Purpose: Phosphoglycerate dehydrogenase (PHGDH) acts as a key metabolic enzyme in the rate-limiting step in serine biosynthesis and plays an important role in metastasis of several cancers. The aim of this study was to investigate the prognostic value of PHGDH in gastric cancer (GC).

Methods: The messenger RNA expression of PHGDH was determined in 20 pairs of cancerous and adjacent nontumor tissues by real-time polymerase chain reaction. Immunohistochemistry of PHGDH was performed on tissue microarray, composed of 482 GC and 64 matched adjacent nontumor tissues acquired from surgery, 20 chronic gastritis, 18 intestinal metaplasia, and 31 low-grade and 66 high-grade intraepithelial neoplasias acquired through gastric endoscopic biopsy. Univariate and multivariate Cox proportional hazard models were used to perform survival analyses.

Results: Both PHGDH messenger RNA and protein product exhibited GC tissue-preferred expression, when compared with benign tissues. The high PHGDH expression was significantly correlated with histological type (P=0.011), tumor stage (P=0.014), and preoperative carcinoembryonic antigen (P<0.001). A negative correlation was found between PHGDH expression and the 5-year survival rate of patients with GC. Furthermore, multivariate analysis indicated that PHGDH was an independent prognostic factor for outcome in GC.

Conclusion: PHGDH is important in predicting patient outcomes and is a potential target for the development of therapeutic approaches to GC.

Keywords: metabolism, gastric cancer, prognosis, serine biosynthesis

Introduction

Gastric cancer (GC) is the fourth most prevalent human cancer worldwide, with an estimated 952,000 new cases diagnosed annually and almost as many deaths. Approximately 70% of GC cases are seen in developing countries. In the People’s Republic of China, GC is the third leading cause of death among cancers, with an age-standardized incidence of 22.7/100,000. Unfortunately, the 5-year survival rate worldwide after surgical resection remains low. High rates of metastasis and recurrence are major obstacles in improving long-term survival after a curative resection. New molecular prognostic markers and therapeutic targets are needed to improve the clinical outcome for patients with this disease.

Over the past 10–20 years, there has been an increasing amount of evidence that the majority of oncogenes and tumor suppressors play vital roles in the regulation of metabolic processes. Tumor growth, for example, appears to be maintained through the “Warburg effect”, which allows tumor cells to rely on aerobic glycolysis to maintain cell growth and proliferation. Furthermore, metabolic reprogramming of tumorigenic cells through modifications in the genome of metabolic enzymes contributes to their...
biomass accumulation and proliferative growth, and there is experimental evidence that tumor cell growth can be suppressed by blocking the activity of its constituent metabolic enzymes.\(^6\) For any of these enzymes to be considered as a target for developing anticancer therapies, there must be evidence of a profound difference in the requirements for the activity of that enzyme in cancerous cells vs normal cells.\(^9\) Recently, researchers have focused on phosphoglycerate dehydrogenase (PHGDH), a key enzyme in the de novo biosynthesis of serine. Specifically, PHGDH catalyzes a rate-limiting step in the conversion of 3-phosphoglycerate to serine.\(^9\) In so doing, it diverts flux away from glycolysis by oxidizing 3-phosphoglycerate to release serine and glycine, thus allowing the rapid production of energy and metabolites required for the high rate of anabolism that drives a dramatically increased proliferation of cancer cells.\(^1\)

Until now, a high level of PHGDH expression has been detected in several types of human tumors; this appears to contribute to pathogenesis and to a poor prognosis for humans with cancer.\(^1,2\) In glioma cells, for example, PHGDH interacts with and stabilizes forkhead box M1, thereby promoting the proliferation, invasiveness, and tumorigenicity of the cell.\(^1\) Elevated rates of PHGDH expression have also been detected in cervical adenocarcinomas and have been found to correlate with advanced tumor stage, increased tumor size, and progression of the disease.\(^1\) In glioma cells, for example, PHGDH interacts with and stabilizes forkhead box M1, thereby promoting the proliferation, invasiveness, and tumorigenicity of the cell.\(^1\) Elevated rates of PHGDH expression have also been detected in cervical adenocarcinomas and have been found to correlate with advanced tumor stage, increased tumor size, and progression of the disease.\(^1\) Rotondo et al\(^1\) identified a similar trend in cervical neoplastic keratinocytes, and PHGDH appears to contribute to oncogenesis in breast cancer and melanoma cells.\(^1\) Conversely, a knockdown of endogenous PHGDH appears to promote apoptosis in human melanomas\(^18\) and inhibit HeLa cell proliferation while increasing sensitivity to cisplatin chemotherapy.\(^1\) Possemato et al\(^19\) found conclusive evidence that PHGDH levels are ~70% higher in estrogen receptor-negative breast tumors than in estrogen receptor-positive breast tumors and account for an estimated 20%–25% of breast cancer cases and as many as 50% of breast cancer deaths within 5 years of diagnosis.\(^2\) A significant correlation between a high rate of PHGDH expression and a shorter time to relapse and worse overall survival (OS) was found in patients with breast cancer that had metastasized to bone.\(^2\) Combining key residues of protein kinase C (PKC)\(\zeta\) to inhibit its enzymatic activity, phosphorylates PHGDH resulted in enhanced intestinal tumorigenesis and related with shorter OS in patients with low levels of PKC\(\zeta\).\(^2\) However, an analysis of data from patients with lung cancer did not demonstrate a relationship between PHGDH and prognosis,\(^2\) and a significantly increased level of PHGDH in tumoral vs peritumoral tissue failed to demonstrate any prognostic value in patients with colon cancer.\(^2\) Until now, the expression of PHGDH and its prognostic role in GC have not been explored. In this study, we sought to determine the prognostic value of various rates of PHGDH expression in benign tissue vs malignant tissue in patients with gastric disease.

**Methods**

**Human tissue specimens and patient clinical information**

We selected 617 formalin-fixed, paraffin-embedded tissue samples from patients with GC \((n=482)\), intestinal metaplasia \((n=38)\), low-grade intraepithelial neoplasia \((n=31)\), or high-grade intraepithelial neoplasia \((n=66)\). We also studied 20 samples of GC-involved tissue and paired tissue samples with normal margins. These tissue blocks were all obtained from the Department of Pathology, Affiliated Hospital of Nantong University, Jiangsu, People’s Republic of China, between 2003 and 2010. The clinical characteristics of the patients with cancer were extracted from their medical records and included the age and sex of the patient, as well as the histological type, differentiation grade, and stage of the tumor, along with the preoperative serum carcinoembryonic antigen (CEA) and carbohydrate antigen-19-9 (CA19-9) levels. None of the patients with cancer had received any type of treatment before surgery. OS was defined as the interval between the initial biopsy-confirmed diagnosis and death or between the initial biopsy-confirmed diagnosis and the last follow-up for surviving patients. The study protocol was approved by the Human Research Ethics Committee of the Affiliated Hospital of Nantong University.

**Tissue microarray construction and immunohistochemistry analysis**

Tissue microarrays (TMAs) were constructed as previously described.\(^3\) In brief, TMAs were generated using the manual Tissue Microarrayer System Quick Ray (UT06; UNITMA, Seoul, South Korea). Immunohistochemical analysis was carried out using a mouse monoclonal antihuman PHGDH antibody \((5 \mu\text{g/mL})\) (Abcam, Cambridge, MA, USA). Reactions were detected using an EnVision™ peroxidase kit (Dako Denmark A/S, Glostrup, Denmark). Samples were incubated with 3,3′-diaminobenzidine plus (Dako Denmark A/S) then counterstained with hematoxylin, dehydrated with graded alcohol, cleared in xylene, and coverslipped in a permanent mounting media.

Written informed consent was obtained from all study participants. All cases were reviewed and scored without knowledge of the clinical characteristics of the patients. PHGDH expression was scored using the semiquantitative
Phosphoglycerate dehydrogenase in gastric cancer

H-score method, taking into account both the staining intensity and the percentage of cells staining at that intensity.\textsuperscript{26} The staining intensity was scored as 0 (no stain), 1+ (weak stain), 2+ (moderate stain), or 3+ (intense stain). The percentage of cells staining at each intensity was determined and multiplied by the intensity score to produce an intensity percentage score. The final staining scores were calculated by adding the four intensity percentage scores. The staining score had a minimum value of 0 (no stain) and a maximum value of 300 (100% of cells with a 3+ staining intensity).

Quantitative real-time polymerase chain reaction findings

Fresh frozen tumor tissue samples (n=20) and matched adjacent samples with normal margins were collected at the Department of Pathology, Affiliated Hospital of Nantong University, for quantitative real-time polymerase chain reaction analysis. Total tissue RNA was extracted using the RNeasy Mini Kit (Qiagen NV, Venlo, the Netherlands). Real-time polymerase chain reaction analysis was carried out according to the manufacturer’s instructions (Quant SYBR Green PCR Kit; TIANGEN BIOTECH, Beijing, People’s Republic of China). PHGDH (NM_006623) primer sequences were as follows: forward 5′-CACATTCTTGCGCTGAAC-3′ and reverse 5′-TTATTAGACGGTTATTGCTGTA-3′. GAPDH was used as an internal control. For relative quantification, 2\(^{-\Delta\Delta C_{t}}\) was calculated and used as an indicator of the level of enzyme expression.

Statistical analysis

The statistical analysis was carried out using the SPSS 22.0 statistical software package (IBM Corporation, Armonk, NY, USA). Cutoff values for high or low PHGDH expression were measured using the X-Tile software (Rimm Lab, Yale University School of Medicine, New Haven, USA; http://www.tissuearray.org/rimmlab).\textsuperscript{27,28} The relationship between PHGDH expression and clinicopathologic variables was estimated using the \(\chi^2\) test, Fisher’s exact test, or t-test, as appropriate. Survival curves were analyzed using the Kaplan-Meier method and compared by log-rank test. The Cox proportional hazard model was used for univariate and multivariate analyses, in which all of the clinicopathologic features served as covariates. Statistical significance was established at \(P<0.05\) (two-tailed).

Results

PHGDH expression in GC tissues

We explored PHGDH expression by performing IHC analysis on TMA comprising 482 GC and 64 matched tumor adjacent tissues from patients with GC. We also examined PHGDH expression in 20 chronic gastritis, 18 intestinal metaplasia, and 31 low-grade and 66 high-grade intraepithelial neoplasias. IHC analysis of TMA sections showed that PHGDH was expressed mainly in the tumor epithelial cells, and staining showed that it occurred primarily in the cytoplasm (Figure 1). The X-Tile-based TMA data analysis indicated a significant cutoff point for OS in GC. For PHGDH, the cutoff selected was 120, ie, a score of 0–120 represented a low rate of expression (PHGDH-low) and a score of 121–300 represented a high rate of expression (PHGDH-high). Overall, only a small proportion of chronic gastritis (20%, 4/20) and matched tumor adjacent tissues (20.31%, 13/64) displayed high PHGDH expression, whereas high expression of this protein was detected in 50.0% (9/18) of intestinal metaplasia, 45.16% (14/31) of low-grade intraepithelial neoplasia, 56.06% (37/66) of high-grade intraepithelial neoplasia, and 45.64% (220/482) of GCs (\(P<0.001\)) (Table 1).

To investigate the difference in the PHGDH gene expression levels between cancerous and normal tissues, total RNA was extracted from fresh GC cancer tissues and matched tumor adjacent tissue samples (n=20). PHGDH expression was significantly higher in the cancerous tissue samples than in their paired peritumoral counterparts (\(P=0.007\)) (Figure 2A).

Relationship between PHGDH expression and clinicopathologic characteristics in GC

To determine whether PHGDH is important in determining clinical outcomes for patients with GC, we examined the relationship between rates of PHGDH expression and clinical parameters in these patients. PHGDH-high expression correlated significantly with the patient’s age (\(P=0.009\)); tumor histology (\(P=0.011\)), stage (\(P=0.014\)), and classification (\(P=0.043\)); preoperative CEA (\(P=0.016\)) and CA19-9 (\(P=0.014\)) levels; and evidence of lymph node metastasis (\(P=0.024\)) and tumor metastasis (\(P=0.005\)) (Table 2).

Prognostic value of PHGDH expression in GC

On examining the relationship between rates of PHGDH expression and prognostic data, we found that patients with GC with PHGDH-high had a significantly worse prognosis than those with PHGDH-low. The 1-, 3-, and 5-year OS for PHGDH-high patients with GC was worse than that for their PHGDH-low counterparts (\(P<0.001\)) (Figure 2B).
We also evaluated prognostic factors for patients with GC using both univariate and multivariate analyses. The univariate analysis revealed that PHGDH-high correlated significantly with a poor OS (hazard ratio [HR]: 2.833; 95% CI: 2.209–3.633; \( P < 0.001 \)) and with previously reported prognostic markers, including differentiation (HR: 1.537; 95% CI: 1.193–1.979; \( P < 0.001 \)), tumor stage (HR: 1.588; 95% CI: 1.47–1.715; \( P < 0.001 \)), preoperative CEA (HR: 2.227; 95% CI: 1.571–3.159; \( P < 0.001 \)), and preoperative CA19-9 (HR: 2.498; 95% CI: 1.705–3.66; \( P < 0.001 \)) (Table 3). The multivariate analysis also revealed that PHGDH-high correlated significantly with a worse OS (HR: 2.605; 95% CI: 1.802–3.767; \( P < 0.001 \)) as well as with advanced tumor stage (HR: 1.62; 95% CI: 1.433–1.83; \( P < 0.001 \)) and preoperative CEA (HR: 1.787; 95% CI: 1.192–2.68; \( P = 0.005 \)) (Table 3). Preoperative CEA levels

**Table 1**  PHGDH expression in gastric benign and malignant tissues

| Characteristic               | n   | PHGDH− (%) | PHGDH+ (%) | Pearson \( \chi^2 \) | P-value |
|-----------------------------|-----|------------|------------|----------------------|---------|
| Stomach                     | 681 | 25.613     | 25.613     | <0.001*              |         |
| Chronic gastritis           | 20  | 16 (80.00) | 4 (20.00)  |                      |         |
| Intestinal metaplasia       | 18  | 9 (50.00)  | 9 (50.00)  |                      |         |
| Low-grade intraepithelial neoplasia | 31  | 17 (54.84) | 14 (45.16) |                      |         |
| High-grade intraepithelial neoplasia | 66  | 29 (43.94) | 37 (56.06) |                      |         |
| Cancer                      | 482 | 262 (54.36)| 220 (45.64)|                      |         |
| Surgical margin             | 64  | 51 (79.69)| 13 (20.31) |                      |         |

**Notes:** PHGDH− indicates low PHGDH expression, and PHGDH+ indicates high PHGDH expression. *\( P < 0.05 \). The data were analyzed by ANOVA with SPSS 20.0 statistical software.

**Abbreviation:** PHGDH, phosphoglycerate dehydrogenase.
Phosphoglycerate dehydrogenase in gastric cancer

(>5 ng/mL; P<0.001) and tumor node metastasis (TNM) stage (P<0.001) also individually influenced survival, with low preoperative CEA levels and early TNM stage predicting a favorable prognosis (Figure 2C and D).

Discussion

Here, we report the findings of the first large-scale study to use high-throughput TMA analyses to examine the prognostic value of PHGDH expression in tumors in a random population of patients with gastric disease. In this study, we found that PHGDH, the key enzyme involved in de novo serine biosynthesis, is significantly elevated in gastric tumor specimens compared with normal gastric epithelial specimens. An increased rate of expression of PHGDH in GC correlated with a more aggressive tumor behavior, a more cancerous histological type, a more advanced stage of disease, and a greater risk of lymph node metastasis.

We also found a strong correlation between PHGDH-high expression and a reduced OS in patients with GC. A multivariate analysis provided further support for the value of PHGDH as an independent prognostic factor, along with such well-established factors as tumor stage. However, such evidence has not been consistent. For example, patients with a high rate of PHGDH expression are prone to a worse prognosis with an advanced tumor stage alone; this is in concordance with most previous studies of other cancers. Additionally, PHGDH reportedly has no prognostic value in patients with colon cancer, and its prognostic value in breast cancer has been assessed in a smaller study.

Notes: *Papillary adenocarcinoma, three cases; adenosquamous carcinoma, three cases; squamous cell carcinoma, three cases; undifferentiated carcinoma, one case; neuroendocrine carcinoma, one case; small cell osteosarcoma, seven cases; carcinoid, one case; focal cancer, twelve cases. **Tubular and papillary adenocarcinoma. *Abbreviations: CA19-9, carbohydrate antigen-19-9; CEA, carcinoembryonic antigen; PHGDH, phosphoglycerate dehydrogenase; TNM, tumor node metastasis.

PHGDH, phosphoglycerate dehydrogenase; TnM, tumor node metastasis.

The data were analyzed by ANOVA with SPSS 20.0 statistical software. The abbreviations: CA19-9, carbohydrate antigen-19-9; CEA, carcinoembryonic antigen; PHGDH, phosphoglycerate dehydrogenase; TNM, tumor node metastasis.

Contradictory. However, its expression in the epithelium of the small intestine,36 cervical adenocarcinomas,19 and in GC tissue (our data) has been associated with a poor prognosis. Furthermore, a recent study showed PHGDH expression in the stroma with an increased tumor grade and a reduced disease-free survival in phyllodes tumor.30 The contradictory nature of findings regarding the prognostic value of PHGDH is exemplified in the studies of lobular vs invasive ductal carcinoma, with high levels of PHGDH found in invasive lobular carcinoma compared with invasive ductal carcinoma, but higher rates of expression of metabolism-related proteins found in invasive ductal carcinoma tissue compared with invasive stromal lobular carcinoma tissue.31 These observations suggest different expression patterns and roles for PHGDH in different types of cancer.

Before PHGDH can be investigated for its potential as a therapeutic target, a significant difference must be found in the requirement for PHGDH activity in cancerous vs normal proliferating cells.6,32 We found that PHGDH expression is significantly higher in GC tissue compared with benign or normal tissue. This strongly implicates PHGDH as an attractive target for anticancer drug development for patients with the subset of tumors that amplify and overexpress its gene. The broader network of metabolic mechanisms involved in cancer must be studied to determine the potential for PHGDH as a metabolic oncogene.29,30 Serine biosynthesis was found to correlate with p73 expression in human lung adenocarcinomas.9 Regulation of PHGDH by EBV-miR-BART1 in nasopharyngeal carcinomas might involve the concomitant overexpression of p130Cas and ERBB2 activation.33 In mice lacking the repressive effect of PKCζ, the rate of both tumorigenesis and PHGDH expression increases.34 In prostate cancer, PHGDH has been found to regulate c-Myc phosphorylation,35 and in human intestinal tumor, it correlates with caspase-3.36 Tagging PHGDH limits its ability to convert 3-phosphoglycerate (3PG) to phosphohydroxypyruvate (PHP). Tagging may involve the addition of an N-terminal epitope to PHGDH to disrupt its ability to sustain cancer cell proliferation.35 The findings of many recent studies suggest that PHGDH inhibition is a viable mechanism for developing anticancer agents for two reasons.36 First, a PHGDH inhibitor that cannot cross the blood–brain barrier would not interfere with serine homeostasis in the central nervous system; this would prevent the neurological effects that have been reported for known PHGDH mutations in humans. Second, serine deficiency disorders can be treated using exogenous serine supplements, and the need for PHGDH in tumors might not be associated with a serine flux.8 Encouragingly, a nonmetabolic role for PHGDH in glioma...
Table 3 Univariate and multivariate analysis of prognostic factors for overall survival in patients with gastric cancer

| Variable | Univariate analysis | Multivariate analysis |
|----------|---------------------|----------------------|

tumorigenesis has been reported and may provide a novel mechanism for developing antitumor therapies.

There are several limitations in our study. First, it is a retrospective observational study; thus, the findings might not be applicable to the general population. Larger prospective studies are needed to confirm our results. Second, the immunohistochemistry data are semiquantitative; additional methods are needed to evaluate and confirm the rates of PhGDH expression in tumor cells. Third, in vitro studies are needed to investigate the mechanism(s) underlying PhGDH activity in tumorigenesis.

Conclusion

We have shown that a higher rate of PhGDH expression is an independent marker of prognosis in GC. Because of its role in tumor-associated serine biosynthesis, future research is warranted to investigate the potential mechanisms by which PhGDH promotes cancer, with the aim of using it as a target for developing new therapeutic approaches to cancer.
