ABSTRACT

Context. The VVDS-Wide survey has been designed to trace the large-scale distribution of galaxies at $z \sim 1$ on comoving scales reaching $\sim 100 \, h^{-1}$ Mpc, while providing a good control of cosmic variance over areas as large as a few square degrees. This is achieved by measuring redshifts with VIMOS at the ESO VLT to a limiting magnitude $I_{AB} = 22.5$, targeting four independent fields with sizes of up to 4 $^\circ$ deg$^2$ each.

Aims. We discuss the survey strategy which covers 8.6 $^\circ$ deg$^2$ and present the general properties of the current redshift sample. This includes 32 734 spectra in the four regions, covering a total area of 6.1 $^\circ$ deg$^2$ with a sampling rate of 22 to 24%. This paper accompanies the public release of the first 18 143 redshifts of the VVDS-Wide survey from the 4 $^\circ$ deg$^2$ contiguous area of the F22 field at RA $= 22^h$.

Methods. We have devised and tested an objective method to assess the quality of each spectrum, providing a compact figure-of-merit. This is effective in the case of long-lasting spectroscopic surveys with varying observing conditions. Our figure of merit is a measure of the robustness of the redshift measurement and, most importantly, can be used to select galaxies with uniform high-quality spectra to carry out reliable measurements of spectral features. We also use the data available over the four independent regions to directly measure the variance in galaxy counts. We compare it with general predictions from the observed galaxy two-point correlation function at different redshifts and with that measured in mock galaxy surveys built from the Millennium simulation.

Results. The purely magnitude-limited VVDS Wide sample includes 19 977 galaxies, 304 type I AGNs, and 9913 stars. The redshift success rate is above 90% independent of magnitude. A cone diagram of the galaxy spatial distribution provides us with the current largest overview of large-scale clustering and its dependence on galaxy properties like luminosity, colour and morphology (e.g. Madgwick et al. 2003; Norberg et al. 2001, 2002; Zehavi et al. 2005; Li et al. 2006). All these features and properties are expected to depend on redshift, and different evolutionary paths can lead to similar observational properties in the local universe. Ideally, one would like to be able to gather similarly large samples over comparably large volumes, at cosmologically relevant distances ($z \gg 0.3$). The first pioneering deep redshift surveys capable of measuring the evolution of clustering date from the 1990s and were limited to a few hundred square arcminutes (e.g. Le Fèvre et al. 1996; Shepherd et al. 2001). Even deeper measurements of clustering evolution were provided by specific color-selected surveys, using the Lyman-break technique, although these give a very biased view of large-scale structure limited to a specific class of objects (e.g. Steidel et al. 1998). More recent surveys like GOODS (e.g. Giavalisco et al. 2004) and DEEP (e.g. Koo 1995) provide

1. Introduction

The large-scale distribution of galaxies contains unique information on the structure of our Universe and the fundamental parameters of the cosmological model. The relation of galaxy properties to large-scale structure in turn provides important clues on the physics of galaxy formation within the standard paradigm in which baryons are assembled inside dark-matter halos (e.g. White & Rees 1978). Redshift surveys of the “local” ($z < 0.2$) Universe such as the 2dFGRS (Colless et al. 2001) and SDSS (Abazajian et al. 2003) contain several hundred thousand galaxies spanning a few thousand square degrees. These large samples and explored volumes have allowed large-scale structure studies to be pushed well into the linear regime at large $h^{-1}$ Mpc while at the same time having a detailed characterization of small-scale clustering and its dependence on galaxy properties like luminosity, colour and morphology (e.g. Madgwick et al. 2003; Norberg et al. 2001, 2002; Zehavi et al. 2005; Li et al. 2006). All these features and properties are expected to depend on redshift, and different evolutionary paths can lead to similar observational properties in the local universe. Ideally, one would like to be able to gather similarly large samples over comparably large volumes, at cosmologically relevant distances ($z \gg 0.3$). The first pioneering deep redshift surveys capable of measuring the evolution of clustering date from the 1990s and were limited to a few hundred square arcminutes (e.g. Le Fèvre et al. 1996; Shepherd et al. 2001). Even deeper measurements of clustering evolution were provided by specific color-selected surveys, using the Lyman-break technique, although these give a very biased view of large-scale structure limited to a specific class of objects (e.g. Steidel et al. 1998). More recent surveys like GOODS (e.g. Giavalisco et al. 2004) and DEEP (e.g. Koo 1995) provide
extended multi-wavelength coverage, but are still limited to small fields. Only recently, thanks to the increased multiplexing ability of spectrographs mounted on 10-m class telescopes, robust clustering studies of the general galaxy population at $z \sim 1$ have become feasible. This opportunity has been exploited by the VVDS (Le Fèvre et al. 2005c) and the DEEP2 (Davis et al. 2003) surveys. The VVDS Deep sample (Le Fèvre et al. 2005c), in particular, covered a reasonably large area ($\sim0.5$ deg$^2$) up to redshift 4 and to a very deep magnitude limit ($I_{AB} = 24$). Major clustering results using these data have included studies of the evolution of galaxy clustering since $z \sim 2$ (Le Fèvre et al. 2005a), its dependence on luminosity, spectral type and stellar mass (Pollo et al. 2006; Meneux et al. 2006, 2008) and the evolution and non-linearity of galaxy bias (Marinoni et al. 2005), together with a direct assessment of the evolution of environmental effects, such as the dependence of colour (Cucciati et al. 2006) or luminosity function (Ilbert et al. 2005; Zucca et al. 2006; Ilbert et al. 2006) on local density. Still, the area surveyed by the VVDS Deep is not yet large enough to fully characterize large-scale structure at high redshift: results from 2dF show that structures of size $\sim50$ h$^{-1}$ Mpc do exist in the local Universe, while in the VVDS-Deep itself a structure at $z \sim 0.9$ is found to fill the full survey field ($\sim14$ h$^{-1}$ Mpc) (Le Fèvre et al. 2005b). The Wide part of the VVDS survey has been conceived specifically to improve upon this, covering structures with size $\sim50$ h$^{-1}$ Mpc at $z \sim 1$, while having the ability to measure the variance in galaxy density on scales of a few square degrees. This will be achieved by measuring redshifts to $I_{AB} = 22.5$ over four separated fields on the sky, with a size of up to $4^\circ$ each.

In this paper we present a first analysis of the currently available redshifts from the VVDS-Wide spectroscopic survey, including in particular the data collected over the full $\sim4$ deg$^2$ area of the F22 field, which are publicly released to the scientific community. The paper is organized as follows. In Sect. 2 we describe the VVDS Wide survey strategy and report on the status of the observations conducted so far; in Sect. 3 we assess redshift reliability depending on data quality, in Sect. 4 we present the main characteristics of the resulting redshift catalog, while in Sect. 5 we present the widest cone diagram currently available up to $z \sim 1.0$, quantify the field to field variance of the redshift distribution and how it can affect smaller size surveys and compare the observed cosmic variance with model predictions.

Throughout this paper, we have used a Concordance Cosmology with $\Omega_m = 0.3$, and $\Omega_{\Lambda} = 0.7$. The Hubble constant is normally parameterized via $h = H_0/100$, while a value $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$ has been used when computing absolute magnitudes.

2. The VVDS wide survey

The VVDS Wide survey uses VIMOS at the ESO VLT to target 4 separate fields, one of which includes the VVDS Deep survey area, evenly distributed on the sky and covering a total of 16 deg$^2$. With a $2 \times 2$ deg$^2$ size, each field can span along the diagonal a transverse comoving size of 116 h$^{-1}$ Mpc at $z \sim 1$. The names and coordinates of each field are given in Table 1.

In each of the areas we have excellent photometric coverage, extending from $U$ to $K$. In addition to the $U$, BVRI, JK surveys conducted by the VVDS team (Radovich et al. 2004; McCracken et al. 2003; Iovino et al. 2005), the sky regions at 02 and 22 h are also covered by the CFHTLS survey\footnote{Based on observations obtained with MegaPrime/MegaCam, a joint project of CFHT and CEA/DAPNIA, at the Canada-France-Hawaii Telescope (CFHT) which is operated by the National Research Council (NRC) of Canada, the Institut National des Science de l’Univers of the Centre National de la Recherche Scientifique (CNRS) of France, and the University of Hawaii. This work is based in part on data products produced at TERAPIX and the Canadian Astronomy Data Centre as part of the Canada-France-Hawaii Telescope Legacy Survey, a collaborative project of NRC and CNRS.} and the UKIDSS survey (Warren et al. 2007). The VVDS Deep field has also been observed at 1.4 GHz at the VLA (Bondi et al. 2003; Ciliegi et al. 2005), by XMM (Pierre et al. 2004; Chiappetti et al. 2005), by Galex (Arnouts et al. 2005; Schiminovich et al. 2005) and by Spitzer (Lonsdale et al. 2003). The spectroscopic sample has been derived from an I selected photometric catalog applying a pure flux limit at $I_{AB} = 22.5$, which provides the best compromise between efficiency in covering a large area and depth of the final spectroscopic sample. A specific choice of the survey was that of not removing stars a priori using colour or compactness criteria, to avoid biases against compact galaxies and AGN.

The original plan of the VVDS Wide survey involved a “two-pass” observing strategy: each of the four areas is covered by two slightly displaced (2 arcmin) grids of adjacent VIMOS pointings (see below for a description of the current implementation of this plan). This strategy allows one to reach a spectroscopic sampling rate of $\sim35\%$ of all galaxies with $I_{AB} < 22.5$, which is important for density reconstruction studies (Marinoni et al. 2005), while keeping the required observing time within reasonable limits. At the same time, the 2-arcmin shifts is chosen so to fill (at least partially) the gaps left by the VIMOS footprint.

For the VVDS Wide survey, the exposure time of each pointing was 45 min in MOS mode, using the Low Resolution Red grism. As in the case of the VVDS Deep survey (see Le Fèvre et al. 2005c), we have used a jitter observing sequence, with 5 steps along the slit, each separated by 0.7 arcsec. This strategy allows us to considerably reduce the fringing produced by the CCDs above $\sim8000 \text{ Å}$ (Le Fèvre et al. 2003), although fringing residuals still appear for the brighter and more extended sources, as well as in those observations where seeing was higher than 1.0 arcsec. The observation preparation, mask layout, and observing strategy is the same as for the VVDS Deep sample: using the VMMPs software (Bottini et al. 2005), we have been able to place $\sim400$ slits on average per VIMOS mask-set down to the limiting magnitude of the VVDS Wide survey. Data have been reduced using the VIMOS Interactive Pipeline and Graphical Interface package (VIPGI, Scodeggio et al. 2005).

The observations presented here were mostly collected during Guaranteed Time observations (5 extended visitor observing runs from Oct. 2002 to Sep. 2004), with a small fraction acquired during two further runs in Guest Observer standard time (service runs in February 2006 and 2007). As summarized visually in Fig. 1, we completed the first pass on the 4.0 deg$^2$ F22 area, plus a second pass on the central $\sim0.5 \times 0.5$ deg$^2$ of the same field. We include here the redshift measurements from the first pass over 0.8 and 1.2 deg$^2$ in F10 and F14 respectively, while a further 2.1 deg$^2$ in these area are under analysis and are not included in this paper (grey dots in Fig. 1). We also include redshifts for all galaxies with $I_{AB} < 22.5$ in the 0.5 deg$^2$ of the F02 field covered by the VVDS-Deep survey to $I_{AB} = 24$. Overall, this data set corresponds to $\sim36\%$ of the original VVDS Wide survey goal.

Given the instrument geometry, with one pass only there are empty crosses not covered by the instrument (see Fig. 1, F10, F14 and outer part of F22 areas). In Table 1 we give both the total area covered so far by the VVDS Wide survey, (i.e. the global area covered by either grey or black points in Fig. 1),
and the effective area, i.e. the area including only fully reduced pointings (black points only) and net of the empty crosses. In Table 1 we also give the total number of pointings reduced so far for each field, and the average sampling rate of measured redshifts at the given magnitude limit.

3. Redshift measurement, data quality, and reliability

Redshifts have been measured using the same “double-check” procedure described in Le Fèvre et al. (2005c), adopting the same grading scheme to characterize the reliability of the measured redshift:

- flag 4: a 100% secure redshift, with high SNR spectrum and obvious spectral features supporting the redshift measurement;
- flag 3: a very secure redshift, strong spectral features;
- flag 2: a secure redshift measurement, several features in support of the measurement;
- flag 1: a tentative redshift measurement, based on weak spectral features and continuum shape;

- flag 0: no redshift measurement possible, no apparent features;
- flag 9: only one secure single spectral feature in emission, typically interpreted as [OII]3727 Å, or Hα.

A similar classification is used for broad line AGN, which we identify as spectra showing at least one “broad line” (i.e. resolved at the spectral resolution of the VVDS). Flags for broad line AGN have the following meaning

- flag 14: secure AGN with 100% secure redshift, at least 2 broad lines;
- flag 13: secure AGN with good confidence redshift, based on one broad line and some faint additional feature;
- flag 19: secure AGN with one single secure emission line feature, redshift based on one line only;
- flag 12: a 100% secure redshift measurement, but lines are not significantly broad, might not be an AGN;
- flag 11: a tentative redshift measurement, spectral features not significantly broad.

Objects appearing by chance within the slit of the main target are identified by adding a “2” in front of the flag. We have classified with flag = –10 objects in slits with a clear observational problem, e.g. objects for which the automated spectra extraction algorithm in VIPGI (Scodeggio et al. 2005) failed, or objects too close to the edge of a slit to allow for a proper sky subtraction. In the following, redshifts with a flag between 2 and 9 (or 12 and 19 in the case of AGN) are referred to as secure redshifts.

3.1. Data quality

When conducting a large spectroscopic survey, carried out over years, under different weather conditions, and with different people involved at different times in the data reduction and redshift measurement process, it is important to identify an objective way to assess the quality of the data and of the reduction process, independent of the redshift measurement success or failure. For the VVDS Deep and Wide surveys, we have devised a method that takes into account the most important observational/reduction factors.

Slit obscuration due to field vignetting, effective exposure time, seeing and sky transparency directly impact on the number of photons collected for each spectrum; the sky brightness at constant exposure time determines the S/N ratio, and the quality of the wavelength calibration has an impact on the accuracy of the redshift measurement. The goal we set was to devise an objective quality parameter that could be used to make an a priori selection of the best data at hand. The final figure of merit we assigned to each spectrum is the combination of all these factors, and it takes into account the most important observational/reduction factors.

Table 1. VVDS Wide survey field position and observing information.

| Field    | RA     | Dec        | Surveyed area | Effective area | N. of pointings | sampling rate |
|----------|--------|------------|---------------|---------------|----------------|--------------|
| 0226-04  | 02h26m00.0s | -04deg30’00” | 0.5           | 0.5           | 20             | 24%          |
| 1003+01  | 10h03m00.0s | +01deg30’00” | 1.9           | 0.6           | 111           | 24%          |
| 1400+05  | 14h00m00.0s | +05deg00’00” | 2.2           | 0.9           | 17            | 22%          |
| 2217+00  | 22h17m50.4s | +00deg24’00” | 4.0           | 3.0           | 51            | 22%          |

1 For 1 pointing, only 1 quadrant has been reduced so far. 2 Reduction of 4 pointings is still partial.

Fig. 1. Layout of observed fields for the VVDS Wide survey: the square represents the planned area to be covered. Black dots correspond to measured redshifts that are used in this paper, while grey dots are from objects that have been observed, but whose redshift is still being finalised. The empty grid corresponds to the VIMOS footprint, which leaves a 2-arcmin-thick empty cross between the four quadrants. All data for the F02 and F22 fields are publicly available at http://cencosw.oamp.fr/.
3.1.1. Slit obscuration

VIMOS takes advantage of the full Nasmyth field of view, but, due to the design of the guiding probe, a fraction of the field of view can be partially vignetted for some positions of the guiding star. This has happened especially during the first observations, before enough experience had been gained on the choice of the guiding star. Obscured slits can be easily identified by looking at the average level of sky counts in each slit, and comparing it with the average sky level for all the slits in the quadrant. When the single slit has a sky level that is lower than 70% of the average sky level, the slit is flagged as “bad”, assigning to it an obscuration parameter being negative or equal to zero. 

A poor (rms \( \leq 3 \) Å) wavelength calibration will end up in a global quality parameter being negative or equal to zero.

3.1.2. Wavelength calibration

As described in Scodeggio et al. (2005), wavelength calibration is performed using both a global fitting and a slit per slit refinement. For some particular slits towards the edge of the field of view, and in particularly unfavourable positions of the instrument during the observation, flexures can be important, and it is not possible to obtain a wavelength calibration of the same quality as usual. Using the wavelength calibration rms for each slit (see Scodeggio et al. 2005) as a measure of the wavelength calibration quality, we can identify such deviant cases. The distribution of the wavelength calibration rms for the VVDS Deep survey (solid line) and the VVDS Wide (dotted line) survey spectra is shown in Fig. 2. There is a small number of slits (1% both in the VVDS Deep survey and in the VVDS Wide survey) showing a wavelength calibration rms above 6 Å, which means that the wavelength calibration has failed. Such slits get a “wavelength calibration quality flag” \( \lambda_{\text{flag}} = 0 \). Furthermore, for some pointings the arc calibration exposure was not usable, and we were forced to calibrate the corresponding spectra using the sky lines. In such cases, the wavelength calibration is never as good as in the standard case, since the sky lines are often broad and/or unresolved at our resolution. This is reflected by the distribution of the wavelength calibration rms for that specific quadrant/pointing, which peaks at \( \sim 3.5 \) Å rather than the usual 1.2 Å. We have considered these slits as an intermediate category, and assigned to them a wavelength calibration quality flag of \(-1\). As all the contributions to the quality parameter are eventually combined in a multiplicative way, all obscured slits will result in a global quality parameter equal to zero.

3.1.3. Sky brightness

Sky brightness depends (at zero order) on moon phase and moon distance. In principle, knowing these two parameters and using a calibration table, the expected sky brightness can be computed. In practice, as we are interested in the global background level, a simpler approach has been adopted:

1. for each slit, the mean one dimensional sky spectrum is obtained by taking the median over the sky two-dimensional image along the spatial direction, to reject border effects;

2. after having discarded obscured slits (see 3.1.1), all one dimensional sky spectra are combined and the median sky spectrum for the whole quadrant derived;

3. such a median sky spectrum is then normalized for the exposure time and integrated over the full wavelength range to obtain the median sky value for that quadrant in that pointing \( \text{med}_{\text{sky}} \);

4. by comparing the median sky values obtained for the same quadrant in the different pointings, we define a “reference sky value” \( \text{ref}_{\text{sky}} \) as the mean of the three lowest “median sky values”;

5. the median sky value per quadrant per pointing is compared to \( \text{ref}_{\text{sky}} \) for that quadrant, and a sky quality factor is defined as

\[
\text{sky qual} = \frac{1}{\sqrt{\text{med}_{\text{sky}} / \text{ref}_{\text{sky}}}}
\]

In Fig. 3, top left, the distribution of the sky quality parameter for the VVDS Deep (solid line) and VVDS Wide (dotted line) surveys is shown. Overall, the VVDS Wide Survey shows a sky quality parameter distribution broader than the VVDS Deep survey. This is expected, as the VVDS Deep survey observations were carried out during dark time, while the VVDS Wide survey ones were partially performed during grey time.

3.1.4. Exposure time

The exposure time for each pointing of the VVDS Deep survey had been planned to be 16 200 s, while for the Wide it should have been 2700 s per pointing. However, in some cases the effective exposure time was less than planned, mainly because meteorological conditions deteriorated during the observation, and exposure time has a direct impact on the signal to noise ratio as a multiplicative factor. There are also a few observations, performed during visitor runs, which were lengthened in an attempt to compensate for high airmass or unstable meteorological conditions. By comparing the actual total exposure time of each quadrant in each pointing \( \text{obs}_{\text{time}} \) to the nominal exposure time \( \text{time} \) to the nominal exposure time...
3.1.5. Sky transparency, seeing and slit losses

Atmospheric conditions have a direct influence on sky transparency, which in turn, and coupled with slit losses, contribute to flux losses in a way that is not possible to separate. In order to estimate their global contribution, an empirical approach has been adopted: for each object, we have integrated its spectrum under the $I$ filter response curve, and compared the thus obtained $I_{\text{flux,spectro}}$ to the equivalent quantity as obtained from photometry ($I_{\text{flux,phot}}$). Then one could in principle compute the effect of seeing, slit losses and transparency on S/N in one step as

$$mag_{\text{qual}} = \sqrt{\frac{I_{\text{flux,spectro}}}{I_{\text{flux,phot}}}}$$

Such a ratio should always be below one, by definition, but, as shown in Le Fèvre et al. (2005c), a small fraction (around a few percent) of objects have a value of $mag_{\text{qual}}$ above 1.0. This is due to a number of second-order effects affecting the measurement, such as: 1) $I_{\text{flux,spectro}}$ is affected by how well zero orders or fringing residuals have been removed; 2) $I_{\text{flux,phot}}$ has its own errors, larger for fainter magnitudes (0.2 mag for objects fainter than $I_{\text{AB}} \sim 23$, for the VVDS Deep survey, McCracken et al. 2003); 3) the brighter and more extended the object, the more inaccurate is the sky subtraction: the sky region that can be used to compute the sky level is small and dominated by pixels affected by slit edge effects. This can lead to an underestimation of the sky level. This more often occurs in the VVDS Wide survey pointings, where the fraction of brighter (~larger) objects is higher, and/or in bad seeing conditions. To quantify the overall contribution of such second order effects, we can define

$$\frac{I_{\text{flux,spectro}}}{I_{\text{flux,phot}}} = \text{transmission} + \text{residuals}$$

where transmission is due to sky transparency and seeing slit width ratio, and, for pointlike sources, should be constant within one observation. Residuals represent the contribution of all the second order effects such as those listed above, and can vary from object to object. In optimal atmospheric conditions, we should have transmission $\sim 1$ and residuals $\sim 0$. Indeed, in the magnitude range between $I_{\text{AB}} \sim 21.5$ and $I_{\text{AB}} \sim 22.5$, where the error on photometric magnitude is negligible and object sizes are small enough not to be affected by slit losses or to hamper a good background estimate, the mean flux ratio is always below one, being affected by sky transparency only. Thus, on a per quadrant and per pointing basis, using only the range $21.5 \leq I_{\text{AB}} \leq 22.5$ we can compute the mean transmission as

$$\text{transmission} = \frac{\langle I_{\text{flux,spectro}} \rangle}{\langle I_{\text{flux,phot}} \rangle}.$$ 

Subsequently, and for each object $i$ for which $I_{\text{flux,spectro}}(i)/I_{\text{flux,phot}}(i)$ is above one, we can estimate the residuals as

$$\text{residuals}(i) = I_{\text{flux,spectro}}(i)/I_{\text{flux,phot}}(i) - \text{transmission}.$$ 

Finally, the contribution of all these factors to the observation quality can be computed as

$$mag_{\text{qual}}(i) = \sqrt{\text{transmission}} \ast \sqrt{1 - \text{residuals}(i)}.$$ 

In Fig. 3, panel e, the distribution of the $mag_{\text{qual}}$ parameter for the VVDS Deep (solid line) and VVDS Wide (dotted line) surveys is shown. Also objects for which no redshift has been measured are included in this panel. Panels $c$ and $d$ show the distribution of the same parameter for stars and galaxies separately. Comparing the two distributions obtained for stars, we see that in the VVDS Deep survey most stars have a figure of merit close to 1, while for the VVDS Wide survey the peak is around 0.8. As stars are less affected by slit losses than galaxies, panel $c$ tells us that the overall better figure of merit for the VVDS Deep survey is mainly due to the better average atmospheric conditions during observations.

3.1.6. Global quality parameter

The above quality parameters have been computed for each object and combined in a multiplicative way as

$$\text{qual} = \text{obscur}_{\text{flag}} \ast \text{A}_{\text{flag}} \ast \text{sky}_{\text{qual}} \ast \text{time}_{\text{qual}} \ast \text{mag}_{\text{qual}}.$$ 

The resulting distribution is shown in Fig. 3 bottom panels, for the VVDS Deep (solid line) and VVDS Wide (dotted line) data.
Negative values of quality pertain to objects with poor wavelength calibration, while a quality parameter of 0 is due to either bad wavelength calibration or to obscured slits. From Fig. 3, panel h, it is apparent that the global distribution of the quality parameter is (slightly) better for the VVDS Deep survey data than for the VVDS Wide survey data. This is essentially due to the $mag_{gal}$ parameter, which is better for the deep survey, while the VVDS Wide survey, in which large and extended galaxies are more abundant, is globally more affected by slit loss effects.

The percentage of galaxies with quality above 0.5 is 79% in the VVDS Deep sample and 58% in the VVDS Wide sample. We note, however, that the quality parameter is not an absolute measure of data quality, but just a relative one: it allows us to select the best quality spectra we have in our samples (i.e. those for which slit losses are small, observed for the nominal exposure time in excellent atmospheric conditions), or conversely, to discard those data for which something during observations or reduction went wrong. We will see in the following section that this does not necessarily prevent, nor assures, 100% reliable redshift measurements.

3.1.7. Data quality parameter and redshift flag

Once the global quality parameter is obtained, it is interesting to see how it relates to the redshift flag. If both estimates are reliable, we expect that objects with a poor value of the quality parameter (i.e. below 0.5) should have a higher probability of an unsuccessful redshift measurement (flag = 0), while objects with a good value of the quality parameter (above 0.5) should have a higher probability of a very secure redshift flag (i.e. 3 or 4). Still, we do not expect the opposite to be totally true, i.e. there may exist spectra with a poor quality but to which the redshift can be securely assigned: in fact, the quality parameter is related to the continuum intensity, its signal to noise, and the absolute flux calibration of the data, while the flag is a measure of the reliability of the redshift, and is strongly affected by the presence, or absence, of prominent emission/absorption lines.

In Fig. 4, for each flag, the distribution of the quality parameter is shown for the VVDS Deep (left) and VVDS Wide (right) surveys. The dotted line indicates the 0.5 value of the quality parameter. As expected, more secure flags are assigned to objects showing, on average, a higher quality parameter, as shown by the peak of the histogram moving towards higher values of quality going to more secure flags. An exception is the flag 9 objects, which show a distribution of the quality parameter comparable to that of the flag 1 objects. This is not a surprise: we recall that a flag 9 is assigned when one secure single spectral feature in emission is visible, and, as anticipated before, an emission line, if strong enough, can be detected even in the presence of a low S/N continuum, or residual fringing patterns.

More quantitatively, in the VVDS Deep survey only 42% of the failed spectra have a quality parameter larger than 0.5, a percentage which goes down to 20% for the Wide survey. On the other hand, 82% of the objects with a very secure redshift flag (flag 3 or 4) in the Deep survey are derived from spectra of good quality (quality > 0.5), a percentage that decreases to 73% in the Wide case.

Thus, the quality parameter statistically strengthens the redshift flag, and justifies it on the basis of the quality of the data. Furthermore, the coupling of the two pieces of information allows one to easily select subsamples of objects for which not only does the redshift have the highest degree of reliability, but the data are above a given quality and thus particularly suitable for detailed studies of the continuum emission.

4. General properties of the spectroscopic sample

In Table 2 we summarize the statistics of redshift measurement for the VVDS Wide sample. For reference, we also report the redshift statistics for the VVDS Deep sample, once it is cut at a limiting magnitude of $I_{AB} < 22.5$. So far, in the 3 Wide survey fields we have accumulated 28166 spectra for primary targets, including 16670 galaxies, 258 QSOs and 9164 stars. There are only 2074 spectra for which the redshift measurement failed; this corresponds to a success rate greater than 92%. There are 21894 secure redshift objects (flag between 2 and 9), almost 80% of the sample. Although the magnitude limit is only $I_{AB} = 22.5$, thanks to the large surveyed area ($\sim 5.0$ deg$^2$ of effective area), we have a fairly large sample of rare, luminous galaxies at high redshift: 979 with $1.0 < z < 1.4$ and 225 with $1.4 < z < 2.0$. The highest secure redshift measured for a galaxy is 4.0573, while the highest secure redshift object is a QSO at $z = 5.0163$. On top of the targeted sample, we also have 772 additional redshifts of objects accidentally falling within the slit. Adding the data collected in the FO2 field limited to $I_{AB} = 22.5$, the VVDS Wide sample comprises almost 20000 galaxies and 304 QSOs with a measured redshift in an area of 6.1 deg$^2$.

4.1. Magnitudes, sampling rate and redshift distribution

In Fig. 5, the magnitude distribution of the photometric parent catalog (top panels, empty histogram) and of the final spectroscopic sample (top panels, shaded histogram) is shown for the three VVDS Wide areas. For comparison, we show the same plot for the VVDS-Deep FO2 field, limited to $I_{AB} = 22.5$. The bottom panels show the fraction of observed over total objects vs. magnitude. In all the three VVDS Wide areas, the fraction of observed objects is between 20% and 25%, over the full magnitude range, very similar to the sampling rate of the VVDS Deep area, once limited at $I_{AB} = 22.5$. The slight trend favouring a better sampling at the faintest magnitude in the FO2 field is due to the intrinsic deeper limiting magnitude of the spectroscopic selection in this area, $I_{AB} < 24$, which increases the probability for
Table 2. Statistics of redshift quality flags for the VVDS Wide sample.

| field/flag | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28 | 29 | total |

Fig. 5. Spectroscopic survey sampling rate of the four fields as a function of magnitude: in the top panels, the apparent magnitude distribution for the parent photometric catalog (empty histogram) and the observed spectroscopic catalog (dashed histogram); in the bottom panels, the ratio of the two, corresponding to the effective sampling rate as a function of apparent magnitude.

Fig. 6. Observed redshift distribution to $I_{AB} = 22.5$ in the four VVDS Wide fields, in redshift bins of $\Delta z = 0.02$. All galaxies with quality flag between 1 to 19 have been used.

Table 3. Statistics on galaxy redshift distributions ($I_{AB} <= 22.5$).

| Field | 1st quartile | Median | 3rd quartile | 1st quartile | Median | 3rd quartile |
|-------|--------------|--------|--------------|--------------|--------|--------------|
| F02   | 0.374        | 0.611  | 0.834        | 0.369        | 0.611  | 0.824        |
| F10   | 0.386        | 0.616  | 0.856        | 0.368        | 0.605  | 0.855        |
| F14   | 0.351        | 0.560  | 0.724        | 0.333        | 0.559  | 0.767        |
| F22   | 0.404        | 0.571  | 0.810        | 0.382        | 0.560  | 0.770        |

4.2. Galaxy luminosities and stellar masses

The large areas explored, coupled with the relative bright magnitude limit, make the VVDS Wide the ideal survey to explore the bright/massive ends of the luminosity/mass function up to redshift $\sim 1$. As an example of the potential of this sample for these studies, in Figs. 7 and 8 we show the absolute $B$ magnitude and stellar mass vs. redshift distribution for the galaxies with secure redshifts in the four areas. Absolute $B$ magnitudes and stellar masses have been derived by fitting the photometric and spectroscopic data with a grid of stellar population

brighter objects of being discarded in favour of fainter ones (see Bottini et al. 2005).

In Fig. 6, the redshift distributions using all available redshifts (irrespective of flags) for the four different areas are shown. Table 3 shows that there are no statistically significant differences between the $N(z)$ obtained using all redshifts, and the ones obtained using only secure redshifts (i.e. flag 2 to 9, redshift confidence $>=80\%$).
4.3. A direct test of star-galaxy separation techniques

As mentioned earlier, the VVDS was deliberately carried out without any star-galaxy separation prior to spectroscopy. When the survey was planned, only ground based $BVRI$ photometry was available (and not over all fields), thus preventing us from using the most efficient color based methods to discriminate between stars and extragalactic objects. Furthermore, the image quality of such ground based photometry was not good enough to apply geometrical arguments to discriminate between point-like and extended sources down to the magnitude limits of the Deep and Wide surveys. Thus, we decided to follow the conservative approach of not attempting any a priori removal of starlike objects based on colors or compactness. This has lead to the high stellar contamination of the spectroscopic sample (up to $\sim$1/3 for the lower galactic latitude fields). Using UKIDSS $K$ photometry, and CFHTLS $z$ photometry available in the F22 and F02 field, we can test with excellent statistics the performances of these star identification methods. We thus applied the $BzK$ criterion described in Daddi et al. (2004) to the spectroscopic sample, coupled with a compactness criterion based on the stellarity index provided by Sextractor: any object with a stellarity index above or equal 0.9 is catalogued as compact. An object is considered as a star if both criteria are satisfied. To optimize the test, we used only objects with secure redshift (redshift flag $>1$) and small photometric errors ($err < 0.1$) in the $B$, $K$ and $z$ Bands.

Applying this technique to the F02 data (which are deeper and at high galactic latitude), we have a residual stellar contamination of only $\sim$2%. In the F22 field, which has a brighter magnitude limit and is located at lower galactic latitude, the residual contamination decreases from 35% to 14%. The price to be paid in terms of galaxies that a priori would have been discarded is about 5% in the F22 field, and about 2% in the F02 case. We have checked which kind of galaxy was typically discarded and found out that they have the spectrum of a normal elliptical galaxy. Overall, we can state on the basis of observed data that the performance of these two coupled methods in discarding stars is highly efficient, at the low price of a small loss of normal early type galaxies In addition, we have applied the colour method in the standard form. Exploring in detail alternative color–color selections using the other available bands is beyond the scope of this paper.

5. Large-scale structure and density fluctuations in the VVDS Wide fields

5.1. Galaxy spatial distribution in the F22 field

In Fig. 9 we show the redshift space cone diagram of all galaxies observed in the F22 area, in co-moving coordinates and projected onto the right ascension plane. The figure shows two declination slices, of 1 degree each, to better show the extension of the different structures. Note that the aspect ratio is stretched along the vertical direction. We can identify galaxy overdensities at $z = 0.28, 0.33, 0.41, 0.53, 0.75, 0.82$ and 0.9, some of which extend over the full surveyed area, both in right ascension and declination: at $z = 0.33$ a very thin wall covers the whole field of view of $24 \times 24$ h$^{-1}$ Mpc; the structure at $z \sim 0.53$ is the most prominent and massive, extending for almost $80$ h$^{-1}$ Mpc along the line of sight, and $40$ h$^{-1}$ Mpc across. Its presence strongly influences the redshift distribution in this field, lowering its median value and steepening its rise at low redshifts. Such a “thick wall” has several subconcentrations, better visible in the slices in declination of Fig. 9. The other visible structures look rather
more compact, with a comoving transverse size of the order of 
20 h^{-1} Mpc, and confined within the 2 square degrees.

5.2. Mean redshift distribution up to I_{AB} = 22.5

In terms of their broad shape and peak position, the galaxy red-
shift distributions in the four areas are relatively similar. At the
same time, however, significant field-to-field variations are ev-
dent (e.g. the thick wall at 0.53 in the F22 field, as outlined
in the previous section). In this and the following sections we
quantify this variance and compare it to theoretical expectations,
as obtained both from the observed two-point correlation func-
tion and from mock surveys built using numerical/semi-analytic
models.

Combining the four fields, appropriately taking into account
the effective area and the sampling rate of each field, we can
derive our current best estimate of the redshift distribution of a
magnitude selected sample to I_{AB} <= 22.5. The result is shown
in Fig. 10 and the corresponding values are reported in Table 4
for convenience. In this figure and table, we use a binning of
\Delta z = 0.1 up to z = 1, and 0.2 at higher redshift, in order to
smooth out the smaller structures present in the different fields.
This represents the most accurate redshift distribution measured
to date at these faint magnitudes, based on \sim 20,000 galaxies over
a total area of 6.1 deg^2, and it can provide an important reference
for galaxy formation models.

5.3. Field to field variations

With this unprecedented area surveyed, it becomes possible to
quantify the variations in each of the four fields with respect to
this average distribution. This is shown in Fig. 11. The top panel
reports the redshift distribution of the four fields, using a \Delta z =
0.1 binning. For reference, around the peak of the distribution
z = [0.5, 0.6] such a redshift bin corresponds to a comoving ra-
dial size of 222 h^{-1} Mpc. Error bars correspond to Poissonian
errors. In the bottom panel of Fig. 11, we show the fractional
difference between the observed N(z) in each field, and the aver-
age distribution. This comparison of the fluctuations in the dif-
f erent fields for fixed redshift bins is inevitably qualitative. In
Fig. 11. Top: redshift distribution (in galaxies per unit effective area) in the four VVDS-Wide areas: F02, black dots and solid line, F10 blue crosses and short dashed line, F14 green squares and long dashed line, and F22, red circles and dotted line. The sampling corrections have been assumed to be independent of redshift. Bottom: field-to-field variations, relative to the globally averaged redshift distribution of Fig. 10.

Table 4. Galaxy surface density as a function of redshift up to a limiting mag $I_{AB} \leq 22.5$ averaged over 6.1 square degrees.

| $z$  | Mean $\text{gal/deg}^2$ | max $\text{gal/deg}^2$ | min $\text{gal/deg}^2$ |
|------|--------------------------|-------------------------|-------------------------|
| 0.15 | 1370                     | 2105                    | 1107                    |
| 0.25 | 1956                     | 2635                    | 1356                    |
| 0.35 | 2644                     | 3085                    | 2367                    |
| 0.45 | 3296                     | 3950                    | 2645                    |
| 0.55 | 4142                     | 5123                    | 3346                    |
| 0.65 | 3877                     | 4310                    | 3546                    |
| 0.75 | 2670                     | 3033                    | 2447                    |
| 0.85 | 2443                     | 2980                    | 2089                    |
| 0.95 | 1509                     | 1851                    | 1145                    |
| 1.1  | 1294                     | 1882                    | 836                     |
| 1.2  | 561                      | 746                     | 439                     |
| 1.3  | 281                      | 357                     | 193                     |
| 1.7  | 74                       | 113                     | 31                      |
| 1.9  | 68                       | 108                     | 31                      |

quantitatively the results illustrated in Fig. 12. For each area size, and each redshift bin, we give the number of sub-fields of that size available, the median value, upper/lower quartiles and maximum and minimum of the observed galaxy density. For the largest area, where only 2 measurements are available, we computed the arithmetic mean instead of the median. For the smaller scales represented (190 arcmin$^2$) the observed large fluctuations (up to a factor of four between adjacent areas) are not surprising, as we are essentially looking at scales of the order of a few Mpc. At redshifts approaching unity, and for large angular sizes (30 arcmin correspond to $10 \, h^{-1}$ Mpc at this redshift) the spread can still be a factor of 2, an indication that important structures
than 10%. The observed variance in the counts at a given redshift can be compared to that expected from the two-point correlation function of the galaxy sample. Following Peebles (1980)

\[ \sigma_v^2 = \frac{1}{V_2} \int d^3x_1d^3x_2 \xi_2 |x_1 - x_2|^\gamma. \]  

(2)

If the galaxy correlation function can be described as a power law, \( \xi(r) = (r/r_0)^{-\gamma} \), then this expression becomes

\[ \sigma_v^2 = J_2(r_0/r)^\gamma \]  

(3)

where \( J_2 = 72.0/[(3 - \gamma)(4 - \gamma)(6 - \gamma)2!] \) and \( r_0 \) and \( \gamma \) are measured from the observations.

Following the same approach as in Le Fèvre et al. (2005a), and using the VVDS-Deep F02 data limited at \( I_{AB} \leq 22.5 \), we have estimated the best fit correlation function parameters in different redshift bins, and used Eq. (3) to check whether the observed variance measured from the field-to-field scatter (as from Eq. (1)) can be recovered consistently by extrapolating the correlation function measured from a much smaller field. The results are shown in Fig. 13, where we plot the observed square-root \( \sigma_v^2 \) of the variance (i.e. the value of the rms fluctuation) against the volume. The red asterisks correspond to the direct measurement, obtained from the scatter among \( N_i \) samples within the given volume. The dashed area shows the same quantity as obtained using the 3\( \sigma \) confidence intervals of the VVDS-Deep F02 correlation function (limited at \( I_{AB} \leq 22.5 \)).

One notes immediately that the variance directly estimated from the galaxy counts in the different fields is in excellent agreement with the cosmic variance as estimated from the correlation function. Only at redshift 0.35 and 0.65 and for volumes of \( \sim 10^5 \) \( h^{-1} \) Mpc\(^3\), field-to-field variance appears smaller than the one predicted from the correlation function parameters. Looking back at the distribution of the number counts (Fig. 11), at these two redshifts we note a remarkable similarity among the different fields, as well as in the galaxy surface density distribution in Fig. 12 and Table 5. This similarity automatically converts to a lower field-to-field variance, which remains compatible with the one computed from the correlation function at a 1.2\( \sigma \) level.

Using 100 quasi-independent mock samples of 2 \( \times \) 2 degrees (for details, see Guzzo et al. 2008) built applying the semianalytic prescription of De Lucia & Blaizot (2007) to the Millennium simulation (Springel et al. 2005; Blaizot et al. 2005), we have computed model predictions for cosmic variance again using Eq. (1). The model predictions (green filled squares) are consistent with the observed field-to-field variance, with a difference that is at most 1.5\( \sigma \) at \( z = 0.65 \) for volumes of \( \sim 10^5 \) \( h^{-1} \) Mpc\(^3\).

### 6. Public data release and database access

We are publicly releasing all redshift measurements in the F22 area through the CENkos (CENtre de COSmologie) database environment on our web site http://cencos.oamp.fr with access to the database built under the Oracle environment, and through VO services (VVDS_WIDE ConeSearch service). The catalog can be searched by coordinates, redshift interval, identification number, in combination with the spectra quality flags. Spectra in FITS format are already available on the same site (or through the VO SSA service) for the F02 area, both from the CENkos site and the VO SSA service VVDS_F02_DEEP. The remaining redshifts, together with all spectra in FITS format, will be available as soon as the whole set of available data are measured.

### 5.4. Measuring cosmic variance

The results of Fig. 12 can be translated from the observational space into a framework which is theoretically easier to interpret in terms of cosmic variance and expectations from galaxy clustering. Given a set of \( N \) identical volumes with volume \( V \), we can define the observed variance among them as

\[ \sigma_v^2 = \frac{\langle N^2 \rangle - \langle N \rangle^2}{\langle N \rangle^2} - \frac{1}{\langle N \rangle} \]  

(1)

(e.g. Somerville et al. 2004), where the last term is the correction for Poissonian shot noise. In the following we will compute \( \sigma_v^2 \) following Eq. (1) only when the Poisson shot noise is smaller

| \( z \) | Area arcmin\(^2\) | \( N \) areas | Median | Upper quartile | Lower quartile | max | min |
|-----|----------------|-------------|--------|--------------|--------------|-----|-----|
| 0.15 | 780            | 19          | 0.34   | 0.42         | 0.29         | 0.48 | 0.25 |
| 0.25 | 1725           | 8           | 0.70   | 0.74         | 0.56         | 0.91 | 0.41 |
| 0.35 | 1725           | 8           | 0.96   | 0.97         | 0.89         | 1.00 | 0.70 |
| 0.45 | 1725           | 8           | 1.24   | 1.42         | 1.10         | 1.51 | 0.75 |
| 0.55 | 1725           | 8           | 1.45   | 1.73         | 1.15         | 1.83 | 0.94 |
| 0.65 | 1725           | 8           | 1.12   | 1.23         | 1.09         | 1.33 | 1.01 |
| 0.75 | 1725           | 8           | 0.85   | 1.05         | 0.77         | 1.14 | 0.60 |
| 0.85 | 1725           | 8           | 0.83   | 0.91         | 0.74         | 0.94 | 0.59 |
| 0.95 | 1725           | 8           | 0.50   | 0.53         | 0.44         | 0.64 | 0.31 |

exist and are not uncommon at such redshift. It is interesting to see, using the larger areas, how much variance we expect in a field of 0.5 deg\(^2\) (1800 square arcminutes) like F02, i.e. the field of the VVDS-Deep survey. For example, at redshift 0.75 we still see peak to peak fluctuations of \( \sim 30\% \) in the counts. We also notice a significant excess fluctuation in the data from the field F22 (red circles) in the redshift bin 0.5–0.6. In particular, all counts are shifted towards higher values, reflecting the presence of the global large-scale fluctuation covering the full field already mentioned in Sect. 5.1.

### Table 5. Galaxy density median values and spread in different area sizes at different redshifts.

For Poissonian shot noise. In the following we will compute \( \sigma_v^2 \) following Eq. (1) only when the Poisson shot noise is smaller
The large number of redshifts available in the F22 field, coupled with a sampling rate of ~23%, allows us to identify and describe several prominent structures present along the line of sight up to 2500 h⁻¹ Mpc. Typical sizes are of the order of 20 h⁻¹ Mpc, but one large clumpy structure extends for almost 80 h⁻¹ Mpc along the line of sight, and 40 h⁻¹ Mpc across.

We give the mean N(z) distribution averaged over 6.1 deg² (Fig. 10) for a sample limited in magnitude to IAB = 22.5. We have estimated field to field variations in terms of number counts (see Fig. 11 and Table 4) and galaxy surface density both as a function of field size and redshift (see Fig. 12 and Table 5), showing that differences as high as a factor of two can exist at z = 1 for still relatively large scales, of the order 30 arcmin, like those considered in many deep surveys today. For fields limited to smaller scales (of the order of 10 arcmin), the spread in galaxy densities can be up to a factor of 2.5. Still, the observed cosmic variance is consistent both with what is derived from the correlation function parameters, and from theoretical simulations (see Fig. 13).

In addition to the evolution of clustering and large-scale structure, this data set is best suited to study in detail the bright end of the luminosity function, as well as the massive end of the mass function, up to z ~ 1 in four different fields observed with identical purely magnitude limited selection.

The redshift catalog for the F22 area is available at the web site http://cencosw.oamp.fr or via ConeSearch VO service VVDS_WIDE.

Acknowledgements. This research has been developed within the framework of the VVDS consortium. This work has been partially supported by the CNRS-INSU and its Programme National de Cosmologie (France), and by Italian Ministry (MIUR) grants COFIN2000 (MM02037133) and COFIN2003 (No. 2003020150) and by INAF grants (PRIN-INAF 2005). The VLT-VIMOS observations have been carried out on guaranteed time (GTO) allocated by the European Southern Observatory (ESO) to the VIRMOS consortium, under a contractual agreement between the Centre National de la Recherche Scientifique of France, heading a consortium of French and Italian institutes, and ESO, to design, manufacture and test the VIMOS instrument.
