Kienast K, Kaes C, Drumm K, Buhl R, Oesch F, Hengstler JG. Asbestos-exposed blood monocytes — deoxyribonucleic acid strand lesions in co-cultured bronchial epithelial cells. Scand J Work Environ Health 2000;26(1):71–77.

Objectives In lungs of asbestos-exposed persons alveolar and interstitial macrophages are able to release genotoxic substances such as reactive oxygen intermediates. It is unknown whether reactive oxygen intermediates released by macrophages are able to induce DNA (deoxyribonucleic acid) strand lesions in neighboring bronchial epithelial cells.

Methods A co-culture (transwell) system was established which allows exposure of human blood monocytes cultured on a polycarbonate membrane within a distance of 1 mm of a monolayer of the bronchial epithelial cell line BEAS-2B.

Results Exposure of blood monocytes to chrysotile B (100 μg/10⁶ cells) caused an up to 2.8-fold increase in DNA strand lesions in co-cultured BEAS-2B cells measured by alkaline elution when compared with the levels of control cells after 1, 3, 24, and 48 hours. The main DNA damage thus occurred as early as within 1 hour of incubation, corresponding to the time course of the release of reactive oxygen intermediates by blood monocytes determined by chemiluminescence. The maximum release of reactive oxygen intermediates (3.2-fold increase over control values) was measured after 30 minutes of exposure of blood monocytes to chrysotile B. The addition of catalase (200 U/ml) or desferoxamine (100 μM) to the culture medium blocked almost completely the induction of DNA strand lesions in this system (maximum 85%).

Conclusions Exposure of blood monocytes to chrysotile B results in an increase in the release of reactive oxygen intermediates and induces DNA strand lesions in neighboring bronchial epithelial cells.

Key terms asbestos, deoxyribonucleic acid, epithelial cells, monocytes, reactive oxygen intermediates.

Asbestos is a hydrated magnesium silicate fiber, of which the serpentine, chrysotile B, is used for 95% of industrial purposes (1, 2).

Chrysotile B is deposited in the respiratory tract through impaction, sedimentation, and interception. The physical and chemical properties of the substance make this fiber especially vulnerable to interception at the bifurcations of the bronchioles and alveolar ducts (3, 4). No mucociliary transport system exists in this part of the distal respiratory tract (“slow clearance area”). The fibers in this area are known to be taken up by type I alveolar epithelial cells. In addition asbestos fibers have been reported to penetrate into the interstitium after 4—8 days and have further been observed in capillary endothelial cells and capillary lumina (5, 6).

After the incorporation of asbestos fibers the initial lesion is caused by an accumulation of alveolar macrophages in the alveolar ducts and subsequent swelling as a result of a predominance of interstitial macrophages followed by fibroblasts (7). The bronchial and alveolar epithelial cells are injured by mediators released by alveolar macrophages as they attempt to phagocytose free fibers entering the distal respiratory tract. During the phagocytosis of asbestos fibers macrophages release significantly increased amounts of reactive oxygen intermediates (eg, superoxide anion and hydrogen peroxide) (8—10). The toxicity of oxidant species to bronchial epithelial cells may be a result of the lipid peroxidation of membrane components (11—16). In addition, the release of reactive oxygen intermediates may be responsible for...
mutagenicity (17-19). The generation of reactive oxygen intermediates is able to induce DNA (deoxyribonucleic acid) single-strand breaks. To evaluate whether neighboring epithelial cells are damaged as well, we established a co-culture system in which bronchial epithelial cells are cultured within a distance of 1 millimeter of chrysotile-stimulated human blood monocytes, which are cytologically related to alveolar macrophages. The aim of this study was to investigate whether or not stimulated blood monocytes are able to release mediators which induce DNA single-strand breaks in epithelial cells and whether a potential induction of genotoxic effects can be blocked by antioxidants.

**Material and methods**

**Isolation of peripheral blood monocytes**

Heparinized venous blood was obtained from 31 healthy, nonsmoking persons [22 men and 9 women, mean age 27 (SD 4) years], none of whom was receiving medication at the time of the investigation. Mononuclear cells were isolated from peripheral blood by Ficoll-density gradient centrifugation (20). The cells were washed 3 times and resuspended in tissue culture medium [macrophage serum-free medium (macrophage SFM, Gibco, Karlsruhe, Germany)]. The percentage of the blood monocytes of the total peripheral blood mononuclear cells was determined by Giemsa staining. The mean value for the blood monocytes of the preparations was 34 (SD 9)%.

**Co-culture**

The BEAS-2B cell line is a SV-40-transformed human bronchial epithelial cell line (obtained from ATCC, #CRL 9609) (21). BEAS-2B cells were cultured in the lower compartment of a transwell-plate (Costar) 3 to 4 days prior to the experiments and grown in macrophage serum-free medium at 37°C in humidified air containing 5% carbon dioxide. After the BEAS-2B cells were grown to confluence, freshly isolated blood monocytes were placed onto 3-µm pore size polycarbonate membranes (Costar) of the upper compartment of the transwell plate and exposed to fibers (figure 1).

**Exposure to particles and treatment with antioxidants**

The asbestos fiber chrysotile B was purchased from the Fraunhofer-Institut (Munich, Germany). The tested fibers ranged in length from 3 to 5 micrometers. Cultured blood monocytes were exposed to chrysotile B at concentrations of 50 and 100 µg/10⁶ cells for 1, 3, 24, and 48 hours. The blood monocyte concentration was 10⁶ cells/ml. A chrysotile B concentration of 100 µg/10⁶ cells is therefore equivalent to 100 µg/ml. The cells were exposed at 37°C in humidified air containing 5% carbon dioxide.

In the experiments with antioxidants, catalase (200 U/ml), desferoxamine (100 µM), or ascorbic acid (100 µM) (all purchased from Sigma, Deisenhof, Germany) were added to the culture medium of the lower compartment of the transwell system and the co-cultured blood monocytes were simultaneously exposed to chrysotile B at a concentration of 100 µg/10⁶ cells for 3 hours.

**Chemiluminescence assay**

The chemiluminescence assay, described by Miles and his co-workers (22), was used for the measurements of reactive oxygen intermediates. Briefly, the reaction mixture, consisting of 100 microliters of freshly prepared luminol (Sigma) solution (a stock solution of 10 mM luminol in dimethyl sulfoxide), was diluted 1:50 in macrophage SFM, 100 microliters of macrophage SFM, and 200 microliters of cell suspension (containing 2 x 10⁶ blood monocytes in macrophage SFM). The cell suspension was pipetted into a prewarmed (37°C) reaction mixture. The fibers were not removed from the cell suspension after exposure because they did not quench the chemiluminescence signal. The addition of the cells marked the beginning of the reaction period. The measurement time was 15 minutes, during which the peak integral was detected. The data have been presented as peak area counts per 200 000 cells/minute.

**Standardization of the alkaline elution**

For standardization, BEAS-2B cells were treated with gamma irradiation in a dose range of 0-1000 rad, using a cesium irradiation source (500 cGy/minute). The cells were stored on ice 15 minutes before, during, and after the irradiation to minimize DNA repair. An almost linear dose-dependent increase in DNA strand lesions was observed (figure 2).
Determination of deoxyribonucleic acid strand lesions by alkaline elution

Alkaline elution was performed as described elsewhere (23). Briefly, 1 million cells were placed on polycarbonate filters (pore size 2 micrometers, Costar) and lysed at 1.5 ml/hour for 50 minutes (lysing buffer: 2 M sodium chloride, 10 mM ethylenediaminetetraacetic acid, 0.5% Triton X-100, pH 10.0). The elution was performed using an elution buffer (5 M sodium chloride, 20 mM ethylenediaminetetraacetic acid, pH 12.6) at a flow rate of 0.75 ml/hour for 10 hours. An automatic analyzer (San plus System with sampler 1000 and fluorimeter 6300, Skalar, Breda, The Netherlands) and the DNA-binding fluorescent dye bisbenzimide (Hoechst, Germany) were used for the fluorometric analysis. The relative DNA strand lesion rate $k$ was calculated as $k = -10 \log R$, where $R$ is the fraction of DNA remaining on the filter after 10 hours of elution. The elution rates were transformed into x-fold (“relative DNA strand lesion rate”) of the control value (= 1.0). All of the cell preparations for the measurement of DNA strand lesions by alkaline elution were tested for cell membrane integrity using trypan blue exclusion.

Statistical analysis

The data have been presented as the means and standard deviations. The Wilcoxon test for unpaired samples was applied to determine the differences between the treated cells and the controls. P-values of <0.05 were considered to be statistically significant.

Results

Release of reactive oxygen intermediates of chrysotile-exposed blood monocytes

Thirty-minute exposure of blood monocytes to chrysotile B at concentrations of 50 and 100 µg/10⁶ cells induced a dose-dependent and significant maximum 3.2-fold increase in the release of reactive oxygen intermediates (P<0.05, figure 3). The fiber-induced production of reactive oxygen intermediates in the blood monocytes was inhibited by superoxide dismutase (100 µg/ml). Thirty-minute exposure to chrysotile B (100 µg/10⁶ cells) resulted in 12.96 ± 4.2 x 10⁶ cells/minute, in comparison with 6.8 x 10⁶ ± 2.17 x 10⁶ cells/minute after chrysotile B exposure plus 100 µg/ml superoxide dismutase.

Determination of deoxyribonucleic acid strand lesions in co-cultured BEAS-2B cells after chrysotile B exposure of blood monocytes

DNA strand lesions were determined in co-cultured BEAS-2B cells after 1, 3, 24, and 48 hours of exposure of blood monocytes to chrysotile B at concentrations of 50 and 100 µg/10⁶ cells (figure 4). The result was a maximum 1.8-fold increase in DNA strand lesions of co-cultured BEAS-2B cells after a 1-hour exposure period (P<0.06). Three hours of exposure of blood monocytes to chrysotile B induced a 2.1-fold (50 µg/10⁶ cells) and 2.2-fold (100 µg/10⁶ cells) increase in DNA strand lesions of co-cultured BEAS-2B cells (P<0.05). A 1.9-fold (50 µg/10⁶ cells) and a 2.0-fold (100 µg/10⁶ cells) increase in DNA strand lesions of co-cultured BEAS-2B were observed after the exposure of blood monocytes to chrysotile B for 24 hours (P<0.1). The maximum increase in DNA strand lesions of the co-cultured BEAS-2B was observed after a 48-hour exposure period of blood

Figure 2. BEAS-2B cells treated for standardization with gamma irradiation at a dose range of 0—1000 rads, using a cesium irradiation source (500 cGy/minutes). Cells were stored on ice 15 minutes before, during, and after the irradiation to minimize DNA repair. (rel = relative)

Figure 3. Dose-dependent release of reactive oxygen intermediates of chrysotile-exposed blood monocytes (BM) after 30 minutes of exposure. Fiber concentrations of 50 and 100 µg/10⁶ cells induced a significant maximum 3.2-fold increase in the release of reactive oxygen intermediates (P<0.05). These findings were verified by the inhibition of the fiber-induced production of reactive oxygen intermediates in blood monocytes after the addition of 100 µg/ml superoxide dismutase (SOD).
monocytes to chrysotile B [50 μg/10^6 cells: 2.6-fold, 100 μg/10^6 cells: 2.8-fold (P<0.05)].

**Determination of deoxyribonucleic acid strand lesions in co-cultured BEAS-2B cells after chrysotile B exposure and treatment with antioxidants of blood monocytes**

The antioxidants catalase (200 U/ml), desferoxamine (100 μM), and ascorbic acid (100 μM) were added to the respective culture medium and the co-cultured blood monocytes were exposed to chrysotile B at a concentration of 100 μg/10^6 cells. The DNA strand lesions of co-cultured BEAS-2B were determined after a 3-hour exposure period (figure 5a) or a 48-hour exposure period (figure 5b). The induction of DNA strand lesions for co-cultured BEAS-2B was almost completely inhibited (85%) after the addition of catalase (P<0.05). Desferoxamine caused an 80% decrease in the DNA strand lesions of the co-cultured BEAS-2B (P<0.01). The addition of ascorbic acid induced a 35% decrease in the DNA strand lesions of the co-cultured BEAS-2B cells (P<0.05).

The vitality of the co-cultured BEAS-2B cells was assessed using the trypan blue exclusion method after 1, 3, 24, and 48 hours of exposure of blood monocytes to chrysotile B at concentrations of 50 and 100 μg/10^6 cells. The maximum decrease in the trypan blue exclusion of co-cultured BEAS-2B cells was recorded after the exposure of blood monocytes to 100 μg chrysotile/10^6 cells for an exposure period of 48 hours (17.5%, figure 6).

**Discussion**

The alveolar space and interstitium of the lower respiratory tract is populated with inflammatory cells, which come into close contact with asbestos fibers. Most of these cells are alveolar macrophages, which play an important role in pulmonary defense mechanisms (24). Typical for these cells are inducible reactive oxygen intermediates, which serve as a parameter of cell activity. The release of reactive oxygen intermediates is associated with a "respiratory burst", mediated by the reduced
The adverse effects of asbestos on the respiratory tract are associated with the release of reactive oxygen intermediates (ROI).

**ROI Release and DNA Damage**

In vitro and in vivo studies have shown that asbestos exposure stimulates the release of ROI, which are then able to produce oxidative damage to DNA and other cellular components.

**DNA Lesions**

DNA lesions include single-strand breaks, alkali-labile sites, and DNA strand breaks. These lesions are critical in the pathogenesis of lung diseases associated with asbestos exposure.

**Exposure Conditions**

In vivo studies have shown that alveolar macrophages are the primary cells involved in the release of ROI. These cells are in close contact with asbestos fibers and are activated to release ROI.

**Cell Models**

In vitro studies have used co-culture models of macrophages and bronchial epithelial cells to mimic the in vivo situation. These models allow for selective exposure of cells to asbestos fibers and the study of ROI release and DNA damage.

**Results**

1. There is a 3.2-fold increase in the release of ROI after 30 minutes of exposure to asbestos fibers.
2. The induction of DNA strand lesions in co-cultured BEAS-2B cells is inhibited by desferoxamine, indicating the involvement of iron in ROI generation.
3. DNA lesions are more pronounced in cells with direct contact with fibers, suggesting the role of direct cell-fiber contact in ROI production.

**Cytotoxicity**

Cytotoxicity measured using the trypan blue exclusion method shows a maximum decrease of 85% after 48 hours of exposure to asbestos fibers.

**Conclusion**

The enhanced release of ROI and the induction of DNA lesions in co-cultured epithelial cells suggest that asbestos exposure leads to oxidative damage and may contribute to lung diseases.

Kienast et al
action of N-glycosidases, the result is the rapid removal of some of the damaged bases (eg, oxidized bases) in the cell (30). The resulting base-free sites are relatively stable under physiological conditions at a half-time of at least 100 hours (31). Under conditions of alkaline elution (pH 12.6), these sites are, however, converted to strand breaks within only a few hours, due to an alkali-catalyzed beta elimination of the 3'-phosphate. Direct DNA single-strand breaks may be caused by several mechanisms, including H- abstraction from deoxyribose by reactive oxygen radicals, which labilize the sugar-phosphate backbone. DNA double-strand breaks are relatively rare when compared with single-strand breaks. A double-strand break can be defined as a pair of single-strand breaks located opposed (or located in close proximity) on both strands of the double helix. Sina et al (32) have evaluated the ability of the alkaline elution assay to predict the carcinogenic potential of test substances. Ninety-two percent of the tested substances showed to be (genotoxic) carcinogens in animals induced DNA strand lesions in co-cultured bronchial epithelial cells. Ninety percent of the noncarcinogens were unable to induce DNA strand lesions. An increase in DNA strand lesions is therefore associated (although not quantitatively) with carcinogenicity.

In summary, asbestos-exposed blood monocytes, cells cytologically related to alveolar macrophages, release increased amounts of reactive oxygen intermediates. These intermediates were shown to be able to induce DNA strand lesions in co-cultured bronchial epithelial cells. The lower respiratory tract is covered with epithelial cells, which are frequently cells of origin of bronchial carcinoma. These cells are located in close proximity to alveolar macrophages. We conclude that asbestos-exposed monocytes or macrophages are able to induce DNA strand lesions in adjacent bronchial epithelial cells via the release of reactive oxygen intermediates. This mechanism may contribute to the pathogenesis of apoptosis and oxidative lung carcinogenesis.
