A brief review of kidney development, maturation, developmental abnormalities, and drug toxicity: juvenile animal relevancy

John Curtis Seely

1 Experimental Pathology Laboratories, Inc., P.O. Box 12766, Research Triangle Park, NC 27709, USA

Abstract: Nonclinical juvenile animal tests perform a valuable role in determining adverse drug effects during periods of organogenesis and/or functional maturation. Developmental anatomic and functional maturation time points are important to consider between juveniles and adults when regarding different organ toxicities in response to drug administration. The kidney is an example of a major organ that has differences in these time points in comparing juveniles to adults and in contrasting humans to laboratory animal species. Toxicologic pathologists, involved in juvenile studies, need to be aware of these time points which are age-related exposure periods of sensitivity to drug toxicity. Age-related developmental anatomic and functional maturation are factors which can affect the way that a drug is absorbed, distributed, metabolized, and excreted (ADME). Changes to any component of ADME may alter drug toxicity resulting in kidney abnormalities, nephrotoxicity, or maturational disorders. Juvenile animal kidneys may either be less resistant or more resistant to known adult nephrotoxic drug effects. Furthermore, drug toxicity observed in juvenile animal kidneys may not always correspond to similar toxicities in humans. Juvenile animal nonclinical toxicology studies targeting the kidneys have to be carefully planned to attain the maximum knowledge from each study. (DOI: 10.1293/tox.2017-0006; J Toxicol Pathol 2017; 30: 125–133)

Key words: kidney, juvenile animals, development, maturation, abnormalities, toxicity

Introduction

It is known that neonates, infants, or adolescents may react to drugs in ways that are difficult to predict from studies in adults. In other words, “juvenile animals are not little adults”. Concerns over the lack of awareness of potential therapeutic drug toxicities in pediatric populations, the use of off-labeled drugs by physicians to treat children, and known medicinal adverse effects in children all contributed to the release of guidelines and recommendations for nonclinical studies evaluating drug products for pediatric populations. Listed in Table 1 are approximate equivalent ages of juveniles in humans, dogs, and rats. Nonclinical juvenile studies are mainly conducted to detect toxicity or maturational defects since differences of sensitivity exist between adults and juveniles that can be chemical specific. Juvenile studies are considered “compacted” animal models serving to study changes over a relatively short period. Juvenile studies help to bridge data deficiencies between reproductive toxicology and adult toxicology studies, and aid in early hazard identification.

The kidney is one of the best characterized organ systems in developmental biology and is regarded as a “model” organ system to study organogenesis. Mammalian kidneys develop similarly but developmental time points vary among species. The process of nephron development or “nephrogenesis” is important to understand since most developmental abnormalities or drug-related injury occurs during the period of nephron formation. Over the past several decades genomic technologies and knock-out mouse models have defined many of the genetic and molecular pathways associated with nephrogenesis.

Toxicologic pathologists may have a fundamental understanding of kidney development but unaware of the histologic differences between juvenile and adult kidneys. Pathologists can refer to a recently published book chapter that illustrates the histologic appearance of the immature rat kidney to use as a guide in their studies.

Developmental time points or “sensitive windows of exposure” are prenatal or postnatal periods of structural and functional kidney development which are vulnerable to chemical or drug administration. For instance, depending on the age at exposure, drug administration may result in renal anomalies or malformations, nephrotoxicity, altered functional maturational, or have no effect. The range of toxicity or lack of toxicity in the juvenile animal is due to a number of factors including the competency of tubule function or the activity of enzymatic pathways in the immature animal.
Kidney Development, Maturation, Abnormalities, Drug Toxicity

The interest and increased numbers of juvenile animal toxicity tests reflect a growing need to predict chemical hazards in pediatric populations. Juvenile kidney studies are emphasized because of the kidney’s ongoing postnatal periods of development and maturation. Nonclinical study protocols designed to evaluate juvenile kidneys may contain procedures, end-points, and histological requirements that are unique for each study and dependent on the drug under investigation. In other cases, newer testing models or study designs may appear as alternatives to previous standardize tests. For instance, the National Toxicology Program’s modified one generation (MOG) study which utilizes animals exposed at defined prenatal and postnatal time points can further examine subsets of F1 generation offspring for organ or systems toxicities. The study design of the MOG study allows for the evaluation of reproductive parameters with the potential of “triggering” additional time points and examinations to look for any test article-related toxicities in juvenile animals.

The overall purpose of this brief review is to introduce and summarize key concepts in normal kidney development, abnormal development, and developmental toxicity. It is not meant to be comprehensive or inclusive of all developmental and pathogenic mechanisms involved with nephrotoxicity in the juvenile kidney.

**Kidney Development**

**Embryology**

Developmentally, all mammals share a common sequential and structural process which arises from the intermediate mesoderm, one of the embryonic germ layers, and includes the appearance of three stages of kidney development; the pronephros, the mesonephros, and the metanephros or the adult kidney as depicted in Fig.1. The pronephros and mesonephros are transient structures in mammals which regress allowing the metanephros to differentiate into the adult kidney.

The pronephros along with its duct is the first stage of kidney development and appears approximately around gestational day (GD) 22 in humans, GD 11 in the rat, and GD 8 in the mouse. It is nonfunctional but important since as the pronephros regresses the caudal portion of the pronephric duct remains and eventually becomes the Wolff-
ian duct. One function of the Wolffian duct is to induce the mesonephros to develop.

The mesonephros is the functional kidney of fish and amphibians but is nonfunctional in adult mammals. However, during mammalian embryogenesis, mesonephric nephrons are formed but later regress. The Wolffian duct elongates growing downwards to join the urogenital sinus. The urogenital sinus eventually differentiates into the urinary bladder. During mesonephros, a diverticulum off the Wolffian duct becomes the ureteric bud (UB).

As the mesonephros regresses, the metanephric kidney develops by the outgrowth and branching of the UB into the metanephric mesenchyme (MM) initiating nephrogenesis or the formation of nephrons. The UB as it contacts the MM continues to branch, each branch representing a future nephron. In addition, the UB has an important role in controlling kidney morphogenesis as well as determining the numbers of nephrons in the kidney. The UB also contributes to the formation of the collecting ducts, renal pelvis, and ureters.

The kidney develops in close relationship with the male and female genital tracts. The Wolffian duct induces development of the Müllerian duct (paramesonephric duct) the anlagen of the female oviducts, uterus, cervix, and the upper portion of the vagina. In males, and under the influence of testosterone, the Wolffian duct is transformed into the male excretory ducts, the epididymis and vas deferens. Subsequently, in males, the Müllerian duct regresses due to the production of anti-Müllerian hormone secreted by the Sertoli cells of the testes.

**Nephrogenesis**

Nephrogenesis begins in the fetus and is completed in humans and mice before birth but continues postnatally in the rat as shown in Table 2. The formation of nephrons involves tightly controlled genetic and molecular pathways which result in the transformation of the MM to epithelial lined structures which undergo further configurational changes to form nephrons. This entire process is termed mesenchymal-to-epithelial transformation (MET). Nephrogenesis begins with the reciprocal inductive interactions between the MM and the UB. Reciprocal induction refers to the mutually dependent exchange of signaling and regulatory molecules between the MM and UB as schematically represented in Fig. 2. Nephrogenesis induction is initiated by glial derived neurotrophic factor (Gdnf) expressed in the MM which induces UB outgrowth. However, further MET development is dependent on UB outgrowth into the MM before the transformation of mesenchyme to epithelium can actually begin. As with any major biological process, the entire process of MET involves a large number of molecules that are encoded by different gene families and regulated by signaling, growth, transcription, extracellular matrix, and other factors.

Table 3 contains a partial list of the more important selective mediators involved in MET. The Wt1 gene, in particular, has been studied extensively since it has been identified as having a prominent role in MET and associated with the Wilms' tumor or nephroblastoma.

Nephrogenesis can be simply depicted as illustrated in Fig. 3. Early stages consist of a “cap” of aggregated MM around the tip of the UB. After contact with the UB, MM cells further condense and begin to epithelialize. As nephrogenesis continues, the primitive epithelium initially forms small vesicles which undergo reorganizational patterning to form comma- and subsequent S-shaped bodies. As the S-shape body elongates, vasculogenesis begins as endothelial cells migrate into the distal end of the S-shaped body. Further nephron differentiation and formation of capillary loops denotes the beginning of glomerulogenesis. Also during this stage, portions of the S-shaped body begin to express markers for proximal and distal tubules. The primitive glomeruli continue to differentiate incorporating the vascular loops and allowing endothelial cells to contact visceral epithelial cells (early podocytes) forming the filtration barrier of the mature glomerulus. Within the MM, a multipotent progenitor pool remains that does not undergo epithelialization ultimately giving rise to interstitial and vascular cells.
Histology

The histological appearance of the rodent kidney at birth and immediate postnatal period is very different from the appearance in adults. Histologically, three densely basophilic cortical zones (nephrogenic, juxtamedullary, and intercortical) may be recognized as well as the renal medulla and the papilla. However, at this time point, tissue maturation within the kidney varies because the medulla appears immature while the papilla appears more mature. Nephrogenic maturation occurs from the deeper cortex (juxtamedullary zone) where older, larger, and more mature glomeruli are found in contrast to the outer cortex (nephrogenic zone) which contains newer, smaller, and immature nephrons that lack full differentiation as shown in Fig. 4. Four stages of nephrogenesis have been described during the postnatal period and are summarized in Table 4. The increase size of the kidney during the postnatal period is due to a combination of tubule hypertrophy and hyperplasia followed by interstitial expansion which is temporally different for each zone. These various zones change quickly underly-

**Table 3.** Selective Molecular Mediators Expressed during Nephrogenesis. Most Molecular Mediators are Expressed and Subjected to Positive and Negative Regulation by a Variety of Other Factors (Data from Kuure et al.; Dressler; McMahon)

| Molecular Mediator | Main Expression Location | Targeted Interaction |
|--------------------|--------------------------|----------------------|
| Gdnf – glial-cell derived neurotropic factor | MM | Initiates UB outgrowth |
| c-ret | UB | Receptor for Gdnf |
| Wt1 – Wilm’s tumor suppressor | MM | Maintains metanephric mesenchyme; regulates glomerulogenensis; |
| Pax 2 | MM | Regulatory factor in early MET |
| Bmp – bone morphogenesis factors | MM | Regulates MET |
| Wnt genes | UB and MM | Regulates MET |
| Eya-1 | MM | Regulates Gdnf and MET |
| Vegf | MM | Regulates endothelial cell proliferation |
| Hox genes | MM | Regulates MET |
| Growth and transcription factors | MM | Signaling and regulatory function |

MM: metanephric mesenchyme, UB: urinary bud, MET: mesenchyme-to-epithelial transformation.

ing the need for collecting age-matched control histological samples at multiple time points for comparative purposes.

**Maturation**

The kidneys, at birth and the postnatal period are marked by growth and physiologic functional changes that adapt to extra-uterine life and progress to adult renal function. Juvenile animals are born functionally immature with regard to renal physiologic capacity and the acquisition of functional maturity may be just as important as structural development when recognizing short or long term adverse drug toxicity effects. In general, immature rat kidneys quickly mature to full functional levels between birth and weanling but full functional maturation may take 2–3 years in the human and 5 months in the monkey. Functional maturity of the kidney lags behind anatomic maturation in all species.

Functional maturity is dependent on many factors. The reduced tubular mass and lack of tubule maturity in neonatal or juvenile kidneys are responsible for an inability to maintain kidney homeostasis. Renal blood flow, glomerular filtration rate (GFR), tubule secretion and absorption, maintenance of acid-base equilibrium, and urine concentrating mechanisms are all reduced in the juvenile animal. Furthermore, levels of organic anion transporters needed to help with drug and toxin elimination, are also reduced. Therefore, functional immaturity exposes the juvenile kidney to more toxic agents by decreasing drug clearance or its ability to detoxify drugs or their metabolites. Paradoxically, in some cases of drug administration, the decrease in functional maturity may actually protect the juvenile kidney due to the inability of the kidney to deliver toxic agents to vulnerable tubules and the decreased ability to concentrate toxic agents in tubules to toxic levels.

Functional maturation end-points in humans and laboratory animals are generally well characterized. Studies in rats have evaluated functional maturation in neonates and weanlings while also examining how effectively juvenile animals can respond to physiological challenges in their ability to maintain kidney homeostasis. Generally, as mentioned previously, these studies indicated that functional maturation, although weak at birth, accelerates rapidly.

Clinical pathology determinations are used not only to monitor drug toxicity but can help determine functional maturation. Conducting clinical pathology assessments on juvenile rodent kidneys present certain problems that need to be addressed. For instance, pups can’t be removed from dams before weanling and sampling of blood or urine volume may not yield quantities sufficient for normal testing clinical determinations. Other concerns might involve the most appropriate type of testing methodology to use and the need for age-matched historical control samples.

**Developmental Abnormalities**

Developmental renal abnormalities or malformations may arise spontaneously, associated with genetic disorders, or can be induced. Table 5 contains an abbreviated list of kidney teratogens reported in humans. Renal abnormalities represent a heterogeneous group of disorders that include, but may not be limited to, agenesis, hypoplasia, dysplasia, ectopic, fused, or cystic kidneys. Although rodents generally have few spontaneous kidney malformations human kidney malformations are among the most common birth defects in humans.

Congenital anomalies of the kidney and urinary tract (CAKUT) account for a reported range of 20–50% of children with chronic kidney disease or abdominal masses in neonates. Many of these kidney abnormalities are linked to specific gene mutations associ-
ated with a defect in kidney organogenesis\textsuperscript{48, 49}. Even small developmental defects may have serious consequences. For example, positioning or branching defects of the UB or misplaced gene expressions may result in congenital renal developmental defects may have serious consequences. For instance, Gdnf deficient mice do not develop kidneys because Gdnf is required to induce UB outgrowth initiating kidney organogenesis\textsuperscript{50, 51}. Interested individuals may want to consult the Genitourinary Developmental Molecular Anatomy Project (GUDMAP) an evolving database that provides research information on developmental kidney research and novel mouse strains targeting specific genes\textsuperscript{52}.

The developing kidney in humans exposed to poor maternal intrauterine conditions such as malnutrition, disease, stress, or poverty seem to develop kidney deficits that have been linked to disease conditions appearing later in adult life\textsuperscript{53, 54}. Barker cited epidemiological studies which found that individuals born from women with clinical histories of fetal intrauterine growth retardation (IUGR) or individuals born with significant lower birth weights were at risk to develop ischemic cardiovascular disease, pulmonary obstructive disease, or hypertension later in adult life\textsuperscript{55}. The assumption arising from these observations was postulated as “fetal programming of adult disease” and hypothesized that adverse events occurring in fetal life could affect adult life\textsuperscript{56}. More fascinating are human studies that demonstrated the direct relationship of lower nephron numbers or deficits to adult hypertension\textsuperscript{56-59}. Animal models using various methods to recreate IUGR such as low protein diets or uterine artery ligation models in rat studies also resulted in reduced populations of nephrons and elevated blood pressure\textsuperscript{60, 61}. Another uterine ligation model using rabbits also resulted in similar renal anomalies\textsuperscript{35}. No renal abnormalities were seen in monkeys also resulted in similar renal anomalies\textsuperscript{35}. No renal abnormalities were seen when ACE inhibitors were given postnatally after completion of nephrogenesis. Exposure with ACE inhibitors to newborn rats, with ongoing postnatal kidney development, induced renal abnormalities similar to those observed in human infants and included papillary

### Table 5. Maternal Factors and Nephroteratogens Associated with Abnormal Kidney Development (Data from Solhaug et al.; Upadhyay and Silverstein)

| Poor maternal health | Maternal malnutrition | Maternal stress | Maternal smoking/alcohol | Illicit drugs | Therapeutic drugs | Radiation | Chemicals | Toxic metals | Environmental toxins |
|----------------------|-----------------------|----------------|--------------------------|--------------|------------------|-----------|-----------|-------------|---------------------|

#### Drug Toxicity

Juvenile renal studies are usually recommended or required when the drug under investigation is targeted for a pediatric population in which drug toxicity was observed in adult animal studies. Therefore, in designing nonclinical juvenile animal kidney studies it is necessary to consider the class of drug, anticipated renal effects, fetal or postnatal age at dosing, the period of dosing, histopathology, clinical pathology requirements, and any ancillary tests in order obtain the maximum information possible. Therefore, juvenile kidney studies are more likely to be designed “case by case”.

As previously discussed, the outcome of renal drug toxicity in the juvenile kidney depends primarily on the age of structural development and the stage of functional maturity. Pharmacokinetic factors that determine the ADME of drugs and the interrelationship between these factors and drug toxicity depends largely on maintaining a fine balance between metabolism and drug clearance mechanisms through the kidneys\textsuperscript{64}. Any disturbances in the expression of genetic factors, altering blood flow and expression of tubule transporters, or by causing maturational delays may influence toxicity\textsuperscript{65, 66}.

Conversely, in some cases, the developing kidney is more resistant to toxicity than the adult\textsuperscript{5}. For instance, the relative tolerance of the developing kidney to some drugs may be explained by the immaturity of pharmacokinetic enzyme systems or by the immaturity and distribution of the renal blood flow which spares certain tubules from receiving toxic concentrations of a drug\textsuperscript{65, 67}. Unfortunately, it was apparent that inadvertent drug administration to pregnant women resulted in abnormal fetal kidney development and birth defects. Drugs recognized as nephroteratogens include aminoglycosides, cyclosporines, angiotensin converting enzyme (ACE) inhibitors, prostaglandin synthetase inhibitors, steroids, furosemide, thalidomide and antiepileptic drugs and are not recommended during pregnancy\textsuperscript{65, 68}. Of recent concern, as the number of older pregnant women become pregnant, is the potential threat of increased fetal exposures to nephroteratogenic drugs\textsuperscript{69}.

An example that is often cited as an age-dependent teratogen is the administration of ACE inhibitors during kidney development. The renin-angiotensin aldosterone system is expressed in the developing kidney and has a role in several normal body functions including regulating blood pressure and extracellular fluid volume\textsuperscript{61}. Interruption of angiotensin-mediated receptor processes by ACE inhibitors resulted in renal dysplasia and other renal abnormalities in infants from mothers given these drugs during pregnancy to treat hypertension\textsuperscript{70}. ACE inhibitors given to pregnant monkeys also resulted in similar renal anomalies\textsuperscript{35}. Of recent concern, as the number of older pregnant women become pregnant, is the potential threat of increased fetal exposures to nephroteratogenic drugs\textsuperscript{69}.
atrophy, thickening of cortical arteries, tubule atrophy, tubule dilatation, fibrosis, and inflammatory cell infiltrates.  

Summary

Kidney development is basically similar for all mammals. During renal organogenesis, 3 sequential stages arise from embryonic mesoderm terminating in the metanephros or adult kidney. Nephrogenesis, or the formation of nephrons, is a process that uniquely transforms metanephric mesenchyme to epithelium and involves a complex and coordinated array of genetic and molecular pathways.

The kidney, like other major organs, has “sensitive windows of exposure”. Exposure to a wide variety of chemicals or drugs at crucial periods may result in malformations, nephrotoxicity, or functional maturation defects depending on the developmental time point of exposure. Although there are species differences “sensitive windows of exposure” time points are generally well known for humans and laboratory animal species.

Congenital anomalies of the kidney or malformations are common in humans but less common in laboratory animals. Genetic mutations associated with specific kidney anomalies are known in both humans and animals. Genetically altered mice are used routinely to investigate the role of genes during kidney development and have assisted in the investigations of genetic mutations and malformations. In addition, kidney malformations may arise from fetal exposure to diverse types of nephroteratogens.

Growth and development of the kidney may be compromised during fetal life and subsequently associated with clinical disease later in adult life. Epidemiological, human, and animal investigations provide strong evidence that the theory “fetal programming of adult disease”, as a cause of some cases of adult hypertension, is a real entity.

The pathology of renal toxicity is essentially similar between juveniles and adults. However, the extent and severity of either direct or indirect drug-related toxicity is strongly influenced by the stage of renal development at the time of drug exposure.

Toxicologic pathologists need to carefully evaluate juvenile kidneys keeping in mind the unique structural and physiological differences between juveniles and adults. Harmonized guidelines for recommending specific agent-related renal clinical pathology, biomarker, or histopathology end-points need to be proposed to standardize historical control data among laboratories and to ensure time relevant data collection. Extrapolation of nonclinical juvenile kidney studies to human risk assessment needs to account for species specific differences in structural and functional maturation.

In summary, and to emphasize the serious relationship between kidney development and drug administration, Schreuder and his colleagues remarked that “No drug, in their experience, has been proven safe to use during renal development.”
