac{1}{n} \| x_1^n - X\hat{\theta} \|_2^2,$$

where

$$X = \begin{bmatrix} x_{n-1} & x_{n-2} & \cdots & x_{n-p} \\ x_{n-2} & x_{n-3} & \cdots & x_{n-p-1} \\ \vdots & \vdots & \ddots & \vdots \\ x_0 & x_{-1} & \cdots & x_{-p+1} \end{bmatrix}.$$  

Note that the matrix of covariates $X$ is Toeplitz with highly interdependent elements. The LS solution is thus given by:

$$\hat{\theta}_{LS} = \arg \min_{\theta \in \Theta} \mathcal{L}(\theta),$$

where

$$\Theta := \{ \theta \in \mathbb{R}^p \mid \| \theta \|_1 < 1 - \eta \}$$

is the convex feasible region for which the stability of the process is guaranteed. In the regime of interest when $n \ll p$, the LS estimator is ill-posed and is typically regularized with a smooth norm. In order to capture the compressibility of the parameters, we consider the $\ell_1$-regularized LS estimator:

$$\hat{\theta}_{\ell_1} := \arg \min_{\theta \in \Theta} \mathcal{L}(\theta) + \gamma_n \| \theta \|_1,$$

where $\gamma_n > 0$ is a regularization parameter. It is easy to verify that the objective function and constraints in Eq. (10) are convex in $\theta$ and hence $\hat{\theta}_{\ell_1}$ can be obtained using standard numerical solvers. Note that the solution to (10) might not be unique. However, we will provide error bounds that hold for all possible solutions of (10), with high probability.

Consistency of the estimator given by (9) was shown in [2] when $n \to \infty$ for Gaussian innovations. In the case of Gaussian innovations the LS estimates correspond to conditional ML estimation and are asymptotically unbiased under mild conditions, and with $p$ fixed, the solution converges to the true parameter vector as $n \to \infty$. However, when $p$ is allowed to scale with $n$, the convergence rate is not known. For fixed $p$, the estimation error is of the order $O(p/n)$ in general [24]. This makes the analysis of LS estimators, and in general regularized M-estimators, very challenging [31]. Nevertheless, such an analysis has significant practical implications, as it will reveal sufficient conditions on $n$ with respect to $p$ as well as a criterion to choose $\gamma_n$, which result in stable estimation of $\theta$. Throughout our analysis, we fix the ambient dimension $p$ and aim at deriving sufficient conditions on $n \ll p$ resulting in stable estimation. In many applications of interest, the data correlations are exponentially decaying and negligible beyond a certain lag, and hence for large enough $p$, autoregressive models fit the data very well in the prediction error sense.

Recall that, the Yule-Walker solution is given by

$$\hat{\theta}_{yw} := \arg \min_{\theta \in \Theta} \mathcal{J}(\theta) = \hat{R}^{-1}\hat{r}^{-1},$$

where

$$\mathcal{J}(\theta) := \| \hat{R}\theta - \hat{r}^{-1} \|_2.$$  

We further consider two other sparse estimators for $\theta$ by penalizing the Yule-Walker equations. The $\ell_1$-regularized Yule-Walker estimator is defined as:

$$\hat{\theta}_{yw, \ell_1} := \arg \min_{\theta \in \Theta} \mathcal{J}_1(\theta) + \gamma_n \| \theta \|_1,$$

where $\gamma_n > 0$ is a regularization parameter. Similarly, using the robust statistics instead of the Gaussian statistics, the estimation error can be re-defined as:

$$\mathcal{J}_1(\theta) := \| \hat{R}\theta - \hat{r}^{-1} \|_1,$$

we define the $\ell_1$-regularized estimates as

$$\hat{\theta}_{yw, \ell_1} := \arg \min_{\theta \in \Theta} \mathcal{J}_1(\theta) + \gamma_n \| \theta \|_1.$$  

B. Greedy estimation

Although there exist fast solvers for the convex problems of the type given by (10), (12) and (13), these algorithms are polynomial time in $n$ and $p$, and may not scale well with the dimension of data. This motivates us to consider greedy solutions for the estimation of $\theta$. In particular, we will consider and study the performance of a generalized Orthogonal Matching Pursuit (OMP) algorithm [32], [33]. A flowchart of this algorithm is given in Table I for completeness. At each iteration, a new component of $\theta$ is chosen using the gradient of the error metric $\mathcal{J}(\theta)$, which is the largest in absolute value.

TABLE I: Generalized Orthogonal Matching Pursuit (OMP)

| Input: $f(\theta), s^*$ | Output: $\hat{\theta}_{OMP} = \hat{\theta}_{OMP}(s^*)$ |
|--------------------------|-----------------------------------------------------|
| Initialization: {        | Start with the index set $S^{(0)} = \emptyset$     |
|                          | and the initial estimate $\hat{\theta}_{OMP}^{(0)} = 0$ |
| for $k = 1, 2, \ldots, s^*$ | $j = \arg \max_i \left| \left( \nabla_i \hat{\theta}_{OMP}^{(k-1)} \right)_{i} \right|$ |
|                          | $S^{(k)} = S^{(k-1)} \cup \{j\}$                  |
|                          | $\hat{\theta}_{OMP} = \arg \min_{\supp(e) \subseteq S^{(k)}} f(\theta)$ |

end
estimate with \( s^* \) components. When the error metric \( L_2(\theta) \) is chosen, the generalized OMP corresponds to the original OMP algorithm. For the choice of the YW error metric \( L_1(\theta) \), we denote the resulting greedy algorithm by ywOMP.

### C. Estimation performance guarantees

The main theoretical result regarding the estimation performance of the \( L_1 \)-regularized LS estimator is given by the following theorem:

**Theorem 1.** If \( \sigma_s(\theta) = O(\sqrt{s}) \), there exist positive constants \( d_1, d_2, d_3 \) and \( d_4 \) such that for \( n > d_1 s^{2/3} \log s \) and a choice of regularization parameter \( \gamma_n = d_2 \sqrt{\log p/n} \), any solution \( \hat{\theta}_{\ell_1} \) to (10) satisfies the bound

\[
\|\hat{\theta}_{\ell_1} - \theta\|_2 \leq d_3 \sqrt{s \log p/n} + d_4 \sqrt{\log p/n} \sqrt{\log p/n}, \tag{14}
\]

with probability greater than \( 1 - O(\frac{1}{n}) \). The constants are only functions of \( \sigma_w^2 \) and \( \eta \) and are explicitly given in the proof.

Similarly, the following theorem characterizes the estimation performance bounds for the OMP algorithm:

**Theorem 2.** If \( \theta \) is \((s, \xi, 2)\)-compressible for some \( \xi < 1/2 \), there exist positive constants \( d_1', d_2', d_3' \) and \( d_4' \) such that for \( n > d_1' s^{2/3} \log s \), the OMP estimate satisfies the bound

\[
\|\hat{\theta}_{\text{OMP}} - \theta\|_2 \leq d_2' \frac{s \log p \log s}{n} + d_3' \frac{\log s}{s^{\frac{1}{4}} - 2} \tag{15}
\]

after \( s^* = \frac{d_5}{\eta} \log \frac{5n^4}{\eta^2} \) iterations with probability greater than \( 1 - O(\frac{1}{n^{5/4}}) \). The constants are only functions of \( \sigma_w^2 \) and \( \eta \) and are explicitly given in the proof.

The results of Theorems 1 and 2 suggest that under suitable compressibility assumptions on the AR parameters, one can estimate the parameters reliably using the \( \ell_1 \)-regularized LS and OMP estimators with much fewer measurements compared to those required by the Yule-Walker/LS based methods. To illustrate the significance of these results further, several remarks are in order:

**Remark 1.** Comparing the sufficient condition \( n = O(s p^{2/3}) \) of Theorem 1 with those of [20–22] for linear models with i.i.d. measurement matrices given by \( n = O(s \log p) \) reveals that a loss of order \( O(p^{2/3}) \) is incurred, although both conditions require \( n < p \). However, this loss seems to be natural as it stems from two major differences of our setting as compared to traditional CS: first, the sample space characterizing the covariates \( x_{n-p+1}^{n} \) is \((n + p - 1)\)-dimensional, whereas in traditional CS the sample space of the measurement matrix is \( np \)-dimensional. Second, each row of the measurement matrix \( X \) highly depends on the entire observation sequence \( x_1^n \), whereas in traditional CS, each row of the measurement matrix is only related to the corresponding measurement. Hence, the aforementioned loss can be viewed as the price of self-averaging of the process accounting for the low-dimensional nature of the covariate sample space and the high inter-dependence of the covariates to the observation sequence. The dominant loss of \( O(p^{2/3}) \) does not seem to be significantly improvable, as AR processes are known for slow convergence to their ergodic state.

**Remark 2.** On the positive side, compared to existing guarantees for LS estimation techniques for AR processes which typically require \( O(p^2) \) measurements [23], our result predicts a significant saving of the order \( p^{2/3} s^{-1} \). It can also be shown that the estimation error for the LS method in general scales as \( \sqrt{p/n} \) [24], which is not desirable when \( n \ll p \). Our result, however, guarantees a much smaller error rate of the order \( \sqrt{s \log p/n} \). Also, the sufficiency conditions of Theorem 2 require high compressibility of the parameter vector \( \theta \) \((\xi < 1/2)\), whereas Theorem 1 does not impose any extra restrictions on \( \xi \in (0, 1) \). Intuitively speaking, these two comparisons reveal the trade-off between computational complexity and measurement/compressibility requirements for convex optimization vs. greedy techniques, which are well-known for linear models [32].

**Remark 3.** The condition \( \sigma_s(\theta) = O(\sqrt{s}) \) in Theorem 1 is not restricting for the processes of interest in this paper. This is due to the fact that the boundedness assumption on the spectral spread implies an exponential decay of the parameters (See Lemma 1 of [25]). Finally, the constants \( d_1, d_2 \) are increasing with respect to the spectral spread of the process \( \rho \). Intuitively speaking, the closer the roots of the filter given by (2) get to the unit circle (corresponding to larger \( \rho \) and smaller \( \eta \)), the slower the convergence of the process will be to its ergodic state, and hence more measurements are required. A similar dependence to the spectral spread has appeared in the results of [25] for \( \ell_2 \)-regularized least squares estimation of AR processes.

**Remark 4.** The main ingredient in the proofs of Theorems 1 and 2 is to establish the restricted eigenvalue (RE) condition introduced in [35] for the covariate matrix \( X \). We will show that if the bounded spectral spread condition holds, then with \( n = O(s p^{2/3}) \) the sample covariance matrix is sharply concentrated around the true covariance matrix and hence the RE condition can be guaranteed. All constants appearing in Theorems 1 and 2 are explicitly given in Appendix A-B. As a typical numerical example, for \( \eta = 0.5 \) and \( \sigma_w^2 = 0.01 \), the constants of Theorem 1 can be chosen as \( d_1 \approx 1000, d_2 \approx 0.5 - 1, d_3 \approx 10, \) and \( d_4 \approx 4 \). The full proofs are given in Appendix A-B.

### D. Minimax optimality

In this section, we establish the minimax optimality of the \( \ell_1 \)-regularized LS estimator for AR processes with sparse parameters. To this end, we will focus on the class \( \mathcal{H} \) of stationary processes which admit an AR(p) representation with \( s \)-sparse parameter \( \theta \) such that \( ||\theta||_1 \leq 1 - \eta < 1 \). The theoretical results of this section are inspired by the enlightening results of [25] on non-asymptotic order selection via \( \ell_2 \)-regularized LS estimation in the absence of sparsity, and extend them by studying the \( \ell_1 \)-regularized LS estimator of (10).

We define the maximal *estimation* risk over \( \mathcal{H} \) to be

\[
R(\hat{\theta}) := \sup_{\theta} \left( \mathbb{E} \left[ ||\hat{\theta} - \theta||_2^2 \right] \right)^{1/2}. \tag{16}
\]
The minimax estimator is the one minimizing the maximal estimation risk, i.e.,
\[
\hat{\theta}_{\minimax} := \arg\min_{\theta \in \Theta} \mathcal{R}_{\text{est}}(\theta). \tag{17}
\]
Minimax estimator \(\hat{\theta}_{\minimax}\) in general, cannot be constructed explicitly \([25]\), and the common practice in non-parametric estimation is to construct an estimator \(\hat{\theta}\) which is order optimal as compared to the minimax estimator:
\[
\mathcal{R}_{\text{est}}(\hat{\theta}) \leq L \mathcal{R}_{\text{est}}(\hat{\theta}_{\minimax}). \tag{18}
\]
with \(L \geq 1\) being a constant. One can also define the minimax prediction risk by the maximal prediction error over all possible realizations of the process:
\[
\mathcal{R}_{\text{pre}}(\hat{\theta}) := \sup_{\theta \in \Theta} E \left[ \left( x_k - \hat{\theta}' x_{k-p} \right)^2 \right]. \tag{19}
\]
In \([25]\), it is shown that an \(\ell_2\)-regularized LS estimator with an order \(p^* = \Theta(\log n)\) is minimax optimal. This order pertains to the denoising regime where \(n \gg p\). Hence, in order to capture long order lags of the process, one requires a sample size exponentially large in \(p\), which may make the estimation problem computationally infeasible. For instance, consider a 2-spars parameter with only \(\theta_1\) and \(\theta_2\) being non-zero. Then, in order to achieve minimax optimality, \(n = \Theta(2^p)\) measurements are required. In contrast, in the compressive regime where \(s, n \ll p\), the goal, instead of selecting \(p\), is to find conditions on the sparsity level \(s\), so that for a given \(n\) and large enough \(p\), the \(\ell_1\)-regularized estimator is minimax optimal without explicit knowledge of the value of \(s\) (See for example, \([36]\)).

In the following proposition, we establish the minimax optimality of the \(\ell_1\)-regularized estimator over the class of sparse AR processes with \(\theta \in \Theta\):

**Proposition 1.** Let \(x^n\) be samples of an AR process with \(s\)-sparse parameters satisfying \(\|\theta\|_1 \leq 1 - \eta\) and \(s \leq \min\left\{ \frac{1 - \eta}{8 \eta \gamma}, \sqrt{\frac{n}{d_1 p^2}}, \frac{n}{d_1 p^2} \right\}\). Then, we have:
\[
\mathcal{R}_{\text{est}}(\hat{\theta}_1) \leq L \mathcal{R}_{\text{est}}(\hat{\theta}_{\minimax}).
\]
where \(L\) is a constant and is only a function of \(\eta\) and \(\sigma^2_w\) and is explicitly given in the proof.

**Remark 5.** Proposition \(\square\) implies that \(\ell_1\)-regularized LS is minimax optimal in estimating the \(s\)-sparse parameter vector \(\theta\), for small enough \(s\). The proof of the Proposition \(\square\) is given in Appendix A-D. This result can be extended to compressible \(\theta\) in a natural way with a bit more work, but we only present the proof for the case of \(s\)-sparse \(\theta\) for brevity. We also state the following proposition on the prediction performance of the \(\ell_1\)-regularized LS estimator:

**Proposition 2.** Let \(x_{n-p+1}\) be samples of an AR process with \(s\)-sparse parameters and Gaussian innovations, then there exists a positive constant \(d_5\), such that for large enough \(n, p\) and \(s\) satisfying \(n > d_1 sp^2/3\), we have:
\[
\mathcal{R}_{\text{pre}}^2(\hat{\theta}_1) \leq d_5 \frac{s \log p}{n} + \sigma^2_w. \tag{20}
\]
It can be readily observed that for \(n \gg s\) the prediction error variance is very close to the variance of the innovations. The proof is similar to Theorem 3 of \([25]\) and is skipped in this paper for brevity.

**IV. APPLICATION TO SIMULATED AND REAL DATA**

In this section, we study and compare the performance of Yule-Walker based estimation methods with those of the \(\ell_1\)-regularized and greedy estimators given in section III. These methods are applied to simulated data as well as real data from crude oil price and traffic speed.

**A. Simulation studies**

In order to simulate an AR process, we filtered a Gaussian white noise process using an IIR filter with sparse parameters. Figure 1 shows a typical sample path of the simulated AR process used in our analysis. For the parameter vector \(\theta\), we chose a length of \(p = 300\), and employed \(n = 1500\) generated samples of the corresponding process for estimation. The parameter vector \(\theta\) is of sparsity level \(s = 3\) and \(\eta = 1 - \|\theta\|_1 = 0.5\). A value of \(\gamma_n = 0.1\) is used, which is slightly tuned around the theoretical estimate given by Theorem 1. The order of the process is assumed to be known. We compare the performance of seven estimators: 1) \(\theta_{\text{LS}}\) using LS, 2) \(\theta_{\text{yw}}\) using the Yule-Walker equations, 3) \(\hat{\theta}_1\) from \(\ell_1\)-regularized LS, 4) \(\hat{\theta}_{\text{OMP}}\) using OMP, 5) \(\hat{\theta}_{\text{yw},\ell_1}\) using Eq. (12), 6) \(\hat{\theta}_{\text{yw},\ell_2,1}\) using Eq. (13), and 7) \(\hat{\theta}_{\text{ywOMP}}\) using the cost function \(J(\theta)\) in the generalized OMP. Figure 2 shows the estimated parameter vectors using these algorithms. It can be visually observed that \(\ell_1\)-regularized and greedy estimators (shown in purple) significantly outperform the Yule-Walker based-estimates (shown in orange).

In order to quantify the latter observation precisely, we repeated the same experiment for \(p = 300\), \(s = 3\) and \(10 \leq n \leq 10^5\). A comparison of the normalized MSE of the estimators vs. \(n\) is shown in Figure 3. As it can be inferred from Figure 3 in the region where \(n\) is comparable to \(p\) (shaded in light purple), the sparse estimators have a systematic performance gain over the Yule-Walker based estimates, with the \(\ell_1\)-regularized LS and ywOMP estimates outperforming the rest.

The MSE comparison in Figure 3 requires one to know the true parameters. In practice, the true parameters are not available for comparison purposes. In order to quantify the performance gain of these methods, we use statistical tests to assess the goodness-of-fit of the estimates. The common chi-square type statistical tests, such as the F-test, are useful when the hypothesized distribution to be tested against is discrete or categorical. For our problem setup with sub-Gaussian innovations, we will use a number of statistical
tests appropriate for AR processes, namely, the Kolmogorov-Smirnov (KS) test, the Cramér-von Mises (CvM) criterion, the spectral Cramér-von Mises (SCvM) test and the Anderson-Darling (AD) [37]-[39]. A summary of these tests is given in Appendix B. Table II summarizes the test statistics for different estimation methods. These tests are based on the known results on limiting distributions of error residuals. As noted from Table II our simulations suggest that the OMP estimate achieves the best test statistics for the CvM, AD and KS tests, whereas the \( \ell_1 \)-regularized estimate achieves the best SCvM statistic.

### B. Application to the analysis of crude oil prices

In this and the following subsection, we consider applications with real-world data. As for the first application, we apply the sparse AR estimation techniques to analyze the crude oil price of the Cushing, OK WTI Spot Price FOB dataset.

This dataset consists of 7429 daily values of oil prices in dollars per barrel. In order to avoid outliers, usually the dataset is filtered with a moving average filter of high order. We have skipped this procedure by visual inspection of the data and selecting \( n = 4000 \) samples free of outliers. Such financial data sets are known for their non-stationarity and long order history dependence. In order to remove the deterministic trends in the data, one-step or two-step time differencing is typically used. We refer to [8] for a full discussion of this detrending method. We have used a first-order time differencing which resulted in a sufficient detrending of the data. Figure 4 shows the data used in our analysis. We have chosen \( p = 150 \) by inspection. The histogram of first-order differences as well the estimates are shown in Figure 5.

A visual inspection of the estimates in Figure 5 shows that the \( \ell_1 \)-regularized LS (\( \hat{\theta}_{\ell_1} \)) and OMP (\( \hat{\theta}_{\text{OMP}} \)) estimates consistently select specific time lags in the AR parameters, whereas the Yule-Walker and LS estimates seemingly overfit the data by populating the entire parameter space. In order to perform goodness-of-fit tests, we use an even/odd two-fold cross-validation. Table III shows the corresponding test statistics, which reveal that indeed the \( \ell_1 \)-regularized and OMP estimates outperform the traditional estimation techniques.

### TABLE II: Goodness-of-fit tests for the simulated data

| Estimate | Test  | CvM | AD  | KS  | SCvM |
|----------|-------|-----|-----|-----|------|
| \( \theta \) | 0.31  | 1.54 | 0.031 | 0.009 |
| \( \hat{\theta}_{\text{LS}} \) | 0.68  | 5.12 | 0.037 | 0.017 |
| \( \hat{\theta}_{\text{yw}} \) | 0.65  | 4.87 | 0.034 | 0.025 |
| \( \hat{\theta}_{\ell_1} \) | 0.34  | 1.72 | 0.030 | 0.009 |
| \( \hat{\theta}_{\text{OMP}} \) | 0.29  | 1.45 | 0.028 | 0.009 |
| \( \hat{\theta}_{\text{yw},\ell_2} \) | 0.35  | 1.80 | 0.032 | 0.009 |
| \( \hat{\theta}_{\text{yw},\ell_1} \) | 0.42  | 2.33 | 0.040 | 0.008 |
| \( \hat{\theta}_{\text{ywOMP}} \) | 0.29  | 1.46 | 0.030 | 0.009 |

### TABLE III: Goodness-of-fit tests for the crude oil price data

| Estimate | Test  | CvM | AD  | KS  | SCvM |
|----------|-------|-----|-----|-----|------|
| \( \hat{\theta}_{\text{LS}} \) | 0.88  | 5.55 | 0.055 | 0.046 |
| \( \hat{\theta}_{\text{yw}} \) | 0.58  | 3.60 | 0.043 | 0.037 |
| \( \hat{\theta}_{\ell_1} \) | 0.27  | 1.33 | 0.031 | 0.020 |
| \( \hat{\theta}_{\text{OMP}} \) | 0.22  | 1.18 | 0.025 | 0.022 |
| \( \hat{\theta}_{\text{yw},\ell_2} \) | 0.28  | 1.40 | 0.027 | 0.021 |
| \( \hat{\theta}_{\text{yw},\ell_1} \) | 0.24  | 1.26 | 0.027 | 0.022 |
| \( \hat{\theta}_{\text{ywOMP}} \) | 0.23  | 1.18 | 0.026 | 0.022 |
C. Application to the analysis of traffic data

Our second real data application concerns traffic speed data. The data used in our simulations is the INRIX® speed data for I-495 Maryland inner loop freeway (clockwise) between US-1/Baltimore Ave/Exit 25 and Greenbelt Metro Dr/Exit 24 from 1 Jul, 2015 to 31 Oct, 2015 [41, 42]. The reference speed of 65 mph is reported. Given the huge length of the data and its high variability, the following pre-processing was made on the original data:

1) The data was downsampled by a factor of 4 and averaged by the hour in order to reduce its daily variability, that is each lag corresponds to one hour.

2) The logarithm of speed was used for analysis and the mean was subtracted. This reduces the high variability of speed due to rush hours and lower traffic during weekends and holidays.

Fig. 6: A sample of the speed and travel time data for I-495.

Figure 6 shows a typical average weekly speed and travel time in this dataset and the corresponding 25-75-th percentiles. As can be seen the data shows high variability around the rush hours of 8am and 4pm. In our analysis, we used the first half of the data (n = 1500) for fitting, from which the AR parameters and the distribution and variance of the innovations were estimated. The statistical tests were designed based on the estimated distributions, and the statistics were computed accordingly using the second half of the data. We selected an order of p = 200 by inspection and noting that the data seems to have a periodicity of order 170 samples.

Figure 7 shows part of the data used in our analysis as well as the estimated parameters. The ℓ₁-regularized LS (θ̂₁) and OMP (θ̂OMP) are consistent in selecting the same components of θ. These estimators pick up two major lags around which θ has its largest components. The first lag corresponds to about 24 hours which is mainly due to the rush hour periodicity on a daily basis. The second lag is around 150 – 170 hours which corresponds to weekly changes in the speed due to lower traffic over the weekend. In contrast, the Yule-Walker and LS estimates do not recover these significant time lags.

| Estimate       | CvM   | AD     | KS      | SCvM   |
|----------------|-------|--------|---------|--------|
| θ̂yw           | 0.012 | 0.066  | 0.220   | 0.05   |
| θ̂₁            | 1.4×10⁻⁷ | 2.1×10⁻⁶ | 6.7×10⁻⁴ | 0.25   |
| θ̂OMP          | 0.017 | 0.082  | 0.220   | 1.49   |
| θ̂ywOMP        | 0.025 | 0.122  | 0.270   | 0.14   |

Statistical tests for a selected subset of the estimators are shown in Table IV. Interestingly, the ℓ₁-regularized LS estimator significantly outperforms the other estimators in three of the tests. The Yule-Walker estimator, however, achieves the best SCvM test statistic.
V. CONCLUSIONS

In this paper, we have investigated sufficient sampling requirements for stable estimation of AR models in the non-asymptotic regime using the $\ell_1$-regularized LS and greedy estimation (OMP) techniques. We have further established the minimax optimality of the $\ell_1$-regularized LS estimator. Compared to the existing literature, our results provide several major contributions. First, to the best of our knowledge, our sufficient sampling bounds are the first of this kind in assessing the estimation performance of sparse AR models in the non-asymptotic regime. Although $\ell_1$-regularized LS and OMP are widely used in practice for AR estimation, the choices of the regularization parameter and the number of greedy iterations, respectively, are often ad-hoc. In contrast, our theoretical results prescribe analytical choices of the aforementioned parameters. In particular, our results suggest an improvement of order $O(p^{1/3} n^{-1})$ over those of [23] which requires $n \sim O(p^2)$ for stable AR estimation. Second, our analysis relaxes the widely-assumed hypotheses of i.i.d. covariates, which is clearly violated for AR estimation. To this end, our results extend those of [24] in establishing the RIP for i.i.d. Toeplitz matrices and [43] in establishing the RE condition for correlated Gaussian designs, to the setting or AR estimation where both the observations and covariates are obtained by the same stochastic process. Moreover, in the linear sparsity regime where $s$ scales linearly with $p$, our results suggest an improvement of order $O(p^{1/3})$ to those of [24]. Third, we established the minimax optimality of the $\ell_1$-regularized LS estimator for compressible AR parameters.

We further verified the validity of our theoretical results through simulation studies as well as application to real financial and traffic data. These results show that the sparse estimation methods significantly outperform the widely-used Yule-Walker based estimators in fitting AR models to the data. Although we did not theoretically analyze the performance of sparse Yule-Walker based estimators, they seem to perform on par with the $\ell_1$-regularized LS and OMP estimators based on our numerical studies. Finally, our results provide a striking connection to our recent work [44, 45] in estimating sparse self-exciting discrete point process models. These models regress an observed binary spike train with respect to its history via Bernoulli or Poisson statistics, and are often used in describing spontaneous activity of sensory neurons. Our results have shown that in order to estimate a sparse history-dependence parameter vector of length $p$ and sparsity $s$ in a stable fashion, a spike train of length $n = O(s^{2/3}p^{2/3} \log p)$ is required. This leads us to conjecture that our results will hold for a larger class of autoregressive processes, beyond those characterized by linear models.

APPENDIX A

PROOFS OF THEOREMS 1 AND 2

A. The Restricted Strong Convexity of the matrix of covariates

The first element of the proofs of both Theorems 1 and 2 is to establish the Restricted Strong Convexity (RSC) for the matrix $X$ of covariates formed from the observed data. First, we investigate the closely related Restricted Eigenvalue (RE) condition. Let $[\lambda_{\min}(s), \lambda_{\max}(s)]$ be the smallest interval containing the singular values of $X^T S X$, where $X_S$ is a sub-matrix $X$ over an index set $S$ of size $s$.

**Definition 1** (Restricted Eigenvalue Condition). A matrix $X$ is said to satisfy the RE condition of order $s$ if $\lambda_{\min}(s) > 0$.

Although the RE condition only restricts $\lambda_{\min}(s)$, in the following analysis we also keep track of $\lambda_{\max}(s)$, which appears in some of the bounds. Establishing the RSC for $X$ proceeds in a sequence of lemmas (Lemmas 1–5 culminating in Lemma 6). We first show that the RE condition holds for the true covariance of an AR process:

**Lemma 1** (from [46]). Let $R \in \mathbb{R}^{k \times k}$ be the $k \times k$ covariance matrix of a stationary process with power spectral density $S(\omega)$, and denote its maximum and minimum eigenvalues by $\phi_{\max}(k)$ and $\phi_{\min}(k)$, respectively. Then, $\phi_{\max}(k)$ is increasing in $k$, $\phi_{\min}(k)$ is decreasing in $k$, and we have

$$\phi_{\min}(k) \downarrow \inf_{\omega} S(\omega), \quad \phi_{\max}(k) \uparrow \sup_{\omega} S(\omega).$$

This result gives us the following corollary:

**Corollary 1** (Singular Value Spread of $R$). Under the sufficient stability assumption, the singular values of the covariance $\Sigma$ of an AR process lie in the interval $[\frac{\sigma^2}{(s+1)^2}, \frac{\sigma^2}{2p^2}]$.

**Proof:** For an AR($p$) process

$$S(\omega) = \frac{1}{2\pi} |1 - \sum_{t=1}^{p} \theta_t e^{-j\omega t}|^2.$$  

Combining $\|\theta\|_1 \leq 1 - \eta < 1$ with Lemma 1 proves the claim.

Note that by Lemma 1, the result of Corollary 1 not only holds for AR processes, but also for any stationary process satisfying $\inf_{\omega} S(\omega) > 0$ and $\sup_{\omega} S(\omega) < \infty$, i.e., a process with finite spectral spread.

We next establish conditions for the RE condition to hold for the empirical covariance $R$.

**Lemma 2.** If the singular values of $R$ lie in the interval $[\lambda_{\min}, \lambda_{\max}]$, then $X$ satisfies the RE condition of order $s_*$ with parameters $\lambda_{\min}(s_*) = \lambda_{\min} - ts_*$ and $\lambda_{\max}(s_*) = \lambda_{\max} + ts_*$, where $t = \max_{i,j} |R_{ij} - R_{ij}|$.

**Proof:** Let $\hat{R} = \frac{1}{n}(X^T X)$. For every $s_*$-sparse vector $\theta$ we have

$$\theta^T \hat{R} \theta \geq \theta^T R \theta - t \|\theta\|_1^2 \geq (\lambda_{\min} - ts_*) \|\theta\|_2^2,$$

$$\theta^T \hat{R} \theta \leq \theta^T R \theta + t \|\theta\|_1^2 \leq (\lambda_{\max} + ts_*) \|\theta\|_2^2$$

which proves the claim.

We will next show that $t$ can be suitably controlled with high probability. Before doing so, we state a key result of Rudzikis [47] regarding the concentration of second-order empirical sums from stationary processes:

**Lemma 3.** Let $x_{n+p+1}$ be samples of a stationary process which satisfies

$$x_k = \sum_{j=-\infty}^{\infty} b_{j-k} w_j,$$ (22)
where \( w_k \)'s are i.i.d random variables with
\[
|\mathbb{E}(w_k^k)| \leq (\hat{c}\sigma_w)^k k!, \quad k = 2, 3, \ldots
\]
for some constant \( \hat{c} \) and
\[
\sum_{j=-\infty}^{\infty} |b_j| < \infty.
\]
Then, the biased sample autocorrelation given by
\[
\hat{r}^b_k = \frac{1}{n+k} \sum_{i,j=1, j-i=k} x_{i} x_{j}
\]
satisfies
\[
\mathbb{P}(|\hat{r}^b_k - r^b_k| > t) \leq c_1(n+k) \exp \left( - \frac{c_2 \sqrt{\sigma_w}}{\sigma_w^2} \frac{t^2(n+k)}{1+c_3 \sqrt{n}} \right),
\]
for positive absolute constants \( c_1, c_2 \) and \( c_3 \) which are independent of the dimensions of the problem and are only functions of \( \hat{c} \).

**Proof:** The lemma is a special case of Theorem 4 under Condition 2 of Remark 3 in [47].

Using the result of Lemma 3, we can control \( t \) and establish the RE condition for \( \hat{R} \) as follows:

**Lemma 4.** Let \( m \) be a positive integer. Then, \( X \) satisfies the RE condition of order \( (m+1)s \) with a constant \( \lambda_{\min}/2 \) with probability at least
\[
1 - c_1 p^2(n+p) \exp \left( - \frac{c_3 \sqrt{\sigma_w}}{1+c_4 \sqrt{n}} \right),
\]
where \( c_1 \) is the same as in Lemma 2, \( c_2 = \frac{c_2}{\sigma_w^2} \sqrt{\frac{\lambda_{\min}}{2(m+1)}} \) and \( c_4 = \frac{c_2 \sqrt{\sigma_w}}{\sigma_w^2} \sqrt{\frac{\lambda_{\min}}{2(m+1)}} \).

**Proof:** First, note that for the given AR process, condition (22) is verified by the Wold decomposition of the process, condition (23) results from the sub-Gaussian assumption on the innovations, and condition (24) results from the stability of the process. Note that
\[
\hat{R}_{i,i+k} = \frac{1}{n} \sum_{i=1}^{n} x_{i} x_{i+k} = \frac{1}{n} \sum_{i,j=1, j=i=k}^{n+k} x_{i} x_{j} = \frac{n+k}{n} \hat{r}^b_k,
\]
for \( i = 1, \ldots, n \) and \( k = 0, \ldots, p-1 \), Eq. (25) implies:
\[
\mathbb{P}(\hat{R}_{i,i+k} - R_{i,i+k} > \tau) \leq c_1(n+k) \exp \left( - \frac{c_2 \sqrt{\sigma_w}}{1+c_3 \sqrt{n}} \right).
\]
By the union bound and \( k \leq p \), we get:
\[
\mathbb{P}(\max_{i,j} |\hat{R}_{ij} - R_{ij}| > \tau) \leq c_1 p^2(n+p) \exp \left( - \frac{c_2 \sqrt{\sigma_w}}{1+c_3 \sqrt{n}} \right).
\]
Choosing \( \tau = \frac{\lambda_{\min}}{2(m+1)} \) and invoking the result of Lemma 2 establishes the result of the lemma.

We next define the closely related notion of the Restricted Strong Convexity (RSC):

**Definition 2 (Restricted Strong Convexity [31]).** Let
\[
V := \{ h \in \mathbb{R}^p \mid \|h_S\|_1 \leq 3\|h_S\|_1 + 4\sigma_s(\theta) \}. \tag{30}
\]
Then, \( X \) is said to satisfy the RSC condition of order \( s \) if there exists a positive \( \kappa > 0 \) such that
\[
\frac{1}{n} h^T X X h = \frac{1}{n} \| X h \|_2^2 \geq \kappa \| h \|_2^2, \quad \forall h \in V. \tag{31}
\]
The RSC condition can be deduced from the RE condition according to the following result:

**Lemma 5** (Lemma 4.1 of [35]). If \( X \) satisfies the RE condition of order \( s_1 = (m+1)s \) with a constant \( \lambda_{\min}/(m+1)s \), then the RSC condition of order \( s \) holds with
\[
\kappa = \frac{\lambda_{\min}(m+1)s}{(m+1)s} \left( 1 - \frac{\lambda_{\max}(ms)}{m\lambda_{\min}(m+1)s) \right)^2. \tag{32}
\]
We can now establish the RSC condition of order \( s \) for \( X \):

**Lemma 6.** The matrix of covariates \( X \) satisfies the RSC condition of order \( s \) with a constant \( \kappa = \frac{s^2}{16s^2} \) with probability at least
\[
1 - c_1 p^2(n+p) \exp \left( - \frac{c_2 \sqrt{\sigma_w}}{1+c_3 \sqrt{n}} \right), \tag{33}
\]
where \( c_7 = \frac{c_2}{\sqrt{n}} \) and \( c_8 = \frac{c_2}{\sqrt{16n(n+2p)}} \).

**Proof:** Choosing \( m = \lceil \frac{22}{16} \rceil \), and using Lemmas 2 and 7 refm:re2, and 5 establishes the result.

We are now ready to prove Theorems 1 and 2.

**B. Proof of Theorem 3**

We first establish the so-called vace condition for the error vector \( h = \theta_{l_1} - \theta \):

**Lemma 7.** For a choice of the regularization parameter \( \gamma_n \geq \|\nabla \mathbb{E}(\theta)\|_\infty = \frac{\gamma_n}{n} \| X^T(x_i^T - \theta) \|_\infty \), the optimal error \( h = \theta_{l_1} - \theta \) belongs to the vace
\[
V := \{ h \in \mathbb{R}^p \mid \|h_S\|_1 \leq 3\|h_S\|_1 + 4\sigma_s(\theta) \}. \tag{34}
\]

**Proof:** Using several instances of the triangle inequality we have:
\[
0 \geq \frac{1}{n} (\|x_i^T - X \theta + h\|_2^2 - \|x_i^T - X \theta\|_2^2)
\]
\[
+ \gamma_n (\|\theta + h\|_1 - \|\theta\|_1)
\]
\[
\geq \frac{1}{n} \| X^T(x_i^T - \theta) \|_\infty \|h\|_1 +
\gamma_n (\|\theta_S + h_S \| + \|h_S\|_1 - \|\theta\|_1)
\]
\[
\geq \frac{\gamma_n}{2} (\|h_S\| + \|h_S\|_1 - \|h_S\|_1 - \|\theta\|_1)
\]
\[
= \frac{\gamma_n}{2} (\|\theta_S\| + \|h_S\|_1 - \|\theta\|_1)
\]
\[
\geq \frac{\gamma_n}{2} (\|\theta_S\| + \|h_S\| - \|\theta\|_1 - 4\sigma_s(\theta))
\]

\]
The following result of Negahban et al. \[31\] allows us to characterize the desired error bound:

**Lemma 8** (Theorem 1 of \[31\]). If \( X \) satisfies the RSC condition of order \( s \) with a constant \( \kappa > 0 \) and \( \gamma_n \geq \|\nabla \varphi(\theta)\|_\infty \), then any optimal solution \( \hat{\theta}_t \) satisfies

\[
\|\hat{\theta}_t - \theta\|_2 \leq 2 \sqrt{\frac{\mathbb{E} \|\nabla \varphi(\theta)\|_\infty}{\kappa}} + \sqrt{\frac{2 \gamma_n \|\nabla \varphi(\theta)\|_\infty}{\kappa}}. \tag{40}
\]

In order to use Lemma 8 we need to control \( \gamma_n = \|\nabla \varphi(\theta)\|_\infty \). We have:

\[
\nabla \varphi(\theta) = \frac{2}{n} X^T (x_\theta^* - X \theta), \tag{35}
\]

It is easy to check that by the uncorrelatedness of the innovations \( w_k \)'s, we have

\[
\mathbb{E} [\nabla \varphi(\theta)] = \frac{2}{n} \mathbb{E} [X^T (x_\theta^* - X \theta)] = \frac{2}{n} \mathbb{E} [X^T w_\theta^*] = 0. \tag{36}
\]

Eq. 40 is known as the orthogonality principle. We next show that \( \nabla \varphi(\theta) \) is concentrated around its mean. We can write

\[
(\nabla \varphi(\theta))_j = \frac{2}{n} x_{n-j+1} \cdot w_\theta^* \tag{40},
\]

and observe that the \( j \)th element of this expansion is of the form \( y_j = x_{n-j+1} w_{n-j+1} \). It is easy to check that the sequence \( y_\theta^* \) is a martingale with respect to the filtration given by

\[
\mathcal{F}_j = \sigma \left( \sum_{j=1}^{n-j} x_j \right),
\]

where \( \sigma(\cdot) \) denotes the sigma-field generated by the random variables \( x_{n-j-1}, x_{n-j}, \ldots, x_{n-j+1} \). We use the following concentration result for sums of dependent random variables \[43\]:

**Lemma 9.** Fix \( n \geq 1 \). Let \( Z_j \)'s be sub-Gaussian \( \mathcal{F}_j \)-measurable random variables, satisfying for each \( j = 1, 2, \ldots, n, \)

\[
\mathbb{E} [Z_j | \mathcal{F}_{j-1}] = 0, \text{ almost surely,}
\]

then there exists a constant \( c \) such that for all \( t > 0 \),

\[
\mathbb{P} \left( \left| \sum_{j=1}^{n} Z_j - \mathbb{E} [Z_j] \right| \geq t \right) \leq \exp \left( - \frac{n t^2}{c^2} \right). \tag{37}
\]

**Proof:** This is a special case of Theorem 3.2 of \[43\] or Lemma 3.2 of \[49\], for sub-Gaussian-weighted random variables. The constant \( c \) depends on the sub-Gaussian constant of \( Z_j \)’s.

Since \( y_j \)'s are a product of two independent sub-Gaussian random variables, they are sub-Gaussian as well. Lemma 9 implies that

\[
\mathbb{P} (|\nabla \varphi(\theta)| \geq t) \leq \exp \left( - \frac{n t^2}{c_0^2 \sigma_w^2} \right). \tag{37}
\]

where \( c_0^2 := \frac{2}{\sigma_w^2} \) is an absolute constant. By the union bound, we get:

\[
\mathbb{P} (\|\nabla \varphi(\theta)\|_\infty \geq t) \leq \exp \left( - \frac{t^2 n}{c_0^2 \sigma_w^2} + \log \frac{1}{\rho} \right). \tag{38}
\]

Let \( d_s \) be any positive integer. Choosing \( t = c_0 \sigma_w^2 \sqrt{1 + d_4} \frac{\log p}{n} \), we get:

\[
\mathbb{P} (\|\nabla \varphi(\theta)\|_\infty \geq c_0 \sigma_w^2 \sqrt{1 + d_4} \frac{\log p}{n} \leq \frac{2}{n^{d_4}}. \]

Hence, a choice of \( \gamma_n = d_2 \sqrt{\frac{\log p}{n}} \) with \( d_2 := c_0 \sigma_w^2 \sqrt{1 + d_4} \), satisfies \( \gamma_n \geq \|\nabla \varphi(\theta)\|_\infty \) with probability at least \( 1 - \frac{1}{n^{d_4}} \). Let \( d_1 = (\kappa c_1')^{2/3} \). Using Lemma 6 the fact that \( n > d_1 s' p^{2/3} \) by hypothesis, and \( p > n \) we have that the RSC of order \( s \) hold for \( \kappa = \frac{\sigma_\delta^2}{2\pi} \) with a probability at least \( 1 - 2c_1 p^3 \exp \left( - \frac{c_0 p^{2/3}}{2} \right) \). Combined these two assertions, the claim of Theorem 1 follows for \( d_3 = 32 c_0 \sigma_\delta \sqrt{1 + d_4} \).

**C. Proof of Theorem 2**

The proof is mainly based on the following lemma, adopted from Theorem 2.1 of \[33\], stating that the greedy procedure is successful in obtaining a reasonable \( s' \)-sparse approximation, if the cost function satisfies the RSC:

**Lemma 10.** Let \( s' \) be a constant such that

\[
s' \geq \frac{8}{\pi^2} \log \frac{5 s}{\eta^2}, \tag{39}
\]

and suppose that \( \varphi(\theta) \) satisfies RSC of order \( s \) with a constant \( \kappa > 0 \). Then, we have

\[
\left| \theta_{\text{OMP}} - \theta_s \right|_2 \leq \frac{\sqrt{\delta_{s'}}}{\kappa}, \tag{40}
\]

where \( \delta_{s'} \) satisfies

\[
\delta_{s'} \leq \sqrt{s' + \|\nabla \varphi(\theta)\|_\infty}. \tag{40}
\]

**Proof:** The proof is a specialization of the proof of Theorem 2.1 in \[33\] to our setting with the spectral spread \( 1/4p^2 \).

In order to use Lemma 10 we need to bound \( \|\nabla \varphi(\theta)\|_\infty \). We have:

\[
\mathbb{E} [\nabla \varphi(\theta)] = \frac{1}{n} \mathbb{E} [X^T (x_\theta^* - X \theta)] = \frac{1}{n} \mathbb{E} [X^T X (\theta - \theta_s)]
\]

\[
= R(\theta - \theta_s) \leq \frac{\sigma_\delta^2}{2\pi \eta^2} \varsigma_\delta(\theta) 1, \tag{40}
\]

where in the second inequality we have used \( (36) \), and the last inequality results from Corollary 1. Let \( d_4' \) be any positive integer. Using the result of Lemma 9 together with the union bound yields:

\[
\mathbb{P} (\|\nabla \varphi(\theta)\|_\infty \geq c_0 \sigma_\delta^2 \sqrt{1 + d_4'} \frac{\log p}{n} + \frac{\sigma_\delta^2 \varsigma_\delta(\theta)}{2\pi \eta^2}) \leq \frac{2}{n^{d_4}}. \tag{40}
\]

Hence, we get the following concentration result for \( \delta_{s'} \):

\[
\delta_{s'} \geq \sqrt{s' + \left( c_0 \sigma_\delta^2 \sqrt{1 + d_4'} \frac{\log p}{n} + \frac{\sigma_\delta^2 \varsigma_\delta(\theta)}{2\pi \eta^2} \right)} \leq \frac{2}{n^{d_4}} \tag{40}
\]

Noting that by (39) we have \( s' + s \leq \frac{4s \log s}{\eta^2} \). Let \( d_4' = (2c_1')^{2/3} \). By the hypothesis of \( \varsigma_\delta(\theta) \leq A s^{-1/4} \) for some
constant $A$, and invoking the results of Lemmas 6 and 10, we get:
\[
\left\| \hat{\theta}_{\text{OMP}}^{(s^*)} - \theta_S \right\|_2 \leq d_2' \sqrt{\frac{s \log s \log p}{n}} + d_2' \sqrt{\frac{s \log s}{n}} \theta(	heta)
\]
where $d_1' = \frac{16\pi \log 2(1 + d_1^2)}{n}$ and $d_2' = \frac{\sqrt{c_{p/3}^2}}{n}$, with probability at least $1 - 2c_1p^3 \exp(-\frac{c_{p/3}^2}{2})$, $|S| \geq 1 - \frac{\sqrt{c_{p/3}^2}}{2}$.

Finally, we have:
\[
\left\| \hat{\theta}_{\text{OMP}}^{(s^*)} - \theta_S \right\|_2 \leq \left\| \hat{\theta}_{\text{OMP}}^{(s^*)} - \theta_S \right\|_2 + \left\| \theta_S - \theta \right\|_2.
\]
Choosing $d_1' = 2d_2'$ completes the proof.

D. Proof of Proposition 7

Consider the event defined by
\[
A := \left\{ \max_{i,j} \hat{R}_{ij} - R_{ij} \leq \tau \right\}.
\]
Eq. (29) in the proof of Lemma 3 implies that:
\[
\mathbb{P}(A^c) \leq c_1p^2(n + p) \exp(-c_2\sqrt{\frac{\tau n}{\tau^2 + \sigma_n^2}} + \sigma_n).
\]
By choosing $\tau$ as in the proof of Theorem 1, we have
\[
\mathcal{R}_2^\mathcal{R}(\hat{\theta}_{\text{minimax}}) \leq \mathcal{R}_2^\mathcal{R}(\hat{\theta}_{\text{est}}) \leq \sup_{\hat{\theta}} \left( \mathbb{E} \left\| \hat{\theta} - \theta \right\|_2^2 \right)
\]
\[
\leq \mathbb{P}(A) d_3^\theta \frac{\log p}{n} + \sup_{\hat{\theta} \in A^c} \mathbb{E} \left\| \hat{\theta} - \theta \right\|_2^2
\]
\[
\leq d_3^\theta \frac{\log p}{n} + 8(1 - \eta)^2 \exp(-c_2\sqrt{\frac{\tau n}{\tau^2 + \sigma_n^2}} + \sigma_n^2) + 3 \log p,
\]
where the second inequality follows from Theorem 1 and the third inequality follows from the fact that $\left\| \hat{\theta}_{i,j} - \theta \right\|_2 \leq 4(1 - \eta)^2$ by the sufficient stability assumption. For $n > d_1^\theta s^2/3$, the first term will be the dominant, and thus we get
\[
\mathcal{R}_2^\mathcal{R}(\hat{\theta}_{\text{minimax}}) \leq 2d_3^\theta \sqrt{\frac{\log p}{n}},
\]
for large enough $n$.

As for a lower bound on $\mathcal{R}_2^\mathcal{R}(\hat{\theta}_{\text{minimax}})$, we take the approach of [25] by constructing a family of AR processes with sparse parameters $\theta$ for which the minimax risk is optimal modulo constants. In our construction, we assume that the innovations are Gaussian. The key element of the proof is the Fano’s inequality:

Lemma 11 (Fano’s Inequality). Let $Z$ be a class of densities with a subclass $Z^*$ of densities $f_\theta$, parameterized by $\theta_i$, for $i \in \{0, \cdots, 2M\}$. Suppose that for any two distinct $\theta_i, \theta_j \in Z^*$, $D_{\text{KL}}(f_{\theta_i} \| f_{\theta_j}) \leq \beta$ for some constant $\beta$. Let $\mathcal{F}$ be an estimate of the parameters. Then
\[
\sup_{Z} \mathbb{E} \left[ \left\| \hat{\theta} - \theta \right\|_2 \right] \geq \frac{1}{4} \sqrt{\frac{3}{\beta}} + \log \frac{2}{M},
\]
where $H_j$ denotes the hypothesis that $\theta_j$ is the true parameter, and induces the probability measure $\mathbb{P}(., H_j)$.

Consider a class $Z$ of AR processes with $s$-sparse parameters over any subset $S \subseteq \{1, 2, \cdots, p\}$ satisfying $|S| = s$, with parameters given by
\[
\theta_{\ell} = \pm e^{-m} 1_S(\ell),
\]
where $m$ remains to be chosen. We also add the all zero vector $\theta$ to $Z$. For a fixed $S$, we have $2^s + 1$ such parameters forming a subfamily $Z_S$. Consider the maximal collection of $\binom{p}{s}$ subsets $S$ for which any two subsets differ in at least $s/4$ indices. The size of this collection can be identified by $A(p, \frac{s}{4}, s)$ in coding theory, where $A(n, d, w)$ represents the maximum size of a binary code of length $n$ with minimum distance $d$ and constant weight $w$ [50]. We have
\[
A(p, \frac{s}{4}, s) \geq \frac{p^{s-1}}{s!},
\]
for large enough $p$ (See Theorem 6 in [51]). Also, by the Gilbert-Varshamov bound [50], there exists a subfamily $Z_S^* \subseteq Z_S$, of cardinality $|Z_S^*| \geq 2^{(s/4) + 1}$, such that any two distinct $\theta_1, \theta_2 \in Z_S^*$ differ at least in $s/16$ components. Thus for $\theta_1, \theta_2 \in Z^* := \bigcup_s Z_S^*$, we have
\[
\left\| \theta_1 - \theta_2 \right\|_2 \geq \frac{1}{4} \sqrt{\frac{3}{\beta}} =: \alpha,
\]
and $|Z^*| \geq 2^{\frac{3}{8} - s/16}$. For an arbitrary estimate $\hat{\theta}$, consider the $s$ testing problem between the $2^{\frac{3}{8} - s/16}$ hypotheses $H_j : \theta = \theta_j \in Z^*$, using the minimum distance decoding strategy. Using Markov’s inequality we have
\[
\sup_{Z} \mathbb{E} \left[ \left\| \hat{\theta} - \theta \right\|_2 \right] \geq \sup_{Z^*} \mathbb{E} \left[ \left\| \hat{\theta} - \theta \right\|_2 \right] \geq \alpha \sup_{Z^*} \mathbb{P} \left( \left\| \hat{\theta} - \theta \right\|_2 \geq \alpha \right)
\]
\[
\geq \frac{\alpha}{2} \sup_{Z} \mathbb{P} \left( \left\| \hat{\theta} - \theta \right\|_2 \geq \alpha \right)
\]
\[
= \frac{\alpha}{2} \sup_{j} \mathbb{P} \left( \hat{\theta} \neq \theta_j | H_j \right).
\]

Let $f_\theta$ denote joint probability distribution of $\{x_k\}_{k=1}^n$ conditioned on $\{x_l\}_{l=1}^{n-p+1}$ under the hypothesis $H_j$. Using the Gaussian assumption on the innovations, for $i \neq j$, we have
\[
D_{\text{KL}}(f_i \| f_j) \leq \sup_{i \neq j} \mathbb{E} \left[ \log \frac{f_i}{f_j} | H_j \right]
\]
\[
\leq \sup_{i \neq j} \mathbb{E} \left[ \frac{1}{2\sigma^2} \sum_{k=1}^n \left( (x_k - \theta_i, x_k - \theta_j)^2 \right) | H_i \right]
\]
\[
\leq \sup_{i \neq j} \frac{n}{2\sigma^2} \mathbb{E} \left[ \left( \left( \theta_i - \theta_j \right) \left( \left( x_k, x_k - \theta_j \right) \right) \right) | H_i \right]
\]
\[
= \frac{n}{2\sigma^2} \sup_{i \neq j} \mathbb{E} \left[ \left( \theta_i - \theta_j \right) \left( \theta_i - \theta_j \right) | H_i \right]
\]
\[
\leq \frac{n\lambda_{\text{max}}}{2\sigma^2} \sup_{i \neq j} \left\| \theta_i - \theta_j \right\|_2^2 \leq \frac{8n \sigma^2}{64\pi^2} \leq \beta.
\]

Using Lemma 11 (44), (45) and (46) yield:
\[
\sup_{Z} \mathbb{E} \left[ \left\| \hat{\theta} - \theta \right\|_2 \right] \geq \frac{\sqrt{e^{-m}}}{8} \left( 1 - \frac{2(2^{\frac{3}{4} - s/16} + \log 2)}{s!} \right).
\]
for $p$ large enough so that $\log p \geq \frac{\log s - \frac{3}{2}}{\frac{3}{2}}$. Choosing $m = \frac{1}{2} \log \left( \frac{4 \log p}{\log \log p} \right)$ gives us the claim of Proposition with $L = \frac{d}{\eta \sqrt{2\pi}}$ for large enough $s$ and $p$ such that $s \log p \geq \log(256)$. The hypothesis of $s \leq \frac{1}{4 \theta \eta} \sqrt{\frac{n}{\log p}}$ guarantees that for all $\theta \in \mathbb{Z}^*$, we have $\|\theta\|_1 \leq 1 - \eta$.

### APPENDIX B

**STATISTICAL TESTS FOR GOODNESS-OF-FIT**

In this appendix, we will give an overview of the statistical goodness-of-fit tests for assessing the accuracy of the AR model estimates. A detailed treatment can be found in [52].

#### A. Residue-based tests

Let $\hat{\theta}$ be an estimate of the parameters of the process. The residues (estimated innovations) of the process based on $\hat{\theta}$ are given by

$$e_k = x_k - \hat{\theta} x_{k-1} - \cdots - \hat{\theta}^{k-p} x_{k-p}, \quad i = 1, 2, \ldots, n.$$ 

The main idea behind most of the available statistical tests is to quantify how close the sequence $\{e_i\}_{i=1}^n$ is to an i.i.d. realization of a known distribution $F_0$ which is most likely absolutely continuous. Let us denote the empirical distribution of the $n$-samples by $F_n$. If the samples are generated from $F_0$ the Glivenko-Cantelli theorem suggests that:

$$\sup_t |F_n(t) - F_0(t)| \xrightarrow{d} 0.$$ 

That is, for large $n$ the empirical distribution $F_n$ is uniformly close to $F_0$. The Kolmogorov-Smirnov (KS) test, Cramér-von Mises (CvM) criterion and the Anderson-Darling (AD) test are three measures of discrepancy between $F_n$ and $F_0$ which are easy to compute and are sufficiently discriminant against alternative distributions. More specifically, the limiting distribution of the following three random variables are known: The KS test statistic

$$K_n := \sup_t |F_n(t) - F_0(t)|,$$

the CvM statistic

$$C_n := \int \left( F_n(t) - F_0(t) \right)^2 dF_0(t),$$

and the AD statistic

$$A_n := \int \left( \frac{F_n(t) - F_0(t)}{F_0(t)(1 - F_0(t))} \right)^2 dF_0(t).$$

For large values of $n$, the Glivenko-Cantelli theorem also suggests that these statistics should be small. A simple calculation leads to the following equivalent for the statistics:

$$K_n = \max_{1 \leq i \leq n} \max \left\{ \left| \frac{i}{n} - F_0(e_i) \right|, \left| \frac{i-1}{n} - F_0(e_i) \right| \right\},$$

$$nC_n = \frac{1}{12n} + \frac{1}{n} \sum_{i=1}^n \left( F_0(e_i) - \frac{2i - 1}{2n} \right)^2,$$

and

$$nA_n = -n - \frac{1}{n} \sum_{i=1}^n (2i - 1) \left( \log F_0(e_i) + \log \left( 1 - F_0(e_i) \right) \right).$$

#### B. Spectral domain tests for Gaussian AR processes

The aforementioned KS, CvM and AD tests all depend on the distribution of the innovations. For Gaussian AR processes, the spectral versions of these tests are introduced in [39]. These tests are based on the similarities of the periodogram of the data and the estimated power-spectral density of the process. The key idea is summarized in the following lemma:

**Lemma 12.** Let $S(\omega)$ be the (normalized) power-spectral density of stationary process with bounded spectral spread, and $\hat{S}_n(\omega)$ be the periodogram of the $n$ samples of a realization of such a process, then for all $\omega$ we have:

$$\sqrt{n} \left( 2 \int_0^\omega \left( \hat{S}_n(\lambda) - S(\lambda) \right) d\lambda \right) \overset{d}{\rightarrow} Z(\omega),$$

(47)

where $Z(\omega)$ is a zero-mean Gaussian process.

The explicit formula for the covariance function of $Z(\cdot)$ is calculated in [39]. Lemma [12] suggests that for a good estimate $\hat{\theta}$ which admits a power spectral density $S(\omega; \hat{\theta})$, one should get a (close to) Gaussian process replacing $S(\omega)$ with $S(\omega; \hat{\theta})$ in (47). The spectral form of the CvM, KS and AD statistics can thus be characterized given an estimate $\hat{\theta}$.
