(Received 13 March 2021; accepted 29 June 2021; published 26 July 2021)

Nanoscale heat engines are subject to large fluctuations which affect their precision. The thermodynamic uncertainty relation (TUR) provides a trade-off between output power, fluctuations, and entropic cost. This trade-off may be overcome by systems exhibiting quantum coherence. This Letter provides a study of the TUR in a prototypical quantum heat engine, the Scovil–Schulz-DuBois maser. Comparison with a classical reference system allows us to determine the effect of quantum coherence on the performance of the heat engine. We identify analytically regions where coherence suppresses fluctuations, implying a quantum advantage, as well as regions where fluctuations are enhanced by coherence. This quantum effect cannot be anticipated from the off-diagonal elements of the density matrix. Because the fluctuations are not encoded in the steady state alone, TUR violations are a consequence of coherence that goes beyond steady-state coherence. While the system violates the conventional TUR, it adheres to a recent formulation of a quantum TUR. We further show that parameters where the engine operates close to the conventional limit are prevalent and TUR violations in the quantum model are not uncommon.

DO: 10.1103/PhysRevE.104.L012103

Introduction. Nanoscale heat engines [1] have become a topic of wide interest in recent years. In such devices quantum effects become relevant and radically alter the dynamical and thermodynamic properties [2–8]. Nanoscale systems are subject to strong fluctuations in the output power \( P \) which become important when quantifying useful properties such as efficiency and precision [9,10]. At the same time, operation of any engine is associated with the entropy production rate \( \sigma \), which quantifies the thermodynamic cost. It is desirable for an engine to have both a low entropy production rate and high precision. Their trade-off can be quantified by the dimensionless thermodynamic uncertainty

\[
Q = \frac{\sigma \ var(P)}{k_B \left\langle P \right\rangle^2}.
\]

where \( \left\langle P \right\rangle \) and \( \text{var}(P) \) denote the mean and variance of the power in the long time limit and \( k_B \) is the Boltzmann constant. The thermodynamic uncertainty relation (TUR) provides a lower bound, \( Q \geq 2 \) [11–17], which highlights the fundamental relevance of the thermodynamic uncertainty \( Q \).

The TUR has been applied to biomolecular processes [11,13,18,19], heat transport [20], and Brownian clocks [21]. Furthermore, experimental realizations are an area of active development [22–26]. Generalizations have been formulated to cover discrete or time-dependent driving [21,27–30], underdamped Langevin dynamics [31–33], and the presence of measurement and feedback [34]. Beyond the classical regime, quantum effects influence work, fluctuations, and entropy production [35–37], altering the TUR bounds on quantum stochastic systems [25,38–42], e.g., due to coherences [43–46] or particle exchange correlations [20,38,47]. Understanding the detailed reasons for such TUR violations and the possible establishment of more general bounds are important questions in ongoing research.

The Scovil–Schulz-DuBois (SSDB) three-level maser is the prototype for quantum heat engines relying on quantum coherence to do work [48]. In this work we study the thermodynamic uncertainty in the SSDB maser in detail, finding TUR violations induced by coherence, in analogy to Ref. [43]. A comparison to a classical model which obeys the TUR allows us to identify regions of operation where quantum dynamics results in improved operation as quantified by a lower value of \( Q \). Interestingly, such a quantum advantage cannot be anticipated from the off-diagonal elements of the density matrix because the fluctuations are not encoded in the steady state alone. TUR violations should thus be seen as a consequence of coherent dynamics going beyond steady-state coherence.

Quantum advantage in the maser. Figure 1 shows the maser [48], where the three levels are the lower \( l \) and upper \( u \) lasing levels and the excited state \( x \). If \( n_l \gg n_u \), where \( n_u \) is the relevant occupation of the Bosonic bath coupled to level \( x \) with energy \( \omega_x \), we obtain inversion between the laser levels, resulting in maser operation. The steady-state work output of this type of engine is well known from earlier analysis in interaction with classical [49–53] or quantized [54] light.

We probe the thermodynamic uncertainty of the SSDB maser \( Q \) and compare it with the uncertainty of an equivalent classical system \( Q^d \), where the coherent transition between \( u \) and \( l \) is replaced by a classical rate (see Fig. 2).
While the classical system always adheres the TUR, we find regions where \( \mathcal{Q} \) can go as low as 1.68, a significant violation enabled by the quantum-coherent dynamics of the maser. These violations occur at intermediate driving strength \( \epsilon \) [see Fig. 2(a)], while the classical model captures the behavior of the quantum model for both weak and strong driving. For small \( \epsilon \) a perturbative treatment of the drive is justified, while for large \( \epsilon \), the statistics is determined by the rates which mediate heat transfer with the baths, \( \gamma_l \) and \( \gamma_u \). Figure 2(b) shows that the most significant TUR violation occurs at low population \( n_{\alpha} \), where the associated temperature and decoherence are low. Interestingly, coherence may also be disadvantageous, i.e., \( \mathcal{Q} > \mathcal{Q}_c \). This disadvantage happens at finite detuning \( |\Delta| > \Gamma \), where \( \Gamma = (\gamma_u n_u + \gamma_l n_l)/2 \) denotes the broadening of the transition [which is equal to the decoherence rate; see Fig. 2(c)].

Recently, it was suggested that quantum systems which evolve according to Lindblad-type master equations adhere to a quantum TUR [41] \( \mathcal{Q} \geq B \) [see [55] for a detailed evaluation of \( B \) for the SSDB]. For the parameters which provided a significant violation of the classical TUR we find that the SSDB maser remains well within adherence to the quantum TUR [see Figs. 2(a)–2(c)].

**The system master equation.** For a quantitative description, the system is assumed to have a Markovian time evolution governed by the Lindblad master equation [56] (we use \( \hbar = k_B = 1 \) in the following),

\[
\dot{\rho} = -i[H(t), \rho] + \sum_{\alpha} \{\gamma_{\alpha}(n_\alpha + 1)\mathcal{D}_{n_\alpha}[\rho] + \gamma_{\alpha} n_\alpha \mathcal{D}_{n_\alpha}[\rho]\},
\]

with the dissipator \( \mathcal{D}_{n_\alpha}[\rho] = \sigma \rho \sigma^\dagger - \frac{1}{2} [\sigma^\dagger \sigma \rho + \rho \sigma^\dagger \sigma] \).

Here we introduced the bath populations \( n_\alpha \) and the respective transition rates \( \gamma_{\alpha} \) for \( \alpha \in \{u, l\} \). The Hamiltonian \( H(t) = H_0 + V(t) \) consists of a bare term \( H_0 = \omega_l \sigma_{ll} + \omega_u \sigma_{uu} + \omega_1 \sigma_{1l} \) and an external classical field \( V(t) = \epsilon (e^{i\omega t} \sigma_{uu} + e^{-i\omega t} \sigma_{lu}) \) with frequency \( \omega \) and strength \( \epsilon \). The transition operators are defined as \( \sigma_{ij} = |i\rangle \langle j| \).

In addition to the quantum SSDB maser we also consider a classical reference system (with a superscript cl) described by the master equation

\[
\dot{\rho}_{\text{cl}} = \gamma_c (\mathcal{D}_{n_{\alpha}}[\rho_{\text{cl}}] + \mathcal{D}_{n_{\alpha}}[\rho_{\text{cl}}]) + \sum_{\alpha} \left\{ \gamma_{\alpha}(n_\alpha + 1)\mathcal{D}_{n_\alpha}[\rho_{\text{cl}}] + \gamma_{\alpha} n_\alpha \mathcal{D}_{n_\alpha}[\rho_{\text{cl}}] \right\},
\]

where we have introduced the classical transition rate

\[
\gamma_c = \frac{2 \epsilon^2 \Gamma}{\Delta^2 + \Gamma^2},
\]

as obtained by Fermi’s golden rule assuming Lorentzian broadening, which provides the same work output as the quantum model.

**The quantities of interest.** In order to calculate \( \mathcal{Q} \) we need the mean and variance of the power as well as the entropy production rate. Let \( N \) denote the number of cycles done in the nominal direction (i.e., \( l \rightarrow x \rightarrow u \rightarrow l \)) minus the number of cycles in opposite direction. In each cycle, a photon is exchanged with each heat bath. As shown in the Supplemental Material [55], we further find \( \langle P \rangle = \omega_0 \langle N \rangle \) and \( \text{var}(P) = \omega_0^2 \text{var}(N) \), consistent with the picture that a single photon is emitted into the drive field per cycle. We note that this simple relation between heat and work was observed before [57] and that it may break down for higher cumulants [58].

The entropy production rate reads [59]

\[
\sigma = -\frac{\dot{Q}_\alpha}{T_u} - \frac{\dot{Q}_l}{T_l},
\]

where \( \dot{Q}_\alpha \) is the net rate of heat transferred from bath \( \alpha \) to the engine. \( T_u \) is the bath temperature defined from the Bose-Einstein distribution

\[
T_u = \frac{\Omega_u}{\ln(1 + \frac{1}{n_u})},
\]

where \( \Omega_u = |\dot{Q}_u/\langle N \rangle| \) denotes the heat per particle transfer. We note that by using Eq. (6), our results hold for both the definition of heat and work via the full or bare Hamiltonian; see Ref. [53] for more information on this debate. This yields a positive definite entropy production rate

\[
\sigma = \ln \left[ \frac{n_l(n_u + 1)}{n_u(n_l + 1)} \right] \langle N \rangle > 0,
\]

as \( \langle N \rangle \) has the same sign as the thermodynamic driving \( n_l - n_u \) [see Eq. (9)]. Inserting the power and entropy into the definition of \( \mathcal{Q} \), we obtain

\[
\mathcal{Q} = \ln \left[ \frac{n_l(n_u + 1)}{n_u(n_l + 1)} \right] F,
\]

where we introduced the Fano factor \( F = \frac{\text{var}(N)}{\langle N \rangle} \).

To determine the mean and variance of \( N \) we employ full counting statistics [60–62], in which we modify the master equations by introducing counting fields to keep track of the number of energy quanta exchanged with the baths. This procedure yields the same mean rate for the quantum and classical models as detailed in the Supplemental Material [55].
The Fano factor can be written as

$$F = n_l(n_u + 1) + n_u(n_l + 1) - 2\langle N \rangle C,$$  \hspace{1cm} (10)

where $C$ takes the values

$$C_{\text{cl}} = \frac{2\gamma_c + 4\Gamma + \gamma_l + \gamma_u}{D},$$

$$C = C_{\text{cl}} + \frac{\Gamma^2 - \Delta_1^2 \gamma_u \gamma_l (3n_l n_u + n_l + n_u)}{\Delta_1^2 + \Gamma^2}.$$

with $D = \gamma_u \gamma_l (3n_l n_u + n_l + m) + 2\gamma_c (3\Gamma + \gamma_u + \gamma_l)$, for the classical and quantum models, respectively.\n
In contrast to the average rate, the variance thus differs between the quantum and classical models. Here $C$ is larger (smaller) than $C_{\text{cl}}$ if the detuning $|\Delta| < \Gamma$. From Eqs. (8) and (10) we find

$$Q - Q_{\text{cl}} = 2\langle N \rangle \ln \left[ \frac{n_l(n_u + 1)}{n_u(n_l + 1)} \right] (C_{\text{cl}} - C).$$  \hspace{1cm} (12)

Bounds for $Q_{\text{cl}}^\Delta$. Based on Eqs. (8) and (10), the thermodynamic uncertainty can be cast into

$$Q = Q_{\text{pop}} + Q_{\text{tr}},$$  \hspace{1cm} (13)

where the first (population) term depends only on the bath populations and is the same for the quantum and classical models,

$$Q_{\text{pop}} = \ln \left[ \frac{n_l(n_u + 1)}{n_u(n_l + 1)} \right] \frac{n_l(n_u + 1) + n_u(n_l + 1)}{n_l - n_u},$$  \hspace{1cm} (14)

This term always adheres to the TUR, i.e., $Q_{\text{pop}} \geq 2$ [55]. The transport term, which is essential for TUR violations, is given by

![Figure 2](image1.png)

**FIG. 2.** Probe of thermodynamic uncertainty for the SSDB maser $Q$ (solid blue line) and the classical reference system $Q_{\text{cl}}$ (dashed orange line) along (a) driving strength $\epsilon$, (b) bath population $n_u$, and (c) detuning $\Delta$. The fixed parameters are $\gamma_u = 2$, $\gamma_l = 0.1$, and $n_l = 5$, while the parameters $n_u = 0.027$, $\epsilon = 0.15$, and $\Delta = 0$ are varied according to the respective panels. The classical TUR limit is indicated by the dotted black line, and the quantum TUR bound $B$ is indicated by the dash-dotted green line.

Monte Carlo exploration. To explore the thermodynamic behavior of the model we systematically evaluated $Q$ by Monte Carlo sampling over a region of the parameter space (see Fig. 3). Both the quantum and classical models operate close to the conventional TUR limit $Q = 2$ in the great majority of sampled operation points. Quantum violations of the conventional TUR are not uncommon [see the inset in Fig. 3(a)]. On the other hand, $Q_{\text{cl}}^\Delta \geq 2$ is always satisfied, as expected for systems based on classical rate equations. The range of $Q$ stretches slightly wider to both smaller and larger values than $Q_{\text{cl}}^\Delta$ due to the possibility of both quantum advantage and disadvantage [see Figs. 3(a) and 3(b)].

![Figure 3](image2.png)

**FIG. 3.** Histograms of sampled values of (a) $Q$ and (b) $Q_{\text{cl}}^\Delta$ from Monte Carlo exploration of the parameter space. Insets show the subset of the sampled data in the vicinity of the classical TUR limit. The parameters are sampled from the uniform distributions $\gamma_u \in [10^{-4}; 5]$, $n_u \in [10^{-2}; 10]$, $\epsilon \in [10^{-2}; 1]$, and $\Delta \in [0; 1]$, and the $10^8$ data points are arranged in bins with a width of 0.01.
with the steady-state coherence ridge \cite{55}. Surprisingly, a similar ridge is found in coherence \( |\rho_{ud}| \) for the classical reference system. The maser parameters are \( \gamma_{\text{r}} = 2, n_u = 0.027, \gamma_{\text{l}} = 0.1, \) and \( n_l = 5 \). While \( Q \) shows a behavior similar to \( \text{Im}[|\rho_{ud}|] \), \( Q^\text{cl} \) shows behavior similar to \( |\rho_{ud}| \).

![FIG. 4. Heat maps of (a) \( Q \) for the SSDB maser, (b) the off-diagonal matrix element \( |\rho_{ud}| \) and its imaginary component (inset), and (c) \( Q^\text{cl} \) for the classical reference system. The maser parameters are \( \gamma_{\text{r}} = 2, n_u = 0.027, \gamma_{\text{l}} = 0.1, \) and \( n_l = 5 \). While \( Q \) shows a behavior similar to \( \text{Im}[|\rho_{ud}|] \), \( Q^\text{cl} \) shows behavior similar to \( |\rho_{ud}| \).]

\[
Q_{tr} = -\ln \left[ \frac{n_l(n_u + 1)}{n_u(n_l + 1)} \right] 2\langle N \rangle C. \tag{15}
\]

In the classical case, Eq. (11) provides \( C^\text{cl} > 0 \), and the transport term is negative. As TUR is always satisfied here, we have the restriction \( 2 \leq Q^\text{cl} \leq Q_{\text{pop}} \). Both inequalities fail in the quantum case, as we have the quantum advantage \( C > C^\text{cl} \) for \( |\Delta| < \Gamma \), and \( C \) can actually become negative for large values of \( |\Delta| \). In agreement with Fig. 3, the thermodynamic uncertainty may thus take on a larger range of values in the quantum case.

Quantum coherence and TUR. Previous work on TUR in quantum systems showed that quantum coherence can be responsible for TUR violations \cite{43,44,46}. In Fig. 4 we compare \( Q \) with the steady-state coherence \( \rho_{ud} = |u\rangle\langle \rho|l \rangle \) between the lasing levels as a function of detuning and driving. We find particularly low values of \( Q \) for zero detuning and moderate driving in Fig. 4(a). This pattern differs entirely from the coherence \( |\rho_{ud}| \) shown in Fig. 4(b), which exhibits a V-shaped ridge \cite{55}. Surprisingly, a similar ridge is found in \( Q^\text{cl} \) [see Fig. 4(c)], which indicates that the absolute value \( |\rho_{ud}| \) cannot be directly related to quantum effects in \( Q \). Furthermore, the V-shaped coherence pattern extends into regions \( |\Delta| > \Gamma \), where quantum effects provide \( Q > Q^\text{cl} \), i.e., a quantum disadvantage.

On the other hand, the inset in Fig. 4(b) shows that \( \text{Im}[|\rho_{ud}|] \) might be a candidate to explain the TUR violations. In this context, we note that

\[
\langle N \rangle = 2\epsilon \text{Im}[|\rho_{ud}|], \tag{16}
\]
as can be seen from the relation \( \langle P \rangle = -\text{Tr}[\langle \partial_t H \rangle \rho] \). Nevertheless, a finite rate does not ensure the presence of coherence, as the classical model produces the exact same amount of power. Equation (12) shows that any quantum advantage is proportional to \( \langle N \rangle \). Thus, it is rather the mean rate, which can be reproduced by the classical model, than the coherence itself, which is of relevance here.

What distinguishes TUR in the quantum system from its classical counterpart is the variance, a quantity that goes beyond what is encoded in the steady state. Hence, the steady-state coherence cannot fully capture what sets quantum-coherent dynamics apart from the classical system. A similar conclusion was reached in Ref. [63].

Conclusion. In this Letter we studied the performance of the Scovil–Schulz-DuBois heat engine in terms of the thermodynamic uncertainty \( Q \). From the analytical expressions we find that the quantum-coherent dynamics exhibits a quantum advantage compared to its classical counterpart if the detuning is less than the broadening, \( |\Delta| < \Gamma \). In cases of great quantum advantage, the maser violates the conventional TUR limit \( Q > 2 \). Parameter points where the engine operates close to the conventional limit are prevalent, and violations are not uncommon. We also showed that this engine adheres to a recent formulation of a quantum TUR.

While quantum advantages and disadvantages over classical systems are related to the quantum-coherent dynamics, we cannot establish a direct relation between the behavior of the steady-state coherence and that of the thermodynamic uncertainty. The thermodynamic uncertainty depends on the variance of the output power, whose properties, unlike the mean, are not fully imprinted onto the state of the system. This illustrates a need to introduce new quantifiers that measure the coherence present in the dynamics of a system going beyond the density matrix.
