ABSTRACT

We present a Hubble Space Telescope image of the FR II radio galaxy 3C 401, obtained at 1.6 μm with NICMOS, in which we identify the infrared counterpart of the brightest region of the radio jet. The jet has a complex radio structure and brightens where bending occurs, most likely as a result of relativistic beaming. We analyze archival data in the radio, optical, and X-ray bands, and we derive its spectral energy distribution. Unlike all of the previously known optical extragalactic jets, the jet in 3C 401 is not detected in the X-rays, even in a long 48 ks X-ray Chandra exposure, and the infrared emission dominates the overall spectral energy distribution (SED). We propose that the dominant radiation mechanism of this jet is synchrotron. The low X-ray emission is then caused by two different effects: (1) the lack of any strong external photon field and (2) the shape of the electron distribution. This affects the location of the synchrotron peak in the SED, resulting in a sharp cutoff at energies lower than the X-rays. Thus 3C 401 shows a new type of jet, with intermediate spectral properties between those of FR I galaxies, which are dominated by synchrotron radiation up to X-ray energies, and FR II galaxies/QSOs, which show strong high-energy emission due to inverse Compton scattering of external photons. This might indicate the presence of a continuous “sequence” in the properties of large-scale jets, analogous to the “blazar sequence” already proposed for subparsec-scale jets.

Subject headings: galaxies: active — galaxies: individual (3C 401) — galaxies: jets — radiation mechanisms: nonthermal

Online material: color figures

1. INTRODUCTION

The study of relativistic jets, which constitute a distinguishing feature of radio-loud active galactic nuclei (AGNs), has recently been revitalized by the discovery that a large number of radio jets are bright in X-rays (e.g., Chartas et al. 2000; Sambruna et al. 2004; Worrall et al. 2001). While the emission process in the radio band is certainly nonthermal synchrotron radiation, the origin for the high-energy emission is still unclear. Synchrotron and inverse Compton radiation are the most accepted interpretations. The former process seems to predominate in low-power jets associated with radio galaxies belonging to the FR I class (Fanaroff & Riley 1974), while in powerful quasars and radio galaxies the dominant mechanism is most likely inverse Compton. In powerful QSOs, the seed photons for scattering may be provided by the cosmic microwave background (CMB) radiation (Tavecchio et al. 2000; Celotti et al. 2001). Such a scenario requires the jet to be relativistic on large scales (up to ~100 kpc or more), so that the CMB photon field is enhanced by relativistic beaming effects. This requirement is thus considered strong further evidence for relativistic motion on large scales, in addition to the well-known jet-to-counterjet asymmetries, lobe depolarization asymmetries (Laing 1988; Garrington et al. 1988), core enhancement (e.g., Giovannini et al. 1994), and superluminal motions in QSOs and radio galaxies in which the jet axis forms a small angle to the line of sight (Rees 1966; Whitney et al. 1971).
Here we focus on 3C 401, which is a powerful FR II radio galaxy located at a redshift of z = 0.201. In the radio, it shows a one-sided jet and two hot spots that are clearly visible, although they do not appear as compact as in more powerful (and more distant) FR II galaxies (Hardcastle et al. 1998). Nevertheless, its high radio power ($L_{178 \text{MHz}} = 2 \times 10^{34} \text{ergs s}^{-1} \text{Hz}^{-1}$) is 1 order of magnitude higher than the fiducial FR I/FR II break. On the other hand, the characteristics of the environment are more typical of FR I radio galaxies, since the object is the cD galaxy of an Abell class 1 cluster of galaxies, while FR II galaxies are generally found in small groups. In the Hubble Space Telescope (HST) optical images (de Koff et al. 1996), the host galaxy appears as an elliptical galaxy of low surface brightness, with no clear sign of dust features. A close companion galaxy is located at $\sim 4''$ from the nucleus of the radio source. From the point of view of its optical spectrum, 3C 401 belongs to the subclass of FR II that are dominated by low-excitation emission lines (i.e., low-excitation galaxies). The object is also more similar to an FR I as far as the nuclear properties are concerned: the host galaxy shows a faint optical unresolved core, which is most likely interpreted as the optical counterpart of the synchrotron radio core, similar to the large majority of 3CR FR I galaxies (Chiaberge et al. 2002). Therefore, its high power associated with FR I–like nuclear characteristics makes 3C 401 an extremely interesting object. A detailed study of the jet in “transition” sources may shed light on the physical processes that determine the properties of jets in sources of different total power.

In § 2 we describe our HST NICMOS (Near-Infrared Camera and Multi-Object Spectrometer) infrared observations, in § 3 we outline the jet morphology and perform photometry, and observations at other wavelengths are analyzed in § 4. In § 5 we derive and model the spectral energy distribution of the jet, and in § 6 we discuss our findings and draw conclusions. The values $H_0 = 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$ and $q_0 = 0.5$ are used throughout the paper.

2. INFRARED HST OBSERVATIONS

We have observed 3C 401 with HST NICMOS as part of our snapshot program GO 10173. Our complete sample is derived from the 3CR catalog of extragalactic radio sources, limited to $z < 0.3$ to take advantage of the highest spatial resolution HST can offer. The sample comprises 115 sources, 18 of which have been observed during previous cycles, as part of other HST programs.

The observations of 3C 401 were performed on 2004 August 11. We used NICMOS2 (NIC2) and the F160W filter, which is
centered at 1.6037 μm and covers the spectral range from 1.4 to 1.8 μm. At the redshift of the source, the Paβ emission line is included in the filter. However, due to its large bandwidth, continuum emission dominates. The field of view of NIC2 is 19′2 × 19′2, and the projected pixel size is 0″076 × 0″075. The total exposure time is 1152 s, split into four images of 288 s allowing four-point dithering with subpixel spacing, in order to improve both the point-spread function (PSF) sampling and bad-pixel removal. The details of the data reduction will be given in a forthcoming paper (J. Madrid et al. 2005, in preparation). Here we only briefly describe the main steps of the reduction.

The raw data have been retrieved from the HST MAST (Multi-mission Archive at Space Telescope) and have been processed by the standard OTFR (on-the-fly reprocessing) calibration pipeline, which uses the latest calibration files. The subsequent reduction has been performed using IRAF. As a first step, we remove the "pedestal effect"4 from each of the images using pedsky, and we subtract the residual background level. We then combine the four calibrated images using the drizzle algorithm (Fruchter & Hook 2002). The final "drizzled" image is shown in Figure 1. The projected pixel size in the final image is 0″038.

The host galaxy of the radio source 3C 401 is the largest object at the center of the field of view. A faint point source is present at the center of the galaxy. A close companion, which appears to be a smaller elliptical galaxy, is clearly visible north of the nucleus of our target. A bright unresolved source located north of the galaxy is present in our image. This object is also visible in optical HST images, in which it is slightly resolved. Since it does not appear to be related to any radio-emitting feature, this object is most likely an infrared-bright field galaxy and will be studied elsewhere.

The most intriguing feature in the image is the IR counterpart of the radio jet, located about 6″ southwest of the nucleus, at a position angle of ~205°. In Figure 2 we show the overlay of the radio contours at 1.5 GHz on our HST NICMOS image. Radio data are from Very Large Array (VLA) Multielement Radio-linked Interferometer Network (MERLIN) observations (Treichel et al. 2001) and have an angular resolution of 0″35 (circular

4 The pedestal effect is one of the main anomalies that appear in NICMOS images. It is a time-varying, quadrant-dependent bias level that appears in all NICMOS images. For more details, see http://www.stsci.edu/hst/nicmos.
beam). We have used the position of the radio core as the reference to align the world coordinate system of the HST image to the radio data frame.

The brightest region of the radio jet, which appears to be located where the jet bends, and its infrared counterpart clearly overlap. However, it appears that the IR jet is detected over a significantly smaller area than is the radio jet. In § 3 we describe the IR jet morphology, and we outline our method for aperture photometry of the components.

3. THE INFRARED JET IN 3C 401: MORPHOLOGY AND PHOTOMETRY

In Figure 3 we show a detail of the jet as it appears in our IR HST image (left panel) and in the VLA MERLIN radio image at 1.5 GHz (right panel). In the IR, the host galaxy stellar component has been subtracted using a simple model obtained by fitting ellipses to the galaxy surface brightness measured at different radii.

At least four emission regions, or "knots," can be identified in the radio jet; component B is the brightest and appears to be the largest at both frequencies. Knots A and B are also detected in the IR image.

Note that component B shows a bright pointlike knot in the infrared that has no radio counterpart at 1.5 GHz. However, the peaks of emission in the infrared and in the radio match quite well at 8.4 GHz (the data are described in § 4.1; see Fig. 4). Furthermore, in the radio maps at both 8.4 and 1.5 GHz, the contours are significantly bent on the southern side of the jet, where the peak of the IR emission is located. Thus we are confident that the IR...
emission peak is part of the jet itself and that it is not produced by any background (or foreground) source.

We measure the flux of component B from our HST H-band image by extracting the counts in a box of $1.7\times 1.2$, and we measure the background in different regions around the jet. We have performed aperture correction to estimate the flux that is lost because of the presence of strong PSF wings. We have performed simulations using a synthetic PSF obtained with Tiny Tim, resulting in a correction factor of 1.12 for the extraction area we use to measure the flux of the jet. The flux, converted from counts s$^{-1}$ into physical units using the PHOTFLAM keyword in the image header, is $6.0 \times 10^{-19}$ ergs cm$^{-2}$ s$^{-1}$ Å$^{-1}$, with estimated total error of $\pm 8\%$. We assume $A_V = 0.197$, which translates into $A_B = 0.034$ to correct for Galactic absorption (as taken from NED).

Results of aperture photometry for the jet are summarized in Table 1.

### Table 1

**Jet Fluxes for Components A, B, and C**

| $\log \nu$ (Hz) | $\log F_\nu$ (ergs cm$^{-2}$ s$^{-1}$ Hz$^{-1}$) |
|----------------|----------------------------------|
| Component A    |                                  |
| 9.1761         | $-24.4560$                       |
| 14.2730        | $-29.1348$                       |
| Component B    |                                  |
| 9.1761         | $-23.551$                        |
| 9.9243         | $-24.032$                        |
| 14.1347        | $-27.979$                        |
| 14.2730        | $-28.223$                        |
| 14.7367        | $-28.858$                        |
| 17.3838        | $<-32.456$                       |
| Component C    |                                  |
| 9.1761         | $-24.0499$                       |
| 14.2730        | $<-29.7620$                      |

We thus measure the flux of the jet in the optical WFPC2 F555W image obtained during two different observations (ObsIDs 3083 and 4370; PI: C. Reynolds) on 2002 September 20 and 21, and are available from the Chandra public archive. We reduce the Chandra data using the Chandra data analysis software CIAO version 3.0.2, with CALDB version 2.25. To correct for the quantum efficiency (QE) degradation issue, we create a new ARF (effective area files) using the file acisD1999-08-13contamN0003.fits released with CALDB version 2.26. We reprocess all the data from level 1 to level 2 with standard procedures. No background flares are present during the observing time. Thus, merging the two data sets, we obtain an event file with total exposure time of 47.52 ks. We extracted the spectrum in the region of the IR jet, and we measure the background in a nearby region.

We measure a $3\sigma$ upper limit to the jet count rate of $3.59 \times 10^{-5}$ counts s$^{-1}$. Since the flux is too low to derive any reasonable fit to the spectrum, we use the redistribution matrix file (RMF) and auxiliary response file (ARF) created by CIAO to reproduce with XSPEC the observed upper limit net count rate with an absorbed power-law model. The value of $N_H$ is fixed to the Galactic absorption ($6.77 \times 10^{20}$ cm$^{-2}$), and the power-law index is fixed to the value of $\alpha = 1$. Note that a different choice for $\alpha$ would not significantly affect the normalization of the power law. The normalization of the power law results in $1926+611$ as our flux and point-source calibrators, respectively.

The jet morphology at 8.4 GHz appears very similar to that observed in the VLA MERLIN map at 1.5 GHz.

### 4.2. TNG K-Band Observations

A K-band image was obtained at the 3.6 m Italian Telescopio Nazionale Galileo (TNG), located at La Palma, Canary Islands, Spain, with ARNICA (Arcetri Near-Infrared Camera; Lisi et al. 1993). The observation was part of our survey of the complete sample of 3CR sources with $z < 0.3$ (PI: A. Ćapetti), which is described by Marchesini et al. (2005). The total integration time is 1152 s, split into 24 exposures of 48 s each to allow for sky subtraction. We reduce the data using the standard technique described by L. K. Hunt et al.$^5$

The jet is detected (at 4 $\sigma$) in the K-band Galileo image. We have extracted the flux from the same region as in the other images, although both the lower resolution and the low detected flux do not allow us to disentangle the different jet components.

### 4.3. Optical HST Images

3C 401 was also observed with HST WFPC2 (Wide Field Planetary Camera 2) in two optical bands, with F702W and F555W filters, as part of programs 5476 and 6967 (PI: W. B. Sparks, for both programs). The presence of cosmic rays in the region of the jet in the F702W image, for which only one image was taken, prevents us from estimating any reliable upper limit in the $R$ band. While no detection can be claimed in the F702W image, the bright blob on knot B is clearly visible in the data taken with the F555W filter, after smoothing the image with a 1 pixel $\sigma$ Gaussian.

We thus measure the flux of the jet in the optical WFPC2 F555W image observed in the VLA MERLIN map at 1.5 GHz. The total integration time is 1152 s, split into 24 exposures of 48 s each to allow for sky subtraction. We reduce the data using the standard technique described by L. K. Hunt et al.$^5$

The jet is detected (at 4 $\sigma$) in the K-band Galileo image. We have extracted the flux from the same region as in the other images, although both the lower resolution and the low detected flux do not allow us to disentangle the different jet components.

### 4.4. Chandra Data

The X-ray data were obtained during two different observations (ObsIDs 3083 and 4370; PI: C. Reynolds) on 2002 September 20 and 21, and are available from the Chandra public archive. We reduce the Chandra data using the Chandra data analysis software CIAO version 3.0.2, with CALDB version 2.25. To correct for the quantum efficiency (QE) degradation issue, we create a new ARF (effective area files) using the file acisD1999-08-13contamN0003.fits released with CALDB version 2.26. We reprocess all the data from level 1 to level 2 with standard procedures. No background flares are present during the observing time. Thus, merging the two data sets, we obtain an event file with total exposure time of 47.52 ks. We extracted the spectrum in the region of the IR jet, and we measure the background in a nearby region.

We measure a $3\sigma$ upper limit to the jet count rate of $3.59 \times 10^{-5}$ counts s$^{-1}$. Since the flux is too low to derive any reasonable fit to the spectrum, we use the redistribution matrix file (RMF) and auxiliary response file (ARF) created by CIAO to reproduce with XSPEC the observed upper limit net count rate with an absorbed power-law model. The value of $N_H$ is fixed to the Galactic absorption ($6.77 \times 10^{20}$ cm$^{-2}$), and the power-law index is fixed to the value of $\alpha = 1$. Note that a different choice for $\alpha$ would not significantly affect the normalization of the power law. The normalization of the power law results in

5.98 × 10⁻⁸ photons cm⁻² s⁻¹ keV⁻¹ at 1 keV, corresponding to \( F_{1\text{keV}} < 0.35 \) nJy (3 \( \sigma \) upper limit).

5. SPECTRAL ENERGY DISTRIBUTION AND EMISSION MODEL

In Figure 5 we show the spectral energy distribution of component B of the jet. Note that although the jet is very faint and only marginally detected in the optical, the optical data point sets a crucial constraint on the shape of the jet SED. The slope is flat \((\alpha = 0.64 \pm 0.06)\) in the radio, and changes to \(\alpha > 1\) in the spectral region between the radio and the IR band.

We have also measured the fluxes for components A and C, in order to investigate any spectral variation along the jet. While A is detected both in the radio and at 1.6 \( \mu \)m, C is only visible at radio wavelengths. For the latter component, we have measured a 3 \( \sigma \) upper limit from our 1.6 \( \mu \)m \( \text{HST} \) image. Both A and B have a broadband spectral index \( \alpha_{1.5\text{GHz}-\text{IR}} = 0.92 \pm 0.01 \), while C is significantly steeper \((\alpha_{1.5\text{GHz}-\text{IR}} > 1.1)\). For component B, we can also set useful lower limits for \(\alpha_{\text{IR}-\text{X}} \geq 1.4\) and \(\alpha_{1.5\text{GHz}-\text{X}} \geq 1.09\), which we use in §6 to compare the properties of our jet with those of other known X-ray and radio jets.

The solid and the dashed lines in Figure 5 correspond to two possible one-zone synchrotron self-Compton (SSC) emission models, obtained with different sets of physical parameters, as summarized in Table 2. The volume of the emitting region has been constrained from the observed size of the IR jet (assumed to be cylindrical), and the spectral slope in the radio band constrains the electron-injected spectrum. For model 1 \((\text{dashed line})\), the value of the magnetic field is close to equipartition \((\text{within a factor} \sim 3)\), while for model 2 \((\text{solid line})\) we fixed the beaming factor to unity, and the magnetic field is derived from fitting the SED, as are the remaining parameters. In the model computation, the geometry of the source is assumed to be spherical, and electrons are constantly injected to reach equilibrium. Synchrotron and SSC losses are taken into account, while electrons can escape from the source with a typical timescale given by \(t_{\text{esc}}\) (see Chiaberge \& Ghisellini 1999). The minimum energy of the injected electron distribution, together with the escape time, are set so as to not overpredict the emission of the lower energy electrons in both the synchrotron and inverse Compton components (i.e., the flat regions of the SED in the radio and X-ray).

6. DISCUSSION AND CONCLUSIONS

A key point in understanding the nature of the jet emission is to address the following question: what is the reason for the observed brightening of the jet at a projected distance from the nucleus of \(\sim 20\) kpc? The jet in 3C 401 appears to be brighter in the region where bending occurs. This can be explained by relativistic beaming, the presence of shocks that accelerate the electrons along the jet, or a combination of the two. While in FR I jets the jet flow most likely slows down to subsonic and subrelativistic velocities on scales smaller than \(\sim 1\) kpc, there are indications that FR II jets are still relativistic all the way to the hot spots. Radio observations suggest that relativistic bulk motion plays a role in the jet of 3C 401. In fact, Hardcastle et al. (1998) have measured that in a region close to the radio core but still on the scale of kpc, the jet-to-counterjet ratio is \(R_{\text{jet}} > 5\). Although this limit does not allow us to set any firm constraint either to the viewing angle to the jet or to the bulk Lorentz factor of the ejected material, it is an indication that the jet is relativistic at least on those scales. Furthermore, it is widely believed that the presence of hot spots in the lobes of the radio emission is a sign that the jets in FR II galaxies are still supersonic in the region where they impact the ambient medium, and are possibly also relativistic (Georganopoulos \& Kazanas 2003). Therefore, we believe that the most likely interpretation is that the enhancement of the flux is partly or entirely due to relativistic beaming. However, with present observations we cannot totally rule out that part of the jet enhancement occurs because of the presence of shocks in the jet. If this is the case, we expect to observe a progressive steepening of the IR-to-UV spectral slope along the jet as a result of electron aging.

We can estimate the amount of beaming involved by comparing the flux of the jet in the detected and undetected region. From the IR image we derive that the jet is enhanced by a factor of \(\sim 20\), as estimated from the ratio between the flux of blob B and the upper limit derived for a region where the jet is undetected. Assuming \(\delta_B = 1\), as obtained from model 2, we find that \(\delta_B(\delta_{\text{und}})^3 \geq 20\) (\(\delta_{\text{und}}\) refers to the region where the jet is undetected); thus \(\delta_{\text{und}} \leq 0.5\). For \(\Gamma = 5\) this implies a change in the viewing angle of \(\angle 35^\circ\) \((\text{from} \theta \geq 60^\circ \text{ to} \theta \approx 35^\circ)\). Note that under the above assumptions, the Lorentz factor cannot be lower than 2, since for \(\Gamma < 2\), \(\delta(90^\circ) > 0.5\). Higher values of \(\Gamma\) imply an even smaller change in the direction of the jet (e.g., from \(\theta \geq 30^\circ\) to \(\theta \approx 25^\circ\), for \(\Gamma = 10\), but there is no strong evidence

![Fig. 5.—SED and two models for component B. The model parameters are given in Table 2. The dashed line corresponds to model 1 in the table; the solid line corresponds to model 2. We also report radio \((1.5\text{GHz})\) and infrared \((1.6\ \mu\text{m})\) measurements for components A and C. [See the electronic edition of the Journal for a color version of this figure.]](image)
for such a fast relativistic motion from the observations. A similar argument holds for model 1, in which we have \( \delta = 0.5 \).

The presence of relativistic motion on large-scale FR II jets is indeed not surprising. However, the evidence for this is mainly indirect. One of the most convincing arguments is derived from the high Lorentz factors required to enhance the cosmic microwave background radiation field, which is upscattered by the relativistic particles in the jet to produce the observed X-ray flux (Tavecchio et al. 2000; Celotti et al. 2001). But contrary to most (if not all) other “optically bright” jets, in the case of 3C 401 we do not detect any X-ray emission. The reason for the lack of significant high-energy flux might be either “intrinsic” or “extrinsic.”

\textit{Intrinsic}.—The particle density in the comoving frame is in fact quite low. From the model fitting, we derive a value for the so-called “compactness parameter,”

\[ l_{\text{mod1}} = L_{\text{inj}}/\sigma_t/\rho m_e c^2 = 6.0 \times 10^{-6} \]

and

\[ l_{\text{mod2}} = L_{\text{inj}}/\sigma_t/\rho m_e c^2 = 2.0 \times 10^{-6} \]

(e.g., Guilbert et al. 1983), which is a measure of the “density” of the source. \( L_{\text{inj}} \) is the injected luminosity in particles, \( \sigma_t \) is the Thomson cross section, \( \rho \) is the size of the source, and \( m_e \) is the electron mass. Thus, the synchrotron emission peak dominates with respect to the high energy (SSC) peak. In this framework, the source is thus dominated by synchrotron emission, while the SSC radiation is intrinsically low.

\textit{Extrinsic}.—When compared to the magnetic energy density, the external photon field is low as well. In fact, we find that for \( z = 0.2 \),

\[ U'_{\text{CMB}}/U_{\text{EM}} \sim 3 \times 10^{-5} \]

(model 1) and 0.1 (model 2), where \( U'_{\text{CMB}} \) is the energy density of the cosmic microwave background calculated in the rest frame of the jet, assuming \( \Gamma = 5 \) and a viewing angle of 30° (Harris & Krawczynski 2002). Thus, synchrotron radiation is again the dominant radiation mechanism.

As pointed out by Celotti et al. (2001), a third source of photons for inverse Compton (IC) scattering may reside in the “beam” from the central quasar hosted by the nucleus of the galaxy. If the jet axis forms a large angle with the line of sight, the central quasar photons, which are preferentially emitted in the direction of the jet axis, can be upscattered by relativistic electrons in the jet. Then, if the jet has a slower shear layer on kiloparsec scales (as has been suggested in order to explain the limb-brightened appearance of the jet in, e.g., the FR II radio galaxy 3C 353; Swain et al. 1998), the IC radiation is not heavily beamed away from the observer, and it can be detected. However, 3C 401 does not appear to harbor any powerful quasar. This can be inferred both from its optical spectral characteristics and from the nuclear SED; 3C 401 is a narrow-lined low-excitation galaxy, which does not appear to require a high ionizing nuclear flux as it does for objects with high-excitation emission lines (QSOs and narrow-lined high-excitation galaxies). Furthermore, the object does not show any strong central thermal emission associated with the active nucleus either in the optical (Chiaberge et al. 2002) or in the IR. This is clearly seen in our \textit{HST} images in which only a faint central nuclear component is observed (the nuclear properties of the complete sample will be discussed in M. Chiaberge et al. 2005, in preparation).

A further characteristic of the jet SED is worth discussing. In order not to produce significant X-ray flux, the electron distribution must have a cutoff at energies confined between the optical and the X-ray band. As derived from the SED modeling, for a magnetic field of \( B = 10^{-4} \) G, the cutoff energy should be located at a Lorentz factor of \( \gamma \sim \text{few} \ 10^6 \). Typical maximum electron energies in synchrotron-dominated FR I jets are significantly higher (up to \( \gamma \sim \text{few} \ 10^7-10^8 \)), while Sambruna et al. (2004) have shown that jets in powerful FR II/quasars have \( \gamma_{\text{max}} \sim 5 \times 10^5 - 10^6 \).

Thus, on the one hand, our 3C 401 jet shows properties that are intermediate between the two classes of synchrotron-dominated, low-power FR I jets and IC-dominated, high-power FR II/QSOs: its bulk velocity on the kiloparsec scale and its electron distribution are typical of high-power jets, while the dominance of synchrotron radiation in the overall SED is typical of low-power jets. On the other hand, the broadband spectral indices \( \alpha_{\text{opt}} \sim 0.9 \) and \( \alpha_{\text{ox}} \gtrsim 1.4 \) of knot B are atypical (see Fig. 4 in Sambruna et al. 2004), as they would lie in an empty region of the \( \alpha_{\text{opt}} - \alpha_{\text{ox}} \) plane.

An intriguing consequence is that there may be a continuous “sequence” in extended X-ray jets, somehow similar to that observed in jets on a much smaller scale in the case of blazars (Fossati et al. 1998; Ghisellini et al. 1998). In this framework, our jet would represent the prototype of the new “intermediate class,” and their study of it may shed light on the physical differences between the various jets. From the point of view of the observations, the most important property of such intermediate jets is that their SED peaks in the infrared region.

However, we must stress that the jet should be studied in much more detail before drawing conclusions. A crucial step would be to produce a spatially resolved spectral energy distribution of knot B, in order to disentangle the bright “spot” seen in the IR (and possibly at 8.4 GHz) from the rest of the jet. If that “spot” is a region of the jet where electrons are being accelerated (for example, where the jet impacts the interstellar/intergalactic medium), then its SED might be substantially different from the rest of the jet, thus affecting our conclusions based on the “spatially integrated” SED shown in this paper. In particular, the region to be explored is from the IR \( K \) band to the near UV, through deep high-resolution observations that only the \textit{HST} can provide. Another important issue to be investigated through deeper high-resolution images is the change in the spectral slope between the different components of the jet. This may shed light on the possible role of shocks in observed jet brightening and change of direction.

We are grateful to Eddie Bergeron and Juan Madrid for helping us to reduce the NICMOS data. M. C. acknowledges the STScI Visitor Program. We thank J. P. Leahy for providing the 1.5 GHz radio map, which is available at http://www.jb.man.ac.uk/atlas. We thank Markos Georganopoulos for insightful discussions. This paper is based on observations obtained at the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Incorporated, under NASA contract NAS 5-26555.
