A review on factors causing Parkinson’s syndrome

Abstract

Parkinson disease (PD) is the most common chronic neurodegenerative disease that affects the brain, resulting in a progressive loss of coordination and movement to death and contributes to about 25–30% cases of dementia. An estimated seven million to 10 million people worldwide have Parkinson’s disease. It is characterized by the classical motor features of parkinsonism related to Lewy bodies and loss of dopaminergic neurons in the substantia nigra, and the major symptoms include problems with resting tremor, rigidity, bradykinesia, postural instability, speech dysfunction, psychiatric symptoms, sleep disorder and fatigue. Presently existing pharmacological and surgical treatments provide relief from a few motor symptoms, but do not halt the ultimate progression of the syndrome. The root cause of Parkinson’s disease remains unknown. Although significant research advances illustrate distinct pathways that closely try to disclose various mitochondrial, genetic, behavioral, environmental, and epigenetic causes that may lead to the development of PD. Most likely all study target the dysfunction of the ubiquitin–proteasome pathway, alpha–synuclein protein, PINK1 protein, PI3K/Akt/mTOR pathway. However, a better understanding of the disease is leading to new diagnostic tools and treatments.

Keywords: Parkinson Disease, Dopamine, Lewy bodies, Shaking Palsy, Substantia nigra.

Introduction

Parkinson’s disease (PD) was medically reported as a neurological syndrome by James Parkinson, who first explained it in “An Essay on the Shaking Palsy” in 1817.1 He illustrated this disease as started with slow, progressive involuntary tremors, followed by a complication in walking, speech, and swallowing.2 Other than motor symptoms, Parkinson’s disease patients gradually experience remarkable nonmotor symptoms as well as cognition decline, sensory abnormalities, behavioral changes, fatigue, sleep disturbances, and other autonomic dysfunctions.3-5 After Alzheimer’s disease (AD), PD is the most common age-related neurodegenerative disease. Although the central pathological feature of Parkinson’s disease (PD) was found to be the degradation of neurons in the substantia nigra pars compacta (SNpc), (Figure 1) the loss of SNpc neurons accelerate striatal dopamine (DA) deficiency.6 Which is accountable for the key motor and nonmotor symptoms of PD.6-7 PD tremor decreases the voluntary movement, so naturally, impair the daily life activities. Rigidity refers to the increased resistance (stiffness) to passive movement of a patient’s limbs. Bradykinesia (very slow body movements) could considerably worsen the standard of life as a result of it takes for much longer to perform daily tasks like consumption of food or dressing, hypokinesia (reduction in movement amplitude), and akinesia (absence of normal obvious movements, like arm swing in walking) evident as a range of symptoms, such as decreased voice volume (hypophonia), paucity of pronormal facial expression (hypomimia), drooling (inability to swallow without pondering it), diminished stride length during walking and slow writing. In addition, PD patients continuously enhance stooped attitude and will lose ordinary postural impulses, resulting in falls and, sometimes, confinement to a wheelchair. Abnormalities and cognition also occur frequently; delayed responses to queries, and slow cognitive process (bradyphrenia).6-7 Many shreds of evidence suggest that phosphatidylinositol-3 kinase (PI3K)/Akt (protein kinase–B) in mammalian target of the rapamycin (mTOR) pathway (PI3K/Akt/mTOR) pathway signaling related to dopaminergic neuron degeneration in PD.6-8 The neuron degeneration concurrently influences the wider region of the brain responsible for dementia.

In PD, dementia is not a presenting feature; it develops at least four years after PD motor symptoms start. Among PD patients, who do not primarily experience dementia the yearly occurrence varies from 2.6% to 9.6%, the additive risk of dementia by the age of 85 years was over 65%.8 Dopamine deficiency in the brain is the known causing factor of PD, yet why this initially occurs is less clear. However, the better understanding of the pathology of Parkinson’s disease is helping to identify potential drug targets for disease management.

Neuropathology of PD

Degenerative parkinsonian disorder currently recognized as heterogeneous, by means of clinically considerable motor and nonmotor features. Similarly, its pathology involves wide regions of the nervous system, different neurotransmitters,9 and the most widely recognized pathologic substrates associated with anomalies within the presynaptic protein and microtubule binding protein. Parkinsonian disorders constitute one among two molecular classes; tauopathies

and α-synucleinopathies supported pathologic aggregation of tau (microtubule binding protein) or the α-synuclein protein (presynaptic protein) within vulnerable neurons and sometimes inside the glial cell. In idiopathic PD, accumulation of α-synuclein in neuronal perikarya (Lewy bodies) and neuronal processes (Lewy neurites). The disease progression is multifocal and involves select peripheral autonomic sensory system neurons and central nervous system neurons. Multiple system atrophy (MSA) is another major α-synucleinopathy. It is also conjointly linked with involuntary dysfunction and in some cases with cerebellar signs. The significant histopathologic feature of MSA is aggregation of α-synuclein inside glial cytoplasmic inclusions (GCI). The loss of pigmentation connects with neuronal loss of dopaminergic neurons in the substantia nigra and noradrenergic neurons in the locus ceruleus. Pigment loss within the locus ceruleus is reliable with PD (Figure 2).10

Figure 2 Shows the Pigment loss in Substantia nigra and locus ceruleus leads Parkinson Disease.

Causes of PD

PD involves the degeneration of dopamine neurons but it is still unknown why this dysfunction happens. However, a certain risk factor which plays a role in increasing the chances of developing PD has been identified.

Age

PD affects the population over the age of 60 (late–onset disease), while in people beyond 85 years old this prevalence reaches 5% more, featuring the effect that propelling age has on the danger of building up this condition. Although, a few numbers of patients (around 5% of all cases) face the symptoms of PD before the age of 60 years (early–onset disease) and the larger part of these cases are caused by mutations in genes.11 Early–onset cases that start before age 20 are sometimes referred to as juvenile–onset Parkinson disease.12 In PD, a neuronal loss is focused on caudal and ventrolateral regions of the SNpc, whereas the dorsomedial aspect of SNpc is affected throughout normal aging.13 Thus, the process that leads age–related dopaminergic neuronal death almost certainly varies from those in PD.1

Gene mutation in familial PD

Etiology of Parkinson’s disease is sporadic (not hereditarily acquired) in nature. Be that as it may, a little level of the PD patients was currently recognized to inherited gene mutations. Genes including DJ–1, ATP13A2, GIGYF2, LRRK2, HTRA2, PARK2 (parkin), SNCA, UCHL1, and PINK1 were related to autosomal dominant and recessive type of familial PD.4 Mutations in α–synuclein gene and a missense mutation in the ubiquitin carboxy–terminal hydrolase L1 (UCHL1) gene have been identified in some familial forms of Parkinson’s disease. This mutation which frequently reduces the catalytic activity of thiol protease, which responsible for the accumulation of proteins and aberrations in the proteolytic pathway. A large amount of UCH–L1 present in Lewy bodies and its contribution in the ubiquitin reliant proteolytic pathway involve it in the disease progression of Parkinson’s disease, decreased enzymatic movement and improved accumulation might be in play at various phases of the sickness. The Ile93Met mutational change in the UCH–L1 gene is predicted to contribute to the genetic aetiology of just a few patients with the familial type of the illness.14

Mitochondrial dysfunction

Mitochondrial dysfunction has been concerned to be essential for the pathologic process of PD since the innovation that N–methyl–4–phenylpyridinium (MPP+) causes swift parkinsonism and SN cell misfortune through restraint of complex I of the electron transport chain.15,16 This identification was trailed by information of diminished complex I action and protein articulation in tissues from patients with PD.17,18 The neurons of the SN are considered to be predominant prone to dysfunction among the mitochondria and help to maintain a function of mitochondria, and particularly their dysfunction in the thrash of SN neurons in PD has been rising over late years.19 Mutational transformations in alpha–synuclein have been appeared to cause fracture of the mitochondrial system and variations in the ultra structure and allocation of the mitochondria suggesting increased and dissemination of the mitochondria proposing expanded mitochondrial fission.20 Transformations in Pink1 and Parkin have been appeared to cause a loss of mitochondrial ultra structure as observed as variation in the electron density of the mitochondria and disintegration of the mitochondrial network.21–23 A loss of DJ–1 causes a potential degradation of mitochondrial membrane and enlarged fragmentation of mitochondria,23,24 and mitochondrial changes have additionally identified when Leucine rich repeat kinase 2 (LRRK2) is transformed.25,26 Parkin over expression has been revealed to develop the mitochondrial calcium handling capability by increasing the interaction of the mitochondria with the ER without an ensuing outcome on the mitochondrial calcium uptake machinery.27 The neurons of the SN, utilize calcium to continue their pace making and movement in this way improvements in how the neurons handle and keep up calcium levels will be enormously powerful on both the movement and survival of these neurons.19 Familial PD gene products (LRRK2, PINK1, and DJ–1) are either localized to mitochondria or direct to a functional insufficiency in mitochondria (Parkin and DJ–1), sustaining an essential part of mitochondria in PD pathology (Figure 3).28
shown the significant role in AD neuropathogenesis being bounteously communicated in Alzheimer hippocampus. This may be considered as one more sign for the possible existence of common regulatory mechanisms in neurodegenerative diseases.

**Oxidative stress**

An oxidative stress plays a significant role in the history of PD. Expanded turnover of dopamine ought to be connected with an oxidative stress resulting from a formation of a high amount of hydrogen peroxide. While the oxidative deamination of dopamine the peroxide is formed by a mitochondrial enzyme catalyst monoamine oxidase (MAO).

\[
\text{Dopamine} + O_2 + H_2O \rightarrow \text{H}_2O + \text{NH}_3 + 3,4-\text{dihydroxyphenylacetaldehyde} \]

Dopamine depletion and production of deaminated metabolites were correlated by a gradual rise (87.8%) in the ratio of oxidized glutathione in brain. This modification was seen in the striatum, which is abundantly innervated by dopamine terminals, except in the frontal cortex, which obtains considerably sparser innervation by catecholamine nerve terminals. The ascent in oxidized glutathione was observed despite the fact that dopamine terminals comprise only 1% or less of the size of the striatum. Clorgyline, an inhibitor of monoamine oxidase type A, prevented the production of oxidized glutathione. These affirm that a particular elevation in neurotransmitter turnover inside nigrostriatal nerve terminals can initiate a change in cellular redox status.

**Braak’s hypothesis**

Braak postulates the speculation that an obscure pathogen either bacteria or virus in the gut could be a reason behind the start of sporadic PD, and they displayed a linked organizing framework for PD in view of a particular model of α-Synuclein spreading. After this numerous including double hit speculation, expressing that sporadic PD initiates in two different places: the neurons in the gut and the neurons of the nasal cavity. This is currently known as Braak’s theory. Which states that microbial items come into contact with olfactory and additionally enteric neurons, which stimulate the collection of α-Synuclein? The accumulated α-Synuclein spreads toward the focal sensory system by means of the vagus nerve and the olfactory globule. In the long run, the amass α-Synuclein touches base at the substantia nigra. These Genetic elements are probably going to contribute to PD, however the correct system stays to be illustrated. Strikingly, the theorized spread of ailment to the spinal cord just happens after the CNS has turned out to be included, thus the spinal cord isn’t thought to be a potential track for the spread of PD from the periphery to the brain.

**Conclusion**

Parkinson’s disease is complex in its clinical expression and treatment. Dopaminergic degeneration is still a mystery for scientists. Many researchers directed the investigations towards pathogenesis, epidemiology, pathology, and genetics. While major research signs of progress have been made, as well as the current recognizable proof of conceivable environmental and genetic risk factors for PD, further molecular docking studies are performed to detect the molecular interactions, active site prediction, and drug interaction based studies and cellular pathway research is necessary to explicate the root causes of PD and to discover enhanced treatments.
