We consider the possible detection of parity violation at the linear level in gravity using polarized anisotropies of the cosmic microwave background. Since such a parity violation would lead to non-zero TB and EB correlations, this makes those odd-parity angular power spectra a potential probe of parity violation in the gravitational sector. These spectra are modeled incorporating the impact of lensing and we explore their possible detection in the context of small-scale (balloon-borne or ground-based) experiments and a future satellite mission dedicated to B-mode detection. We assess the statistical uncertainties on their reconstruction using mode-counting and a (more realistic) pure pseudospectrum estimator approach. Those uncertainties are then translated into constraints on the level of parity asymmetry. We found that detecting chiral gravity is impossible for ongoing small-scale experiments. However, for a satellite-like mission, a parity asymmetry of 50% could be detected at 68% of confidence level (at least, depending on the value of the tensor-to-scalar ratio), and a parity asymmetry of 100% is measurable with at least a confidence level of 95%. We also assess the impact of a possible miscalibration of the orientation of the polarized detectors, leading to spurious TB and EB cross-correlations. We show that in the context of pseudospectrum estimation of the angular power spectra, self-calibration of this angle could significantly reduce the statistical significance of the measured level of parity asymmetry (by e.g. a factor ~ 2.4 for a miscalibration angle of 1 degree). For chiral gravity and assuming a satellite mission dedicated to primordial B-mode, a non detection of the TB and EB correlation would translate into an upper bound on parity violation of 30% at 95% confidence level for a tensor-to-scalar ratio of 0.2, excluding values of the (imaginary) Barbero-Immirzi parameter comprised between 0.2 and 4.9 at 95% CL.

I. INTRODUCTION

The anisotropies of the cosmic microwave background (CMB) are currently the most powerful probe of the physics underlying the primordial universe. Those anisotropies arise into three flavors: total intensity and two degrees of freedom describing its linear polarization. Though CMB polarized anisotropies are measured using two Stokes parameters, Q and U, they are most conveniently described using a gradient-like, E-mode, and a curl-like, B-mode [1, 2].

Such a decomposition of the linearly polarized anisotropies is meaningful at a physical level as it is directly linked to the primordial cosmological perturbations sourcing CMB anisotropies. For instance, on the linear level the B-modes can be sourced by the primordial gravitational waves [3, 5] and not by the scalar fluctuations, thought to be largely responsible for the observed total intensity and E-mode anisotropies. Consequently, a detection of the B-mode anisotropy at large angular scales (\(\ell \lesssim 100\)) in excess of what is expected from the gravitational lensing signal could be seen as a direct validation of inflationary theories, as the latter are considered to be the most likely source of the gravity waves, and could allow for discrimination between different inflationary models. It could also set useful constraints on the reionization period [6]. At smaller angular scales, B-modes are expected to be mainly due to gravitational lensing of CMB photons which converts E-modes into B-modes [7] and therefore their detection – a source of constraints on the matter perturbation evolution at redshifts \(z \sim 1\) when light massive neutrinos and elusive dark energy both play potentially visible roles. Very recently, the direct detection of the lensing-induced B-mode and the primordial B-mode has been reported by the POLARBEAR experiment [8] and the BICEP2 experiment [9], respectively.

In the standard cosmological paradigm, the TB and EB cross-correlations are vanishing. However, they remain important quantities to be estimated from the data. This is because on the one hand, these odd-parity cross-spectra are comprehensive, end-to-end, null tests of the presence of instrumental and/or astrophysical systematic effects still present in the data (see e.g. [10, 11]). On the other hand, as some non-standard cosmological mechanisms could produce nonvanishing odd-parity cross-spectra, their detection could become a smoking gun of such effects with potentially far-reaching consequences for our understanding of the Universe. Examples of such mechanisms include a primordial stochastic magnetic field, which generates TB and EB correlations, if this magnetic field possesses a helical component [12, 14] or a pseudoscalar inflaton field which naturally couples

*Electronic address: agnes.ferte@ias.u-psud.fr
†Electronic address: julien.grain@ias.u-psud.fr
to the electromagnetic field in a parity-dependant way [15, 17]. Similar effects can be obtained due to a rotation of the plane of linear polarization of the CMB photons traveling from the last scattering surface to our detectors. This could result from either the Faraday rotation induced by interaction with background magnetic fields [15, 21] or interactions with pseudoscalar fields on the trajectory of CMB photons [22].

In this paper, we consider the case of odd-parity angular power spectra as probes of parity violation in the primordial Universe as induced by gravity. The implication of chiral gravity on CMB anisotropies has been first explored in Ref. [23] and then in Ref. [24] where it was shown that if parity is violated by gravitation at the linear level, CMB polarized anisotropies should exhibit non vanishing $EB$ and $TB$ cross-correlations. This idea has been theoretically strengthened in Refs. [25–27], and the idea that gravity could be parity dependent can be traced back to its formulation by e.g. Cartan and Kibble [28] or Ashtekar [29]. The possible detection of such parity asymmetry using CMB datas coming from a satellite-like mission has been discussed in Refs. [30, 31], in Ref. [32] in the Horava-Lifshitz framework and in Ref. [33] (including the case of a balloon-borne experiment in the latter).

We amend and elaborate on this proposal of Refs. [23, 24, 30, 31, 33] in three directions. First, chiral gravity leads to primary $TB$ and $EB$ cross-correlations which are latter on, deformed by the weak gravitational lensing by large scale structure. As this could potentially lead e.g. $EE$ correlations to leak into $EB$ correlations (which would partially mask the primary $EB$), we therefore include in the predicted $C_\ell$'s the impact of lensing. Second, we make use of a Fisher matrix formalism to assess the potential detection of chiral gravity from the measurements of CMB polarized anisotropies in two typical experimental setups: small-scale experiments as motivated by operating (or forthcoming) balloon-borne or ground-based experiments such as POLARBEAR, SPTPOL, QUBIC or ACTPOL, for ground-based experiments [34], and, such as SPIDER or EBEX, for balloon-borne experiments [35], and, satellite-like missions as motivated by e.g. LiteBIRD, PRISM or PIXIE proposals [36]. Estimation of the uncertainties on the reconstructed $C_{\ell}^{TB(EB)}$ (subsequently used in the Fisher matrix) is based first on a naive mode-counting (as a reference), and, second, on Monte-Carlo simulations coupled to a realistic statistical, pure pseudospectrum based estimators of angular power spectra. Thirdly, we assess the impact of a miscalibration of the orientation of the polarized detectors which creates spurious $TB$ and $EB$ correlations coming from $TE$ and $EE$, $BB$ respectively.

The paper is organized as follows. The section III is devoted to the theoretical prediction of the $TB$ and $EB$ angular power spectra including the impact of weak gravitational lensing by large scale structure. We present the statistical uncertainties on the reconstruction of $C_{\ell}^{TB(EB)}$ using pure pseudospectrum estimators in Sec.

III. The results of the application of such an approach to the two above-defined typical cases of CMB experiments dedicated to polarization, small-scale experiments and satellite-like missions, are presented in Secs. IVB and V respectively. We finally conclude and discuss the potential detection of chiral gravity within CMB anisotropies in the last section, Sec. VI and discuss the relevance and extension of those results to other possible sources of parity violation in the primordial universe.

The technical details are provided in the appendices A and B.

II. ANGULAR POWER SPECTRA IN CHIRAL GRAVITY

A. Primary anisotropies

If parity invariance is broken by gravity, the amount of gravitational waves produced during inflation differs from one helicity state to another. As a consequence, the primary CMB polarized anisotropies gain non vanishing $TB$ and $EB$ cross-correlations. Using the line of sight solution of the Boltzmann equation [38] and following Ref. [24], the different angular power spectra are given by

$$C_\ell^{XX} = \int dk \left\{ \Delta^X_{\ell} S(k, \eta_0) \Delta^X_{\ell} S(k, \eta_0) P_S(k) \right\}$$

In the above, $X = T, E$ or $B$ and $\Delta^X_{\ell} S(T)$ is the transfer function for scalar(tensor) modes. The number $\varepsilon$ is equal to $(+1)$ for the $TT$, $EE$, $BB$ and $TE$ angular power spectra, and, equal to $(-1)$ for the $TB$ and $EB$ angular power spectra. Clearly, the $TB$ and $EB$ cross-correlations are equal to zero if $P_T^R(k) = P_T^L(k)$ at all $k$ values, as expected in a parity invariant primordial universe. However, if for any reason $P_T^R(k) \neq P_T^L(k)$, then the primary CMB anisotropies would exhibit non vanishing $TB$ and $EB$ cross-correlations. In the following, the $TT$, $EE$, $BB$ and $TE$ correlations will be denoted even power spectra and the $TB$ and $EB$ correlations will be called odd power spectra.

The primary correlations of $BB$, $TB$ and $EB$ types are only sourced by the tensor mode and these angular power spectra are given by

$$C_\ell^{BB} = \int dk \left( \Delta^B_{\ell, T}(k, \eta_0) \right)^2 P_T^{(+)T}(k),$$
$$C_\ell^{TB} = \int dk \Delta^T_{\ell, T}(k, \eta_0) \Delta^B_{\ell, T}(k, \eta_0) P_T^{(-)T}(k),$$
$$C_\ell^{EB} = \int dk \Delta^E_{\ell, T}(k, \eta_0) \Delta^B_{\ell, T}(k, \eta_0) P_T^{(-)T}(k),$$

with

$$P_T^{(+)T}(k) = P_T^R(k) \pm P_T^L(k).$$
Following Ref. [21][27], the primordial power spectra of the left-handed and right-handed gravitational waves differ by two different effective Newton constants. As a consequence, one expects a change in amplitude but identical spectral indices for $P_{T}^{L}$ and $P_{T}^{R}$, i.e. $r_{R} \neq r_{L}$ and $n_{R} = n_{L}$. The same modifications are also obtained in the framework of pseudoscalar inflation [15][17]. We subsequently model the primordial power spectra by

$$\mathcal{P}_{T}^{(\pm)}(k) = \mathcal{A}_{S} \times \left(\frac{k}{k_{0}}\right)^{n_{T}},$$

with $\mathcal{A}_{S}$ the amplitude of the potential for scalar perturbations at the pivot scale, $k_{0}$, (set equal to 0.002 Mpc$^{-1}$ in our study) and, $n_{T}(= n_{R} = n_{L})$ the tilt of the tensor modes. The parameters $r_{(\pm)} = r_{R} \pm r_{L}$ stand for the tensor-to-scalar ratio amounting the amplitude of $P_{T}^{(\pm)}$. The parameter $r_{(+)}$ is positive-valued while $r_{(-)}$ can be either positive-valued ($r_{R} > r_{L}$) or negative-valued ($r_{R} < r_{L}$). Since the $BB$ correlations are only generated by $\mathcal{P}_{T}^{(+)}$ and the $TB$ and $EB$ correlations by $\mathcal{P}_{T}^{(-)}$, the amplitude of $C_{\ell}^{BB}$ measures the cosmological parameter $r_{(+)}$, while the amplitudes of $C_{\ell}^{TB}$ and $C_{\ell}^{EB}$ measure the parameter $r_{(-)}$. In a parity invariant universe, $r_{R} = r_{L}$ and one easily obtains $r_{(+)} = r$, the standard tensor-to-scalar ratio, and $r_{(-)} = 0$. We stress that there is a priori no reason for $r_{(+)}$ to be equal to the tensor-to-scalar ratio of standard cosmology, $r$, except in the case of parity invariant universe. However, what is constrained thanks to a measurement of $C_{\ell}^{BB}$ is $r_{(+)}$ and from that perspective, $r_{(+)}$ plays the same role as $r$.

Parity breaking is amounted by the parameter:

$$\delta = \frac{r_{(-)}}{r_{(+)}} = \frac{r_{R} - r_{L}}{r_{R} + r_{L}},$$

which varies from $-1 \leq \delta \leq 1$ since both $r_{R}$ and $r_{L}$ are greater than or equal to zero. Parity is not broken by gravity if $\delta = 0$. The case of no production of left-handed(right-handed resp.) gravitational waves corresponds to $\delta = 1(-1)$ resp.

Moreover, the opposite convention of $\delta$ can be adopted, as in [30]. It simply changes the sign of the $EB$ and $TB$ correlations. Indeed, through parity transformation, i.e.

$$r_{(+)} \rightarrow r'_{(+)} = r_{(+)} \quad \text{and} \quad \delta \rightarrow \delta' = -\delta,$$

(corresponding to $r_{R} \rightarrow r'_{R} = r_{L}$ and $r_{L} \rightarrow r'_{L} = r_{R}$), the primary CMB anisotropies are changed to

$$C_{\ell}^{TB} \rightarrow C_{\ell'}^{TB} = -C_{\ell}^{TB},$$

$$C_{\ell}^{EB} \rightarrow C_{\ell'}^{EB} = -C_{\ell}^{EB},$$

leaving the four other power spectra unchanged.

**B. Impact of lensing**

During their propagation from recombination to today, CMB photons travel through the potential-well of large scale structures deforming their trajectories because of gravitational lensing. This distorts the spatial distribution of primary anisotropies and deforms their angular power spectra. However, the gravitational lensing is usually neglected as mentioned in Ref.[31]. We propose here to derive the impact of lensing by large scale structure and to show the obtained lensed power spectra. To this end, we adopt the harmonic formalism developed in Ref. [39], extended here to account for the presence of primary $TB$ and $EB$ correlations which are non-zero (see also Ref. [40][41] for a real-space formalism). This computation is explicitly given in App. A and we only provide here the final results. For temperature, one obtains:

$$\tilde{C}_{\ell}^{TT} = [1 + R^{T}] C_{\ell}^{TT} + \sum_{\ell_{1}, \ell_{2}} F_{\ell_{1}, \ell_{2}}^{T} C_{\ell_{1}}^{\phi \phi} C_{\ell_{2}}^{TT},$$

with

$$R^{T} = -\frac{1}{2} \ell(\ell + 1) \sum_{\ell_{3}} \ell_{3}(\ell_{3} + 1) 2 \ell_{1} + 1 \frac{1}{4\pi} C_{\ell_{3}}^{\phi \phi},$$

$$F_{\ell_{1}, \ell_{2}}^{T} = \frac{1}{4} \left[ (\ell_{1} + 1) + \ell_{2}(\ell_{2} + 1) - \ell(\ell + 1) \right]^{2} \times \frac{(2\ell_{1} + 1)(2\ell_{2} + 1)}{4\pi} \left[ \begin{array}{ccc} \ell & \ell_{1} & \ell_{2} \\ 0 & 0 & 0 \end{array} \right]^{2}.$$
that any leakages of primary $C_{\ell}^{TE}$ into $\tilde{C}_{\ell}^{TB}$ are a non-negligible, if not dominant, contaminant of the primary $TB$ cross-correlation. As primary $TE$ are not affected by parity breaking, this would have significantly lowered the efficiency of using the (necessarily lensed) $TB$ angular power spectrum as a probe of chiral gravity.

Finally, the lensed angular power spectra for polarized anisotropies read

$$\tilde{C}_{\ell}^{EE} = [1 + R^P] C_{\ell}^{EE} + \sum_{\ell_1, \ell_2} F_{\ell_1, \ell_2}^{(+)} C_{\ell_1}^{\phi \phi} C_{\ell_2}^{EE}$$

$$+ \sum_{\ell_1, \ell_2} F_{\ell_1, \ell_2}^{(-)} C_{\ell_1}^{\phi \phi} C_{\ell_2}^{BB}$$

$$\tilde{C}_{\ell}^{BB} = [1 + R^P] C_{\ell}^{BB} + \sum_{\ell_1, \ell_2} F_{\ell_1, \ell_2}^{(+)} C_{\ell_1}^{\phi \phi} C_{\ell_2}^{BB}$$

$$+ \sum_{\ell_1, \ell_2} F_{\ell_1, \ell_2}^{(-)} C_{\ell_1}^{\phi \phi} C_{\ell_2}^{EE}$$

$$\tilde{C}_{\ell}^{EB} = [1 + R^P] C_{\ell}^{EB}$$

$$+ \sum_{\ell_1, \ell_2} \left(F_{\ell_1, \ell_2}^{(+)} - F_{\ell_1, \ell_2}^{(-)}\right) C_{\ell_1}^{\phi \phi} C_{\ell_2}^{EB},$$

with

$$F_{\ell_1, \ell_2}^{(\pm)} = \frac{1}{16} [\ell_1(\ell_1 + 1) + \ell_2(\ell_2 + 1) - \ell(\ell + 1)]^2$$

$$\times \frac{(2\ell_1 + 1)(2\ell_2 + 1)}{4\pi}$$

$$\times \left[ \left( \begin{array}{cc|c} \ell & \ell_1 & \ell_2 \\
0 & -2 \\
\end{array} \right) + \left( \begin{array}{cc|c} \ell & \ell_1 & \ell_2 \\
-2 & 0 & 2 \\
\end{array} \right) \right]^2,$$

and

$$R^P = -\frac{1}{2} [\ell(\ell + 1) - 4] \sum_{\ell_3} \ell_3(\ell_3 + 1) \frac{2\ell_3 + 1}{4\pi} C_{\ell_3}^{\phi \phi}.$$

As is the case for $TB$ correlations, the lensed $EB$ power spectrum is not affected by the primary $EE$ and $BB$ power spectra. This once again means that the potential observation of a (necessarily lensed) non-vanishing $EB$ angular power spectrum is a direct tracer of non-zero $EB$ correlations prior to lensing. In the more precise setting of this study, this means that observing non-vanishing $EB$ (as well as non-vanishing $TB$) is a direct view of primary $EB$ cross-correlations due to parity breaking, though $\ell$-modes are reshuffled by lensing.

### C. Numerical results

The explicit computation of the six angular power spectra is done by numerically solving for the Boltzmann equations. To this end, we modified the CLASS Boltzmann code \(^1 \) incorporating two different primordial power spectra for left-handed and right-handed

---

\(^1 \) http://class-code.net

---

![FIG. 1: Upper panel: Angular power spectra for primary CMB anisotropies for $BB$ (black curve), $TB$ (red curves) and $EB$ (blue curves) correlations. The parameters $r_{(+) }$ is set equal to 0.05 and $\delta$ varies from 0.1 (meaning 10% of parity violation) to 1 (100% of parity violation). Solid lines correspond to positive values of the angular power spectra and dashed lines correspond to negative values. Changing from $|\delta|$ to $-|\delta|$ with $r_{(+) }$ unchanged changes the sign of $C_{\ell}^{TB}$ and $C_{\ell}^{EB}$ and leaves $C_{\ell}^{BB}$ unaffected. We note that smaller $|\delta|$ translates into smaller $|\delta_{(+) }|$. Lower panel: Same as upper panel but taking into account the impact of gravitational lensing.](http://example.com/fig1.png)
valued, this parity break is in the right-handed sector, meaning that left-handed tensor modes are not produced at all. The shape of the power spectrum for negative values of $\delta$ is easily inferred from using the transformation rule of the $C_\ell$'s under parity transformation: changing from $(\delta)$ to $(-\delta)$ with $r_{(+)}$ unchanged changes the sign of $C_\ell^{TB}$ and $C_\ell^{EB}$ and leaves $C_\ell^{BB}$ unaffected. For $\delta > 0$, the $TB$ angular power spectrum is negative at the largest scale, $\ell \leq 10$, and the $EB$ spectrum is negative-valued for $\ell = 2$. From the transformation rule under parity, this means that for negative values of $\delta$, the $TB$ angular power spectrum is positive for multipoles smaller than 10 while the $EB$ quadrupole becomes positive. The impact of lensing on the $TB$ and $EB$ power spectra is shown in the lower panel of Fig. 1. As already underlined, gravitational lensing has only a mild impact on the odd-parity angular power spectra.

III. UNCERTAINTIES ON ANGULAR POWER SPECTRUM RECONSTRUCTION

A. Experimental setups

For numerical investigations, we define two fiducial experimental setups. Though idealized, they are chosen to reflect the general characteristics of forthcoming CMB experiments dedicated to $B$-modes detection. Those characteristics which crucially impact on the angular power spectrum reconstruction are the noise level, the beam width and a peculiar sky coverage.

First, we consider the case of a possible satellite experiment aimed at primordial $B$-mode detection. For such an experiment, we relied on the EPIC-2m [44] specifications for the noise level and the beam width, setting these to 2.2 $\mu$K-arcmin for the noise level and 8 arcmin for the beam width. For the peculiar sky coverage of such a ‘nearly full-sky’ experiment, we consider the galactic mask R9 used for polarized data in WMAP 7yr release (see 45) adding the point-sources catalog mask. So we obtain a $\sim 71\%$ sky coverage patch showed in the upper panel of Fig. 2.

Second, we consider the case of small-scale experiments inspired by the EBEX, balloon-borne experiment [45]. The noise level and the beam width are respectively set equal to 5.75 $\mu$K-arcmin and 8 arcmin. The observed part of the sky covers $\sim 1\%$ of the total celestial sphere and its peculiar shape is displayed in the lower panel of Fig. 2. It consists of a square patch of an area of $\sim 400$ square degrees including holes to mimic polarized point-sources removal.

B. Analytical and numerical error bars

We use two approaches to derive the error bars and the covariance matrix on the estimated angular power spectra, denoted $\Sigma$ in the following. The first one is based on simple mode-counting. This underestimates the uncertainties as leakages due to cut-sky effects (and the full complexity of the mask) are not taken into account. Second, we make use of Monte-Carlo simulations using a pure pseudospectrum code for reconstructing the angular power spectra from the maps of the Stokes parameters [46].

1. Mode-counting expressions

The naïve mode counting derivation of the covariance matrix leads to:

$$\langle \Sigma_{\ell_1,\ell_2}^{XY,X'Y'} \rangle = \delta_{\ell_1,\ell_2} \left( \frac{1}{(2\ell + 1)f_{\text{sky}}} \right) \times \left[ \left( C_\ell^{XX} + \frac{N_\ell^{XX}}{B_\ell^2} \right) \left( C_\ell^{YY} + \frac{N_\ell^{YY}}{B_\ell^2} \right) + \left( C_\ell^{XY} + \frac{N_\ell^{XY}}{B_\ell^2} \right) \left( C_\ell^{YX} + \frac{N_\ell^{YX}}{B_\ell^2} \right) \right]$$

FIG. 2: Upper panel: Sky area as observed by the fiducial satellite-like experiment as considered in this work. The sky coverage is $\sim 71\%$ of the total celestial sphere. The mask is a combination of the galactic mask R9 and the point-sources catalog used for polarized data in WMAP 7yr release. Lower panel: Sky area as observed by the fiducial balloon-borne, small-scale experiment as considered in this work. The sky coverages is $\sim 1\%$ of the total celestial sphere.
with $X$, $X'$ and $Y$, $Y'$ taking the values $T$, $E$ and $B$. In the above formulas, the quantities $f_{\text{sky}}$, $B_\ell$ and $N_{\ell}^{XX'}$ described the impact of the instrumental strategy on the CMB anisotropies reconstruction: $f_{\text{sky}}$ stands for the observed (or kept in the analysis) fraction of the sky, $B_\ell$ is the multipolar decomposition of the beam of the telescope, and $N_{\ell}^{XX'}$ describes the instrumental noise power spectrum entering in the estimation of $\hat{C}_{\ell}^{XY}$. As explained in the appendix C of Ref. 44, this noise power spectrum vanishes for $TE$, $TB$ and $EB$ cross-correlations as long as the noise in the $I$, $Q$, and $U$ maps is not correlated between two different Stokes parameters. We will assume here that this is indeed the case.

It is worth to mention that because none of the angular power spectra are vanishing in this setting, the six angular power spectra shows cross-correlations. As an example, the correlations between the $BB$ and $TB$ estimators are given by:

$$
\Sigma_{\ell\ell'}^{BB, TB} = \frac{2\delta_{\ell\ell'}}{(2\ell + 1)f_{\text{sky}}} \hat{C}_{\ell}^{TB} \left[ \hat{C}_{\ell}^{BB} + \frac{N_{\ell}^{BB}}{B_\ell} \right],
$$

which is non zero for non-vanishing $C_{\ell}^{TB}$.

2. Error bars from pure pseudospectrum

We also estimate the statistical uncertainties on the reconstructed $C_\ell$'s using a more elaborated approach based on Monte-Carlo simulations. Though the above-mentioned formulas are easy to handle with, they underestimate the error bars expected using realistic statistical tools to reconstruct the angular power spectra from maps of the CMB sky. In particular, it neglects the impact of leakages due to cut-sky effects in the case of pseudospectrum-based estimation of the $C_\ell$'s. Those leakages between multipoles and between polarization modes (see e.g. Ref. 41) increase the sampling variance of angular power spectra estimations. For the more specific case of $B$-modes, such an increase could be dramatic as the much higher $E$-mode leaks into the much weaker $B$-mode. Those leakages can be corrected on average but, if not corrected at the level of the variances of the estimators, the much higher $C_{\ell}^{EE}$ and $C_{\ell}^{TE}$ will inevitably contribute to the sampling variance of $C_{\ell}^{BB}$, $C_{\ell}^{TB}$ and $C_{\ell}^{EB}$, thus significantly increasing it. We therefore rely on the $\chi^2$pure code 40 which implements the so-called pure pseudospectrum estimators, correcting for $E/B$ mixing on average and at the level of variances 50. The pure decomposition of the polarization field introduced in Ref. 51 allows $E$ and $B$-modes to be exactly separated on a partial sky and for any single realization of the CMB polarized anisotropies, a sufficient condition for removing any $E$-modes leaking into $B$ for all the statistical moments of the angular power spectra estimators.

A prescription based on the pure decomposition has been introduced in Ref. 50 (and later elaborated on in Refs. 52, 53) to built a pseudospectrum estimator for $C_\ell$ free of any $E/B$ mixing. This approach has finally been extended to incorporate odd power spectra in Ref. 40 (see also Ref. 54 for a flat sky implementation of the pure pseudospectrum estimator).

It was shown that the so-called hybrid computation is the most accurate for estimating $BB$, $TB$ and $EB$ angular power spectra for the case of small-scale experiments covering $\sim 1\%$ of the celestial sphere, and assuming a parity invariant universe, i.e. $C_{\ell}^{BB} = C_{\ell}^{EB} = 0$ 44. More recently, the need for such a pure approach in the context of satellite experiments, allowing for an estimation of the $C_\ell$'s over $\sim 71\%$ of the celestial sphere, has been provided for the specific case of the $BB$ angular power spectrum 59. Such a pseudospectrum approach is therefore a method of a choice for analyzing forthcoming data currently taken by small-scale experiments as well as a potential, long-term, satellite mission dedicated to $B$-mode.

We use the $\chi^2$pure code in a Monte-Carlo setting to derive realistic estimates of the statistical uncertainties (including sampling variance and noise variance) for the two above-defined different experimental configurations. The angular power spectra are estimated within band-power with the first bin ranging from $\ell = 2$ to $\ell = 20$ and the following bins having a width of $\Delta_\ell = 40$.

C. Results for the two experimental configurations

Our numerical results for the uncertainties on the reconstruction of the odd-power spectra are depicted in Fig. 3 for the two above-described experimental configurations, and the two approaches to compute the error bars. Black curves are the input angular power spectra. Solid-orange curves stand for the error bars using an $\ell$-by-$\ell$ mode counting derivation, Eq. (23). Dashed-red curves are the error bars obtained from 500 Monte-Carlo simulations using the pure pseudospectrum reconstruction of the angular power spectra. This has to be compared to the binned mode-counting computation of those error bars given by the dashed-orange curves, i.e.

$$
|\Sigma|_{b,b}^{A,A} = \sum_{\ell \in b} \left[ \frac{\ell(\ell + 1)}{2\pi\Delta_\ell} \right]^2 |\Sigma|_{\ell\ell}^{A,A},
$$

where we used the fact that the mode-counting covariance is diagonal in the $\ell$-space.

We consider here the case of $r_{(+)} = 0.1$ and $\delta = 1$ (i.e. $r_{(-)} = 0.1$), in line with the latest constraints on the tensor-to-scalar ratio 9, 50.

---

2 The so-called hybrid computation means that angular power spectra are estimated using pure pseudomultipoles of $B$-types and standard pseudomultipoles of $E$-type.
FIG. 3: Uncertainties on the reconstructed $C_{\ell}^{TB}$ (left panels) and $C_{\ell}^{EB}$ (right panels) angular power spectra for two experimental configurations: a satellite mission covering $\sim 71\%$ of the sky (upper panels) and a small-scale experiment covering $\sim 1\%$ of the sky (lower panels). Black curves are the input angular power spectra. Solid-orange curves stand for the error bars using a $\ell$-by-$\ell$ mode counting derivation. Dashed-red curves are the error bars obtained from 500 Monte-Carlo simulations using the pure pseudospectrum reconstruction of the angular power spectra. This has to be compared to the binned mode-counting computation of those error bars given by the dashed-orange curves.

1. Analytical error bars

As shown in Sec. II, the $TB$ angular power spectra is higher in amplitude than the $BB$ spectrum, and one could be tempted to deduce that detecting $TB$ cross-correlations would be easier than detecting $BB$ correlations. However, one can expect rather high error bars on the reconstructed $\tilde{C}_{\ell}^{TB}$ at large angular scales simply because of the sampling variance. Indeed the sampling variance for the $TB$ correlations reads

$$\Sigma_{\ell\ell}^{TB,TB} = \frac{1}{(2\ell + 1) f_{\text{sky}}} \left[ (C_{\ell}^{TB})^2 + C_{\ell}^{TT} C_{\ell}^{BB} \right].$$

The $TB$ and $BB$ spectra are sourced by tensor perturbations only. However, the $TT$ spectrum is generated by both scalar and tensor perturbations. We therefore expect $\sqrt{C_{\ell}^{TT} C_{\ell}^{BB}} \gg \tilde{C}_{\ell}^{TB}$ and the signal-to-noise ratio for $TB$ roughly scales as

$$\frac{\tilde{C}_{\ell}^{TB}}{\sqrt{\Sigma_{\ell\ell}^{TB,TB}}} \sim \sqrt{(2\ell + 1) f_{\text{sky}}} \left( \frac{\tilde{C}_{\ell}^{TB}}{\sqrt{C_{\ell}^{TT} C_{\ell}^{BB}}} \right),$$

which is much smaller than unity because $C_{\ell}^{TT}$ is sourced by scalar perturbations\(^3\). The same argument applies to the case of the $EB$ cross-correlations as scalar perturbations contribute via $\tilde{C}_{\ell}^{EE}$.

This is clearly highlighted in Fig.2, focusing on the orange curve. For the noise levels considered here, the uncertainties are completely dominated by the sampling variance from $\ell = 2$ to $\ell = 1000$ and, more precisely, by the term $\sqrt{C_{\ell}^{TT(EE)} C_{\ell}^{BB}}$ for $\tilde{C}_{\ell}^{TB(EB)}$. Detecting the $TB$ and $EB$ angular power spectra multipole by multipole is impossible even in this rather optimistic case ($\delta = 1$ and $r(+) = 0.1$) and one should rely on binning for a positive detection of such $C_{\ell}$’s in this framework.

\(^3\) For $BB$, the signal-to-noise ratio is given by $\sqrt{(\ell + 1/2) f_{\text{sky}}}$ for such an ideal case dominated by the sampling variance. Clearly, detecting $\tilde{C}_{\ell}^{BB}$ is easier than detecting $\tilde{C}_{\ell}^{TB}$ though the later is higher in amplitude than the former.
2. Error bars from pure pseudospectrum

The error bars on the $C_{\ell}^{TB(EB)}$'s using the pure pseudospectrum estimation is depicted by the dashed-red curves. For the case of the satellite-like mission, the $TB$ angular power spectrum can be detected in the three first bins while the detection of $EB$ is not possible without a drastic increase of the width of the bandpowers. For the case of small-scale experiments, neither the $TB$ spectrum nor the $EB$ one can be measured, at least with the size of the bandpower here-adopted.

We note here that the expected uncertainties shown in Fig. 3 are very high so that one could be tempted to conclude that a detection of $r_{(-)}$ is impossible. Nevertheless, the fact that detecting $\tilde{C}_{\ell}^{TB(EB)}$ multipole by multipole (or bin by bin) is not possible does not necessarily imply that detecting $r_{(-)}$ is impossible, for the detection of such a parameter is done by resumming the angular power spectrum over bandpowers. Since those bandpowers are assumed to be uncorrelated, this will inevitably decrease the uncertainty on $r_{(-)}$ by a factor $\sim \sqrt{N}$, with $N$ the total number of resummed bins.

IV. FORECASTS ON CHIRAL GRAVITY

A. Fisher matrix formalism

1. Fisher matrix

Detecting chiral gravity using CMB polarized anisotropies translates into the possible detection of non-vanishing CMB angular power spectra of odd type, and subsequently into the possible measurement of $r_{(-)}$ from those odd power spectra. To this end, we will rely on a simple Fisher analysis [57] to translate the uncertainties on the odd power spectrum reconstruction into errors on the recovery of $r_{(-)}$ (see also Ref. [58] for a more elaborated approach). Such an approach has already been proved to be useful in such a context for e.g. forecasting constraints on bouncing cosmology in loop quantum cosmology [59].

As explained in Sec. II the six estimated CMB angular power spectra are cross-correlated and this additional source of information should be kept in the Fisher analysis. We therefore use the six angular power spectra as our “input” data and define the Fisher information matrix as follows:

$$[F]_{ij} = \sum_{A,A',b,b'} \left( \sum \Delta C_{\ell}^{A} \frac{\partial C_{\ell}^{A'}}{\partial \theta_i} \right) \left( \sum \Delta C_{\ell}^{A'} \frac{\partial C_{\ell}^{A}}{\partial \theta_j} \right),$$

where the $A$ and $A'$ superscripts run over $TT$, $EE$, $BB$, $TE$, $TB$ and $EB$, and $b, b'$ denote the bandpowers. Our set of parameters is $\theta_i = (r_{(+)}, r_{(-)})$ and the above Fisher information matrix is just the inverse of the covariance matrix for $\theta_i$ assuming the likelihood to be gaussian. The marginalized signal-to-noise ratio $(S/N)_i$ for a given parameter $\theta_i$ is finally given by $(S/N)_{\theta_i} = \theta_i / \sqrt{\det[F]_{ii}}$.

It is worth mentioning that though only $C_{\ell}^{TB}$ and $C_{\ell}^{EB}$ do depend on $r_{(-)}$, the constraints that can be set on that parameter using the six angular power spectra will be different than the constraint obtained by using solely the two-odd-parity angular power spectra. In the latter case, the covariance matrix entering the Fisher information matrix would be a sub-block of the full covariance matrix. However, the inverse of that sub-block is not equal to the sub-block of the inverse of the full covariance as long as the estimated $TB$ and $EB$ power spectra are correlated to the other spectra, which is indeed the case here.

2. Parameterizing the input angular power spectra

Information about $r_{(+)}$ is in principle contained in the six angular power spectra. However, the $TT$, $EE$ and $TE$ correlations are mainly generated by the scalar inhomogeneities and we can safely set those angular power spectrum to their best-fit shape and considered them as independent of $r_{(+)}$. This approximation is valid as in this study, we will consider values of $r_{(+)}$ smaller than 0.2. Information about $r_{(-)}$ is solely contained in the $TB$ and $EB$ cross-correlations. We therefore modeled the CMB anisotropies as $\tilde{C}_{\ell}^{BB} = f(r_{(+)}))$ as a function of $r_{(+)}$ and, $\tilde{C}_{\ell}^{TB(EB)} = f(r_{(-)}))$ as functions of $r_{(-)}$. The parameters $r_{(+)}$ provide the global amplitude of the $B$-related angular power spectra. Those power spectra can therefore be parametrized as an amplitude, given by $r_{(+)}$ for $\tilde{C}_{\ell}^{BB}$ and given by $r_{(-)}$ for $\tilde{C}_{\ell}^{TB(EB)}$, multiplied by a template (plus a constant term coming from lensing for the specific case of the $BB$ spectrum). The different templates will be denoted using calligraphic font, $\mathcal{T}$.

As a function of $r_{(+)}$, the lensed $BB$ angular power spectrum reads

$$\tilde{C}_{\ell}^{BB}[r_{(+)}] = r_{(+)} \times \mathcal{T}_{\ell}^{BB} + \mathcal{T}_{\ell,lens}^{EE\rightarrow BB},$$

with $\mathcal{T}_{\ell}^{BB}$ and $\mathcal{T}_{\ell,lens}^{EE\rightarrow BB}$ two fiducial angular power spectra, independent of $r_{(+)}$, and given by

$$\mathcal{T}_{\ell}^{BB} = \left[ 1 + R_{\ell}^{P} \right] C_{\ell}^{BB}[r_{(+)} = 1]$$

$$+ \sum_{\ell_1, \ell_2} F_{\ell_1, \ell_2}^{(+)} C_{\ell_1}^{\phi\phi} C_{\ell_2}^{BB}[r_{(+)} = 1],$$

and

$$\mathcal{T}_{\ell,lens}^{EE\rightarrow BB} = \sum_{\ell_1, \ell_2} F_{\ell_1, \ell_2}^{(-)} C_{\ell_1}^{\phi\phi} C_{\ell_2}^{EE}.$$
angular power spectra involved in $C^{BB}_{\ell,\ell'=s}$ is obtained using the Planck best fit. The two odd angular power spectra are similarly expressed using two fiducial power spectra which do not depend on $r_\ell$, i.e.

$$\tilde{C}^{TB(E)}_\ell[r_\ell]=r_\ell \times T^{TB(E)}_\ell,$$

with

$$T^{TB}_\ell = \left[ 1 + R^{TB}_\ell \right] C^{TB}_\ell[r_\ell=1] + \sum_{\ell_1,\ell_2} F_{\ell \ell_1 \ell_2}^{TB} C^{TB}_\ell C^{TB}_{\ell_1}[r_\ell=1],$$

and

$$T^{EB}_\ell = \left[ 1 + R^{EB}_\ell \right] C^{EB}_\ell[r_\ell=1] + \sum_{\ell_1,\ell_2} \left( F^{(+)}_{\ell \ell_1 \ell_2} - F^{(-)}_{\ell \ell_1 \ell_2} \right) C^{\phi\phi}_\ell C^{EB}_{\ell_2}[r_\ell=1].$$

As is the case for the $BB$ angular power spectrum, the two fiducial power spectra $C^{TB(E)}_\ell[r_\ell=1]$ are easily computed using the line of sight solution and setting $r_\ell$ equal to 1.

The parameter $r_\ell$ plays the same role as $r$ in standard cosmology. As a consequence, any observational constraint on $r$ can be directly translated into a constraint on $r_\ell$. We remind that from temperature as measured by the PLANCK satellite, the tensor-to-scalar ratio is bounded from above: $r < 0.11$ at 95% CL [56], while the latest measurement of polarization by the BICEP2 experiment constrains $r = 0.2^{+0.07}_{-0.05}$ [9]. This latest constraint on the tensor-to-scalar ratio probably needs some confirmation. As a consequence, we will explore values of $r_\ell$ ranging from 0.007 to 0.2 with a specific focus on the $r_\ell = 0.05, 0.1$ and 0.2

### B. Detection of $r_\ell$: satellite mission

#### 1. Results with mode-counting covariance

We first consider the case of the signal-to-noise ratio on the parameter $r_\ell$. A preliminary study is to inquire the values of the signal-to-noise ratio obtained on the above-mentioned parameters relying on a simple mode-counting error bars estimation. This warrants an efficient exploration of the measurable range of $r_\ell$ and $\delta$ using the $X^2$PURE code for a correct estimation of the uncertainties.

Let us first briefly mention that taking into account the $TT$, $EE$, $BB$ and $TE$ power spectra brings an additional amount of information thus increasing the signal-to-noise ratio on $r_\ell$. This additional piece of informations simply consists in the fact that those angular power spectra do not depend on $r_\ell$ and it is finally transferred into the ending values of $\langle F \rangle_{r_\ell, r_\ell}$ since the TB and EB spectra are correlated to the four other ones. Without such correlations, adding $TT$, $EE$, $BB$ and $TE$ would have not change the signal-to-noise ratio. Considering the case of $r_\ell = 0.1$, the derived signal-to-noise ratio on $r_\ell$ using solely $TB$ and $EB$ would be $\sim 5$, to be compared to 5.6 using the full set of angular power spectra (see Tab. 1).

![Table I: Signal-to-noise on $r_\ell$ for different values of $r_\ell$ in the case of satellite mission and using a mode-counting expression for the error bars on the angular power spectra reconstruction. The underlined values correspond to a detection at 2$\sigma$ of parity violation.](image)

The table I summarizes our results on $(S/N)_{r_\ell}$ for different values of $r_\ell$ and $r_\ell$ (keeping in mind that $r_\ell \leq r_\ell$) using the mode-counting expressions for the covariance of the $C_\ell$ and marginalized over $r_\ell$. We note that the correlations between $r_\ell$ and $r_\ell$ are small for the ranges of values here-explored, i.e.

$$\frac{F_{r_\ell, r_\ell}}{\sqrt{F_{r_\ell, r_\ell} F_{r_\ell, r_\ell}}} \sim 10^{-3}.$$ 

However, the signal-to-noise ratio for a fixed value of $r_\ell$ decreases for higher values of $r_\ell$ since the higher $r_\ell$, the higher $\tilde{C}^{BB}_\ell$ and the higher the uncertainties on $\tilde{C}^{TB(E)}_\ell$. This translates inevitably into higher uncertainties on $r_\ell$.

* A 2$\sigma$ detection of parity violation is guaranteed if $r_\ell \geq 0.05$ and $r_\ell \geq 0.05$. The values of $r_\ell = 0.03$ appears as a threshold value since for $r_\ell < 0.03$ the signal-to-noise ratio is systematically below unity. For this precise value of $r_\ell = 0.03$, the signal-to-noise ratio on $r_\ell$ varies from 1.44 to 2.44, for $r_\ell = 0.1$ (a parity violation of 30%) and $r_\ell = 0.03$ (a parity violation of 100%), respectively.

Moreover, for a tensor-to-scalar ratio $r = 0.2$ as favored by the BICEP2 experiment [3], a detection of chiral gravity with at least 2$\sigma$ is expected for parity violation greater or equal to 35%.

The figure 4 shows the $(S/N)_{r_\ell}$ (black crosses) and $(S/N)_{r_\ell}$ (colored lines) as a function of $r_\ell$ and for different level of parity violation, $\delta$ ranging from 10% to 100%. (We remind that for a fixed value of $\delta$, the value of $r_\ell$ increases for higher values of $r_\ell$.) For $r_\ell \leq 0.11$ (as favored by the PLANCK results on temperature anisotropies), a 3$\sigma$ detection of parity violation can be achieved for $\delta \geq 70\%$ and a 2$\sigma$ detection is possible for a parity violation greater than 50%, and a minimal value of $r_\ell \sim 0.05$ appears as mandatory for such a detection.
For $r(+) = 0.2$ (as favored by polarization measurements of BICEP2), $\delta = 40\%$ could be detected at $3\sigma$.

2. Results with pure pseudo-$C_\ell$ covariance

Based on this optimistic exploration of the detectable range of parity violation, we then estimate realistic statistical error bars on the reconstructed angular power spectra in the context of the pure pseudospectrum estimators. Our results are summarized in the table II considering $r(+) = 0.05$, $0.1$ and $0.2$ and $\delta = 0.5$ and $1$.

For the most optimistic case, i.e. $r(+) = 0.2$ and $\delta = 1$, the obtained signal-to-noise ratio on the $r(-)$ parameter is $(S/N)_{r(-)} = 5.46$ then a detection at $5\sigma$ would be possible. This has to be compared to a $10\sigma$ detection assuming the (underestimated) mode-counting derivation of the statistical uncertainties. If for that same value of $r(+) = 0.2$, parity violation is reduced to $\delta = 0.5$ (corresponding to $r(-) = 0.1$), its detection is reduced by more than a factor $2$, the signal-to-noise ratio on $r(-)$ being $\sim 2.5$. The same conclusions are drawn for the case of $r(+) = 0.1$, the signal-to-noise ratio ranging from $3.67$ for $\delta = 1$ down to $1.51$ for $\delta = 0.5$, using the pure reconstruction of B-modes. We finally look at the case of $\delta = 1$ and $r(+) = 0.05$. The obtained result is: $(S/N)_{r(-)} = 2.35$ meaning a detection of chiral gravity of at least $2\sigma$ for $\delta = 1$. (For the same situation and assuming the mode-counting estimation of the error bars, a $3\sigma$ detection would have been inferred.) Similarly, if the level of parity violation is only of $50\%$ (corresponding to $r(-) = 0.025$), the signal-to-noise ratio is reduced by a factor $\sim 2$.

We also consider the extreme case where parity is not violated, $\delta = 0$, and setting $r(+) = 0.05$ and $r(+) = 0.2$. In the first case, the computed value of the uncertainty on the value of $r(-)$ is $\sigma_{r(-)} = 0.023$. This fixes a minimal detectable value of $r(-) \sim 0.046$ at $95\%$ CL for such a possible satellite mission dedicated to $B$-mode, assuming $r(+) = 0.05$. In that case, detecting $EB$ and $TB$ power spectra compatible with zero corresponds to an upper bound on the level of parity violation of $\delta \leq 0.92$ at $95\%$ CL. For $r(+) = 0.2$, this upper bound becomes $\delta \leq 0.39$ at $95\%$ CL.

3. Impact of miscalibration angle

There are many systematic effects affecting the reconstruction of the Stokes parameter starting from the time stream data. Among them, a miscalibration of the projection on the sky of the polarization orientation of the detectors will turn out into a rotation of the Stokes parameter, $P_\pm \rightarrow P^{(\text{obs})}_\pm = e^{\pm 2\Delta\psi} \times P_\pm$. A way to estimate $\Delta\psi$ is to put the detecting $TB$ and $EB$ correlation equal to zero as they are expected to vanish in standard cosmology. In the context of cosmological parity-violation parametrized by e.g. $r(-)$, the miscalibration angle has to be estimated from $TB$ and $EB$ jointly to $r(-)$. We propose to quantify how the miscalibration of the polarization angle can deteriorate the previous obtained constraints on chiral gravity.

As a consequence of this systematic effect, the observed angular power spectra are a linear combination of the real CMB angular power spectra. With non-vanishing $TB$ and $EB$ cross-correlations, the observed angular power spectra are:

\begin{equation}
\tilde{C}_\ell^{TT} \text{ (rot)} = \tilde{C}_\ell^{TT},
\end{equation}

\begin{equation}
\tilde{C}_\ell^{TE} \text{ (rot)} = \cos(2\Delta\psi)\tilde{C}_\ell^{TE} - \sin(2\Delta\psi)\tilde{C}_\ell^{TB},
\end{equation}

\begin{equation}
\tilde{C}_\ell^{TB} \text{ (rot)} = \sin(2\Delta\psi)\tilde{C}_\ell^{TE} + \cos(2\Delta\psi)\tilde{C}_\ell^{TB},
\end{equation}

\begin{equation}
\tilde{C}_\ell^{EE} \text{ (rot)} = \cos^2(2\Delta\psi)\tilde{C}_\ell^{EE} + \sin^2(2\Delta\psi)\tilde{C}_\ell^{BB} + \sin(4\Delta\psi)\tilde{C}_\ell^{EB},
\end{equation}

\begin{equation}
\tilde{C}_\ell^{BB} \text{ (rot)} = \sin^2(2\Delta\psi)\tilde{C}_\ell^{EE} + \cos^2(2\Delta\psi)\tilde{C}_\ell^{BB} - \sin(4\Delta\psi)\tilde{C}_\ell^{EB},
\end{equation}

\begin{equation}
\tilde{C}_\ell^{EB} \text{ (rot)} = \frac{1}{2} \sin(4\Delta\psi) \left( \tilde{C}_\ell^{EE} - \tilde{C}_\ell^{BB} \right) + \cos(4\Delta\psi)\tilde{C}_\ell^{EB}.
\end{equation}

As compared to the results shown in e.g. Ref. [61], one...
FIG. 5: A miscalibration of the polarization angle impacts the amplitude and shape of the power spectra. The unrotated power spectra of the $B$-modes and the $TB$ and $EB$ cross-correlations are depicted in black solid curves from left to right panels. The difference between the rotated power spectra and the unrotated is represented in dashed lines for different values of the miscalibration angle $\Delta \psi$. The biases, $\Delta r_{(\pm)} = (r_{(\pm)}^{(\text{bias})} - r_{(\pm)})$, and their associated error bars are depicted in Fig. 5 as a function of $\Delta \psi$ and for different input values of $r_{(\pm)}$. It shows that for $\Delta \psi \lesssim 0.1$ degree, the measured $r_{(\pm)}$ is compatible with the input value, $r_{(\pm)}$, within the 1σ uncertainty. For higher values of $\Delta \psi$, the bias would translate into a false detection of parity violation. We mention that most of the bias comes from the $EB$ spectrum since its intrinsic CMB contribution is rapidly dominated by spurious power spectra due to the miscalibration, i.e. $\Delta C_{EB} \approx 2(\Delta \psi)C_{EB}^{\text{rot}}$ with the first term being the intrinsic $EB$ correlations and the second term the spurious $EB$ correlation as induced by miscalibration of the orientation of the polarisers. This means that positive-valued $\Delta \psi$ leads to a positive bias while negative values of $\Delta \psi$ leads to a negative bias.

The first effect of a miscalibration on the detection of parity violation would be to bias the measurement of $r_{(\pm)}$ if such rotation is not taken into account in the modelized $C_{\ell}$'s. Assuming that $C_{\ell}^{A}(th)$ is not rotated by the miscalibration angle though the observed spectra are, the recovered, and therefore biased, value of $r_{(\pm)}$, noted $r_{(\pm)}^{(bias)}$, is obtained by minimizing the $\chi^2$:

$$\chi^2 = \sum_{A,A',b,b'} \left( C_{b}^{A}(th) - C_{b}^{A}(obs) \right) \Sigma A,A',b,b'^{-1} \left( C_{b'}^{A'}(th) - C_{b'}^{A'}(obs) \right),$$

(39)

with $C_{b}^{A}(th)$ the theoretically predicted angular power spectra, considered as functions of the set of parameters enlarged to $\theta_i = (r_{(\pm)}, \Delta \psi)$, and $C_{b}^{A}(obs)$ the reconstructed angular power spectra. The error bars on the reconstructed values of the parameters is the Fisher information matrix at the peak of the likelihood and is given by Eq. (36), assuming that the estimated power spectra $C_{b}^{A}(obs)$ are unbiased.

can notice the additional contribution of $\tilde{C}_{\ell}^{TB}$ and $\tilde{C}_{\ell}^{EB}$. However, even in the case of vanishing $TB$ and $EB$ spectra, such miscalibration leads to spurious non-vanishing odd-parity angular power spectra. In Fig. 5 the intrinsic CMB angular power spectra (solid-back curves), $\tilde{C}_{\ell}$, and the leaked power due to rotation (dashed-colored curves), $\Delta C_{\ell} = (\tilde{C}_{\ell}^{(rot)} - \tilde{C}_{\ell})$, are displayed for the $BB$, $TB$ and $EB$ correlations and $\Delta \psi = 0.1$, 0.5 and 1 degree.

We note that the above modeling of the impact of miscalibrating the orientation of the detectors implicitly assumes that such angle is identical over the entire observed patch. If some variations are allowed, the resulting angular power spectra would be a convolution of the intrinsic CMB spectra with the angular power spectra of the rotation angle. This would significantly increase the complexity of the problem as this convolution mixes different patches. If some variations are allowed, the resulting angular power spectra would be a convolution of the intrinsic power spectra of the rotated power spectra and the unrotated is represented in dashed lines for different values of the miscalibration angle $\Delta \psi$. The difference between the rotated power spectra and the unrotated is represented in dashed lines for different values of the miscalibration angle $\Delta \psi$. The biases, $\Delta r_{(\pm)} = (r_{(\pm)}^{(bias)} - r_{(\pm)})$, and their associated error bars are depicted in Fig. 5 as a function of $\Delta \psi$ and for different input values of $r_{(\pm)}$. It shows that for $\Delta \psi \lesssim 0.1$ degree, the measured $r_{(\pm)}$ is compatible with the input value, $r_{(\pm)}$, within the 1σ uncertainty. For higher values of $\Delta \psi$, the bias would translate into a false detection of parity violation. We mention that most of the bias comes from the $EB$ spectrum since its intrinsic CMB contribution is rapidly dominated by spurious power spectra due to the miscalibration, i.e. $\Delta C_{EB} \approx 2(\Delta \psi)C_{EB}^{\text{rot}}$ with the first term being the intrinsic $EB$ correlations and the second term the spurious $EB$ correlation as induced by miscalibration of the orientation of the polarisers. This means that positive-valued $\Delta \psi$ leads to a positive bias while negative values of $\Delta \psi$ leads to a negative bias.

d. Statistical uncertainties with mode-counting–The proper approach consists in fitting for the three
parameters $\theta_i = (r_{(\pm)}, r_{(-)}, \Delta \psi)$ by minimizing the $\chi^2$. The final estimate will be unbiased and the uncertainties are given by the Fisher information matrix assuming that the theoretical power spectra are appropriately modeled, i.e. $C_b^{(\text{th})} = C_b^{(\text{rot})}$. As $r_{(-)}$ and $\Delta \psi$ could be degenerated, one should expect the marginalized error bars on $r_{(-)}$ to be enlarged.

Using the mode-counting for estimating the covariance on the reconstructed angular power spectra, our numerical investigations show that the signal-to-noise ratio on $r_{(-)}$, for $r_{(\pm)}$ ranging from 0.004 to 0.2 and $\Delta \psi$ varying from 0.1 to 1 degree, are only degraded by a factor $\sim 10^{-5}$ as compared to the case without such miscalibration angle, meaning that the jointed reconstruction of $\Delta \psi$ with $r_{(-)}$ only marginally affects the detection of parity violation. This is in perfect agreement with the results obtained in e.g. Ref. [33] where they consider both parity violation in the primordial universe and homogeneous cosmic birefringence. However, this conclusion is only valid assuming the mode-counting expressions for the covariance on the estimated angular power spectra. In the appendix [B] we prove the following statement: assuming that i) the covariance matrix on the estimated angular power spectra, $\Sigma$, is given by the mode-counting expression, ii) the entire set of correlations between the six estimated angular power spectra is taken into account, and, iii) the covariance matrix $\Sigma$ is dominated by the sampling variance, then it is shown that the sub-block $(r_{(\pm)}, r_{(\pm)})$ of the Fisher information matrix is equal to the Fisher matrix as derived without any miscalibration angle, and that the correlations between $r_{(\pm)}$ and $\Delta \psi$ does not depend on the values of $\Delta \psi$. Theoretically speaking, the hypothesis of the sampling variance dominated regime is not met at small angular scales. However, most of the constraints on $r_{(\pm)}$ come from the largest angular scales where noise variance is negligible. As a consequence, supposing that uncertainties are dominated by sampling variance is a valid assumption in practice. Moreover, our numerical results shows that the parameters $r_{(\pm)}$ are poorly degenerated with $\Delta \psi$ for the range of values of $\Delta \psi$ here-considered, i.e.

$$\frac{\mathbf{F}_{r_{(\pm)}, \Delta \psi}}{\sqrt{\mathbf{F}_{r_{(-)}, r_{(-)}} \mathbf{F}_{\Delta \psi, \Delta \psi}}} \sim 10^{-6} - 10^{-5}.$$ 

This means that in practice, the (symmetric) Fisher information matrix is well approximated by

$$\mathbf{F} \approx \begin{pmatrix} F_{r_{(\pm)}, r_{(\pm)}} & F_{r_{(\pm)}, r_{(-)}} & \epsilon_{(\pm)} f_{(\pm)}(r_{(\pm)}) \\ F_{r_{(-)}, r_{(-)}} & \epsilon_{(-)} f_{(-)}(r_{(-)}) & F_{r_{(-)}, \Delta \psi} \\ F_{\Delta \psi, \Delta \psi} & F_{\Delta \psi, r_{(-)}} & F_{\Delta \psi, \Delta \psi} \end{pmatrix},$$

with $F_{r_{(\pm)}, r_{(\pm)}}$ derived without a miscalibration error, as in Sec. [IV B 1] and $\epsilon_{(\pm)} \sim 10^{-5}$. As a consequence, the signal-to-noise ratio as derived in the previous section, Sec. [IV B 1] remains relevant even with a non-vanishing miscalibration angle.

We have further checked the above argument by two numerical experiments. On the one hand, we significantly increased the noise level which breaks the hypothesis of being sampling-variance dominated. On the other hand, we only take the diagonal of the covariance matrix $\Sigma$, which break the hypothesis of using all the information through the correlations between different angular power spectra. In both cases, we do observe that the signal-to-noise ratio on e.g. $r_{(-)}$ indeed decreases for higher values of $\Delta \psi$. We have also checked numerically that $\mathbf{F}_{r_{(\pm)}, \Delta \psi}$ does not depend on the value of $\Delta \psi$.

c. Statistical uncertainties with the pure pseudospectrum approach— We have finally investigated the effect of a joint reconstruction of the miscalibration angle, $\Delta \psi$, and $r_{(-)}$ in the context of the pure pseudospectrum estimation of the $C_l$’s. We consider the two cases $r_{(+)}/r_{(-)} = 0.1$ and 0.2 and subsequently derive the signal-to-noise ratio on $r_{(-)}$ marginalized over both $r_{(\pm)}$ and $\Delta \psi$. If $\Delta \psi$ is indeed equal to zero, the detection of $r_{(-)}$ is only marginally affected since the signal-to-ratio ratio is degraded by a relative factor of $10^{-4}$. However, this signal-to-noise ratio is reduced for higher values of $\Delta \psi$. For $\Delta \psi = 0.1$ degree, $(S/N)_{r_{(-)}}$ is reduced to 5 for $r_{(+)}/r_{(-)} = 0.2$ (to be compared to 5.46 without miscalibration) and to 2.96 for $r_{(+)}/r_{(-)} = 0.1$ (to be compared to 3.67). This corresponds to a decrease by a factor $\sim 1.09$. For $\Delta \psi = 1$ degree, the reduction factor is $\sim 2.4$, obtaining $(S/N)_{r_{(-)}}=2.23$ for $r_{(+)}/r_{(-)} = 0.2$ and $(S/N)_{r_{(-)}}=1.58$ for $r_{(+)}/r_{(-)} = 0.1$. This shows that the non-degeneracy between $r_{(\pm)}$ and $\Delta \psi$ (as mentioned in Ref. [33]) is only valid in the context of the mode-counting expression for the covariance.

We believe the fundamental reason for such a result is that pseudospectrum based estimators does not allow for accessing to the whole set of correlations between the six estimated angular power spectra, due to the joint effect of mode-mixing and binning. Since keeping track of all the correlations was one of the mandatory assumptions
used in App. [3] this probably explains why in the more realistic case of pure pseudospectrum reconstruction of the $C_{l}$’s, non-vanishing $\Delta \psi$ then impacts on the significance of the estimation of $r_{(-)}$.

d. Inhomogeneous cosmic birefringence—As previously underlined, the impact of miscalibrating the orientation of the polarized detectors is identical to the cosmological effect of homogeneous cosmic birefringence. However, such cosmic birefringence can also have an inhomogeneous contribution. This could be the case if e.g. a scalar field coupled to the fermion current (therefore generating CPT violation) also exhibits some inhomogeneities in its energy density, as it should be since such a scalar field inevitably evolves in a perturbed FLRW space-time [62, 63]. In that case the rotation angle due to cosmic birefringence splits into an homogeneous part, $\alpha$, and an inhomogeneous part, $\delta \alpha (\vec{n})$, with $\delta \alpha \ll 1$. This allows for performing a Taylor expansion to infer the impact of that inhomogeneous sector on the CMB angular power spectra.

Considering this additional contribution and the presence of primary $EB$ and $TB$ contribution, the observed angular power for e.g. $TB$ correlations will receive new contributions proportional to $(\sin(2\alpha)C_{l}^{TB} + \cos(2\alpha)(C_{l}^{TB} - C_{l}^{BB})) \times \langle \delta \alpha^2 \rangle$. Similar terms arise for the $EB$ spectrum where $(\sin(2\alpha)C_{l}^{TB} + \cos(2\alpha)(C_{l}^{TB} - C_{l}^{BB}))$ is replaced by $(\sin(4\alpha)(C_{l}^{EE} - C_{l}^{BB})/2 + \cos(4\alpha)C_{l}^{EB})$. (We refer the interested reader to Refs. [62, 63] for a more detailed computation and we only focus here on orders of magnitude.) Those corrections are of second order, being proportional to $\langle \delta \alpha^2 \rangle$. Following Ref. [62], the amplitude of $\langle \delta \alpha^2 \rangle$ has been estimated to be of the order of $10^{-3}$. This means that the biases derived by assuming a purely homogeneous birefringence may changed by a factor $\sim 10^{-3}$, which is well within the statistical uncertainties, making our previously derived results still relevant for inhomogeneous cosmic birefringence.

C. Detection of $r_{(-)}$: small-scale experiment

Our results on the signal-to-noise for $r_{(-)}$ in the case of a small-scale experiment are summarized in Tab. [III] assuming the mode-counting for the derivation of the covariance matrix. Clearly in this case, the measurement of such a parameter is impossible as $\langle S/N \rangle r_{(-)} < 1.5$, even in the most optimistic case of $r_{(+)} = r_{(-)} = 0.2$. This is because most of the constraints on $r_{(-)}$ comes from the largest angular scale which are unachievable for an experiment covering 1% of the celestial sphere.

Using the covariance as obtained from a pure pseudospectrum estimation of the angular power spectra only degrades the signal-to-noise ratio. For example, in the case of $r_{(+)} = r_{(-)} = 0.1$ (i.e. $\delta = 1$), we obtain $\langle S/N \rangle r_{(-)} = 0.2$, as compared to 0.64 by using the mode-counting approach.

For a parity-invariant primordial universe, i.e. $r_{(-)} = 0$, the marginalized uncertainty on $r_{(-)}$ for $r_{(+)} = 0.05$ is

| $r_{(+)}$ | $r_{(-)}$ |
|---------|---------|
| 0.2     | 0.1     |
| 0.07    | 0.05    |
| 0.03    | 0.007   |

$\sigma_{r_{(-)}} = 0.36$. Therefore, the $\delta$ parameter is greater than unity which is theoretically irrelevant, meaning that no significant upper bound on the level of parity violation can be established using data from ongoing or forthcoming small-scale experiments.

V. CONCLUSION AND DISCUSSION

In this paper, we investigate the constraints that could be set on chiral gravity from the detection of the CMB $TB$ and $EB$ correlations, taking into account statistical uncertainties as incurred by pure pseudospectrum reconstruction of the CMB angular power spectra and considering the impact of miscalibrating the orientation of the polarized detectors. (We stress that all the constraints we have set are for positive values of $r_{(-)}$. They however equally apply to negative values of $r_{(-)}$ as in practice, the derived constraints are for $|r_{(-)}|$.)

We have shown that such a detection of parity violation leading to non zero $C_{l}^{TB(EB)}$ is beyond the scope of forthcoming small-scale measurements of CMB polarized anisotropies. Even in the most optimistic case of 100% of parity violation and a tensor-to-scalar ratio of 0.2, and underestimating the uncertainties by using a mode-counting approach, the signal-to-noise ratio on the amplitude of parity asymmetric tensor mode is only of $\sim 1.2$, and it rapidly diminishes to values smaller than unity for smaller values of the tensor-to-scalar ratio, $r_{(+)}$, or a smaller percentage of parity violation. This is because most of the constraints come from the largest angular scales which cannot be measured with enough significance by those experiments. Moreover, even in the case of vanishing $TB$ and $EB$ cross-correlations, the statistical uncertainties on their reconstruction via pure pseudospectrum estimators lead to an upper bound of the level of parity violation of more than 100% at 95% CL.

Since this level is theoretically bounded from above at 100%, this means that no significant constraint can be set on this type of parity violation using data from ongoing or forthcoming small-scale experiments.

In the case of a potential satellite mission dedicated to primordial $B$-mode, we have shown that a detection with
at least 2σ is possible for 100% of parity violation and a tensor-to-scalar ratio of at least 0.05. A 1σ detection is still achieved for 50% of parity violation and a tensor-to-scalar ratio of at least 0.05 and a 2.5σ detection would be possible for \( r_{\perp} = 0.2 \). We found that by a measurement of vanishing \( TB \) and \( EB \) angular power spectra using pure pseudospectrum estimators, the level of parity violation is bounded from above: \( |\delta| \leq 0.92 \) at 95% CL. We have also shown that for such an experimental configuration where sampling variance is dominating at the largest scales – precisely those scales which allows for constraining parity violation –, the impact of self-calibrating the miscalibration angle could have a significant impact on the final estimation of the level of parity violation, the reported signal-to-noise ratio being degraded by a factor of \( \sim 1.09 \) for a miscalibration angle of 0.1 degree and, more significantly, by a factor \( \sim 2.4 \) for an angle of 1 degree. In this very last case, a 2σ detection of parity violation becomes possible only for \( \delta = 1 \) and \( r_{\perp} = 0.2 \). We stress that such an impact is revealed in the context of the pseudospectrum estimation of the angular power spectra. By making use of the naïve mode-counting expression for the covariance of the reconstructed \( C_\ell \)'s, it is formally shown that self-calibration of the orientation of the polarizers does not impact on the significance of the reconstruction of \( r_{\perp} \) assuming that the covariance is dominated by sampling variance and that one have access to the entire set of cross-correlations between the six estimated angular power spectra. Nevertheless, this last assumption is broken by pseudospectrum estimators (because of mode-mixing and binning) leading to degeneracies between \( r_{\perp} \) and \( \Delta \psi \).

In the context of chiral gravity from the Ashtekar formulation of general relativity, the parameter \( \delta \) amounting the level of parity breaking is related to the imaginary Barbero-Immirzi parameter via \( \delta = 2\gamma / (1 - \gamma^2) \) [20]. (We will restrict to the case of purely imaginary values of \( \gamma \) though the formalism can be extended to the case of any arbitrary complex values of \( \gamma \) [27].) The (absolute) level of parity breaking is encoded in \( |\delta| \) leading to \( |\gamma| = (1 \pm \sqrt{1 - \delta^2}) / |\delta| \). Considering the statistical error bars from a pseudospectrum reconstruction of the \( C_\ell \)'s, detecting \( |\gamma| = 1 \) is possible using data from a satellite mission with a statistical significance ranging from 2.3σ to 5.4σ for a tensor-to-scalar ratio ranging from 0.05 to 0.2, respectively. Assuming a detection of \( |\delta| = 0.5 \) translates into a detectable value of \( \gamma = 0.26 \) or \( \gamma = 3.73 \), meaning that such a form of chiral gravity is detectable with CMB polarized anisotropies if \( 0.26 \leq |\gamma| \leq 3.75 \). The significance of that detection for a future satellite mission ranges from 1.1σ to 2.5σ for a tensor-to-scalar ratio of 0.05 and 0.2. Detecting \( TB \) and \( EB \) angular power spectra which are consistent with zero leads to an upper bound on the parity violation level \( |\delta| \leq 0.92 \) at 95% CL for \( r_{\perp} = 0.05 \) and \( |\delta| \leq 0.39 \) at 95% CL for \( r_{\perp} = 0.2 \). This would mean that \( 0.66 \leq |\gamma| \leq 1.5 \) is excluded at 95% CL for \( r_{\perp} = 0.05 \) (the exclusion range at 68% CL would be \( 0.24 \leq |\gamma| \leq 4.1 \)), and that \( 0.2 \leq |\gamma| \leq 4.9 \) is excluded at 95% CL for \( r_{\perp} = 0.2 \) (the exclusion range at 68% CL would be \( 0.098 \leq |\gamma| \leq 10.1 \)).

In the context of a pseudoscalar inflaton, the amount of parity violation is given by [17]

\[
|\delta| = \frac{8.6 \times 10^{-7} \left( \frac{H^2}{2M_{Pl}^2} \right)}{1 + 8.6 \times 10^{-7} \left( \frac{H^2}{2M_{Pl}^2} \right)} \left( \frac{e^{4\pi \xi}}{\xi^6} \right)
\]

and

\[
r_{\perp} = 8.1 \times 10^2 \left( \frac{H^2}{M_{Pl}^2} \right) \left[ 1 + 8.6 \times 10^{-7} \left( \frac{H^2}{2M_{Pl}^2} \right) \right].
\]

This has to be compared to the upper bound reported in Ref. [17], which is related to their \( X = e^{2\pi \xi / \xi^3} \) which is related to \( r_{\perp} \) and \( \delta \) via

\[
X = \left( \frac{1.37 \times 10^7}{\sqrt{r_{\perp}}} \right)^{\frac{1}{\sqrt{1 - |\delta|}}} \left( 1 + \frac{|\delta|}{1 - |\delta|} \right).
\]

As compared to Ref. [17], \( X \) is related to their \( X \) parameter via \( X = \epsilon \times \bar{X} \) with \( \epsilon \) the first slow-roll parameter. For \( r_{\perp} = 0.05 \), one obtains the following upper bound on \( \bar{X} \): \( \bar{X} \leq 73 \times 10^7 \) at 95% CL. For \( r_{\perp} = 0.2 \), this upper bound is strengthened to \( \bar{X} \leq 3 \times 10^7 \) at 95% CL. This has to be compared to the upper bound reported in Ref. [17]: \( \bar{X} \leq 6 \times 10^7 \) at 95% CL, using the upper bound set by Planck on primordial non-gaussianities, \( f_{NL} < 150 \) [65]. This means that constraining such models with \( TB \) and \( EB \) is on par with the constraints that can be set with measurements of non-gaussianities assuming a rather high value of \( r_{\perp} \).

**Acknowledgments**

The authors would like to warmly thank J. Lesgourges for helpful discussions about the CLASS code as well as J. Peloton and R. Stompor for suggesting to look at the impact of a miscalibration angle. J.G. is grateful to T. Cailleteau, L. Smolin and F. Vidotto for enlightening discussions on chiral gravity at the linear level. A.F. is thankful to E. Lesgourgues, J. Peloton, T. Cailleteau, T. Spergel and R. Stompor for suggesting to look at the exclusion range at 68% CL would be 0.098 ≤ |γ| ≤ 10.1. In the context of a pseudoscalar inflaton, the amount of parity violation is given by [17]:

\[
|\delta| = \frac{8.6 \times 10^{-7} \left( \frac{H^2}{2M_{Pl}^2} \right)}{1 + 8.6 \times 10^{-7} \left( \frac{H^2}{2M_{Pl}^2} \right)} \left( \frac{e^{4\pi \xi}}{\xi^6} \right)
\]

and

\[
r_{\perp} = 8.1 \times 10^2 \left( \frac{H^2}{M_{Pl}^2} \right) \left[ 1 + 8.6 \times 10^{-7} \left( \frac{H^2}{2M_{Pl}^2} \right) \right].
\]

For a given value of \( r_{\perp} \), one can express \( \frac{H^2}{M_{Pl}^2} \) as a function of \( e^{4\pi \xi} / \xi^6 \) and plug it into \( |\delta| \). Following Ref. [17], one introduces the parameter \( \tilde{X} = e^{2\pi \xi / \xi^3} \) which is related to \( r_{\perp} \) and \( \delta \) via

\[
\tilde{X} = \left( \frac{1.37 \times 10^7}{\sqrt{r_{\perp}}} \right)^{\frac{1}{\sqrt{1 - |\delta|}}} \left( 1 + \frac{|\delta|}{1 - |\delta|} \right).
\]

As compared to Ref. [17], \( \tilde{X} \) is related to their \( X \) parameter via \( X = \epsilon \times \bar{X} \) with \( \epsilon \) the first slow-roll parameter. For \( r_{\perp} = 0.05 \), one obtains the following upper bound on \( \bar{X} \): \( \bar{X} \leq 73 \times 10^7 \) at 95% CL. For \( r_{\perp} = 0.2 \), this upper bound is strengthened to \( \bar{X} \leq 3 \times 10^7 \) at 95% CL. This has to be compared to the upper bound reported in Ref. [17]: \( \bar{X} \leq 6 \times 10^7 \) at 95% CL, using the upper bound set by Planck on primordial non-gaussianities, \( f_{NL} < 150 \) [65]. This means that constraining such models with \( TB \) and \( EB \) is on par with the constraints that can be set with measurements of non-gaussianities assuming a rather high value of \( r_{\perp} \).

**Appendix A: Lensed angular power spectra with primary TB and EB correlations**

Weak lensing of the primary anisotropies remaps the primary anisotropies by a displacement fields \( \delta \ell = \nabla \phi \)
with $\nabla$ the covariant derivative on the sphere and $\phi$ the projected potential of the large scale structures. By denoting $\hat{X}$ the *lensed* CMB anisotropies (we keep untilled notations for the primary CMB anisotropies), this translates into $T(i\hat{i}) \rightarrow \hat{T}(i\hat{i}) = T(i\hat{i} + \delta i\hat{i})$ and $P_\pm(i\hat{i}) \rightarrow P_\pm(i\hat{i} + \delta i\hat{i})$. This displacement field is supposed to be small in amplitude and one can therefore perform a Taylor expansion up to second order of the lensed CMB anisotropies around their unlensed value. With such a Taylor expansion, it is shown that the remapping of CMB primary fluctuations appears as a reshuffling of the multipoles $X_{\ell m}$ according to some convolution kernel involving the harmonic decomposition of the projected potential, $\phi_{\ell m}$ [33]. This reshuffling acts between different $\ell$-multipoles but also between different polarization modes as lensed $B$-modes receive contribution from primary $E$-modes and vice versa. For temperature, it reads:

\[
\tilde{T}_{\ell m} = T_{\ell m} + \sum_{\ell_1, m_1} \sum_{\ell_2, m_2} \phi_{\ell_1 m_1} T_{\ell_2 m_2} \times I_{m_1 m_2}^{\ell_1 \ell_2} + \frac{1}{2} \sum_{\ell_1, m_1} \sum_{\ell_2, m_2} \sum_{\ell_3, m_3} \phi_{\ell_1 m_1} T_{\ell_2 m_2} \phi_{\ell_3 m_3}^{*} \times J_{m_1 m_2 m_3}^{\ell_1 \ell_2 \ell_3},
\]

(A1)

with

\[
I_{m_1 m_2}^{\ell_1 \ell_2} = \int_{4\pi} Y_{\ell m}^{*} (\nabla a Y_{\ell_1 m_1}) (\nabla a Y_{\ell_2 m_2}) \, d\hat{\hat{i}},
\]

(A2)

\[
J_{m_1 m_2 m_3}^{\ell_1 \ell_2 \ell_3} = \int_{4\pi} Y_{\ell m}^{*} (\nabla a Y_{\ell_1 m_1}) (\nabla a Y_{\ell_3 m_3}^{*}) (\nabla a \nabla b Y_{\ell_2 m_2}) \, d\hat{\hat{i}}.
\]

(A3)

Similarly for polarization, one obtains:

\[
\tilde{E}_{\ell m} = E_{\ell m} + \sum_{\ell_1, m_1} \sum_{\ell_2, m_2} \phi_{\ell_1 m_1} [E_{\ell_2 m_2} \times (+) I_{m_1 m_2}^{\ell_1 \ell_2} + iB_{\ell_2 m_2} \times (-) J_{m_1 m_2}^{\ell_1 \ell_2}],
\]

(A4)

\[
\tilde{B}_{\ell m} = B_{\ell m} + \sum_{\ell_1, m_1} \sum_{\ell_2, m_2} \phi_{\ell_1 m_1} [B_{\ell_2 m_2} \times (+) I_{m_1 m_2}^{\ell_1 \ell_2} - iE_{\ell_2 m_2} \times (-) J_{m_1 m_2}^{\ell_1 \ell_2}],
\]

(A5)

with

\[
(\pm) I_{m_1 m_2}^{\ell_1 \ell_2} = \int_{4\pi} [2Y_{\ell m}^{*} (\nabla a Y_{\ell_1 m_1}) (\nabla a Y_{\ell_2 m_2}) \pm -2Y_{\ell m}^{*} (\nabla a Y_{\ell_1 m_1}) (\nabla a -2Y_{\ell_2 m_2})] \, d\hat{\hat{i}},
\]

(A6)

\[
(\pm) J_{m_1 m_2 m_3}^{\ell_1 \ell_2 \ell_3} = \int_{4\pi} [2Y_{\ell m}^{*} (\nabla a Y_{\ell_1 m_1}) (\nabla b Y_{\ell_3 m_3}^{*}) (\nabla a \nabla b Y_{\ell_2 m_2}) \pm -2Y_{\ell m}^{*} (\nabla a Y_{\ell_1 m_1}) (\nabla b Y_{\ell_3 m_3}^{*}) (\nabla a \nabla b -2Y_{\ell_2 m_2})] \, d\hat{\hat{i}}.
\]

The kernels $I_{m_1 m_2}^{\ell_1 \ell_2}$ and $J_{m_1 m_2 m_3}^{\ell_1 \ell_2 \ell_3}$ have properties which greatly simplifies the forthcoming computations.

The final derivation of the lensed angular power spectrum is obtained by considering the correlators $\tilde{C}_{\ell}^{XZ} = \langle \tilde{X}_{\ell m} \tilde{Z}_{\ell m} \rangle + \langle \tilde{X}_{\ell m} \tilde{Z}_{\ell m} \rangle / 2$, and making use of the statistical isotropy of the primary fluctuations, i.e. $\langle X_{\ell m} Z_{\ell m}^{*} \rangle = C_{\ell}^{XZ} \delta_{\ell \ell'} \delta_{m m'}$ and $\langle \phi_{\ell m} \phi_{\ell' m'} \rangle = C_{\ell}^{\phi\phi} \delta_{\ell \ell'} \delta_{m m'}$; following Ref. [33], we also consider that
the projected potential causing the deflection of CMB photons is not correlated to the primary anisotropies of CMB and we neglect any curl-like contribution to the deflection field.

1. Properties of $I_{m1m2}^{\ell1\ell2}$ and $J_{m1m2}^{\ell1\ell2}$

a. First property

The first important property is that $I_{m1m2}^{\ell1\ell2}$ is an ‘even’ quantity:

$$
\left\{
\begin{array}{ll}
I_{m1m2}^{\ell1\ell2} = 0 & \text{for } (\ell + \ell_1 + \ell_2) = 2n + 1, \\
I_{m1m2}^{\ell1\ell2} \neq 0 & \text{for } (\ell + \ell_1 + \ell_2) = 2n.
\end{array}
\right.
$$

(A7)

As shown in Refs. [39, 70], $I_{m1m2}^{\ell1\ell2}$ is rewritten as a function of the Gaunt integral

$$
I_{m1m2}^{\ell1\ell2} = \frac{1}{2} \left[ (\ell_1, \ell_1 + 1) + (\ell_2, \ell_2 + 1) - \ell(\ell + 1) \right] \times \int \frac{Y_{\ell+1}^*(\mathbf{i}) Y_{\ell_1 m_1}^*(\mathbf{i}) Y_{\ell_2 m_2}^*(\mathbf{i})}{\sqrt{\pi}} \, d\mathbf{i}.
$$

(A8)

The second line of the above is precisely the Gaunt integral, $G$, which is re-expressed as a function of the Wigner-3$j$’s, i.e.

$$
G = (-1)^m \sqrt{\frac{(2\ell + 1)(2\ell_1 + 1)(2\ell_2 + 1)}{4\pi}} \times \left( \begin{array}{ccc} \ell & \ell_1 & \ell_2 \\ m & m_1 & m_2 \end{array} \right) \left( \begin{array}{ccc} \ell & \ell_1 & \ell_2 \\ 0 & 0 & 0 \end{array} \right).
$$

(A9)

Since

$$
\left( \begin{array}{ccc} \ell & \ell_1 & \ell_2 \\ m & m_1 & m_2 \end{array} \right) = (-1)^{\ell+\ell_1+\ell_2} \left( \begin{array}{ccc} \ell & \ell_1 & \ell_2 \\ -m & -m_1 & -m_2 \end{array} \right),
$$

it is obvious that the Wigner-3$j$ is vanishing for $m = m_1 = m_2 = 0$ for $\ell + \ell_1 + \ell_2 = 2n + 1$. As a consequence, $I_{m1m2}^{\ell1\ell2}$ is also equal to zero for odd values of $\ell + \ell_1 + \ell_2$.

b. Second and third properties

The second and third important properties are that $(+)^{I_{m1m2}^{\ell1\ell2}}$ is an ‘even’ quantity, and, $(-)^{I_{m1m2}^{\ell1\ell2}}$ is an ‘odd’ quantity, i.e.:

$$
\left\{
\begin{array}{ll}
(+)^{I_{m1m2}^{\ell1\ell2}} = 0 & \text{for } (\ell + \ell_1 + \ell_2) = 2n + 1, \\
(+)^{I_{m1m2}^{\ell1\ell2}} \neq 0 & \text{for } (\ell + \ell_1 + \ell_2) = 2n.
\end{array}
\right.
$$

(A11)

and

$$
\left\{
\begin{array}{ll}
(-)^{I_{m1m2}^{\ell1\ell2}} \neq 0 & \text{for } (\ell + \ell_1 + \ell_2) = 2n + 1, \\
(-)^{I_{m1m2}^{\ell1\ell2}} = 0 & \text{for } (\ell + \ell_1 + \ell_2) = 2n.
\end{array}
\right.
$$

(A12)

Those two properties are simply proved by noticing that

$$
\int 2Y_{\ell_1 m_1}^*(\nabla a Y_{\ell_1 m_1}) (\nabla a^2 Y_{\ell_2 m_2}) \, d\mathbf{i} = \quad \text{(A13)}
$$

$$
(-1)^{\ell+\ell_1+\ell_2} \int 2Y_{\ell_1 m_1}^*(\nabla a Y_{\ell_1 m_1}) (\nabla a^2 Y_{\ell_2 m_2}) \, d\mathbf{i}.
$$

From that, it is obvious that $(+)I_{m1m2}^{\ell1\ell2} = 0$ for odd values of $\ell + \ell_1 + \ell_2$ while $(-)I_{m1m2}^{\ell1\ell2} = 0$ for even values of $\ell + \ell_1 + \ell_2$.

This can also be seen from the explicit expressions of $(+)I_{m1m2}^{\ell1\ell2}$ as functions of the Wigner-3$j$ since

$$
\begin{align*}
(+)I_{m1m2}^{\ell1\ell2} &= \frac{1}{2} \left[ (\ell_1, \ell_1 + 1) + (\ell_2, \ell_2 + 1) - \ell(\ell + 1) \right] \\
&= (-1)^{m+2} \frac{(2\ell + 1)(2\ell_1 + 1)(2\ell_2 + 1)}{4\pi} \\
&\times \left( \begin{array}{ccc} \ell & \ell_1 & \ell_2 \\ -m & m_1 & m_2 \end{array} \right) \left( \begin{array}{ccc} \ell & \ell_1 & \ell_2 \\ -2 & 0 & -2 \end{array} \right).
\end{align*}
$$

From the symmetry of the Wigner-3$j$’s involved in the last line, it is clear that $(+/-)I_{m1m2}^{\ell1\ell2} = 0$ for odd(even) values of $\ell + \ell_1 + \ell_2$.

c. Fourth property

The last useful property is

$$
\sum_{m1} (-)^m I_{m1m1}^{\ell1\ell1} = 0.
$$

(A15)

To prove it, one should first notice that (see Eqs. (59) and (60) of [39])

$$
\sum_{m1} \nabla a Y_{\ell_1 m_1} \nabla b Y_{\ell_1 m_1}^* = \frac{\ell_1(\ell_1 + 1)}{4\pi} \left[ (m_+)_a (m_-)_b \\
+ (m_-)_a (m_+)_b \right],
$$

(A16)

and

$$
[(m_+)_a (m_-)_b + (m_-)_a (m_+)_b)] \nabla_a \nabla b \pm s Y_{\ell m} = - \left[ \ell(\ell + 1) - s^2 \right] \pm 2Y_{\ell m}.
$$

(A17)

with $\tilde{m}_{\pm} = (\tilde{e}_0 \mp i \tilde{e}_2)/\sqrt{2}$. From those two expressions, one easily derive that

$$
\sum_{m1} (-)^m J_{m1m1}^{\ell1\ell1} = F(\ell, \ell_1) \int 4\pi \left[ 2Y_{\ell m}^* Y_{\ell m} \right] \pm 2Y_{\ell m} \right] d\mathbf{i},
$$

with $F(\ell, \ell_1)$ a numerical factor depending on $\ell$ and $\ell_1$. The integral in the right-hand side of the above expression is vanishing since the $\pm 2Y_{\ell m}$’s forms an orthonormal basis on the celestial sphere.
2. Temperature power spectrum

The case of $TT$ correlation is rather straightforward: it only consists of reshuffling $\ell$-multipoles without any contribution from primary power spectra but $C^{TT}_\ell$. The lensed power spectrum is therefore not affected by non-vanishing $TB$ and $EB$ and reads:

$$C^{TT}_\ell = \left[ 1 + \sum_{\ell_3} C^{\phi\phi}_{\ell_3} \sum_{m_3} \text{Re} \left[ I_{m_3 m_3 m_3}^{\ell_3 \ell_3} \right] \right] C^{TT}_\ell + \sum_{\ell_1, \ell_2} C^{TT}_\ell C^{\phi\phi}_{\ell_1} \sum_{m_1, m_2} |I_{m_1 m_2}^{\ell_1 \ell_2}|^2. \quad (A19)$$

From the expression of $I_{m_1 m_2 m_3}^{\ell_1 \ell_2}$ as a function of the Wigner-3$j$’s and using that

$$\sum_{m_1, m_2} \left( \begin{array}{ccc} \ell & \ell_1 & \ell_2 \\ m & m_1 & m_2 \end{array} \right) \left( \begin{array}{ccc} \ell' & \ell_1 & \ell_2 \\ m' & m_1 & m_2 \end{array} \right) = \frac{\delta_{\ell \ell'} \delta_{m m'}}{2\ell + 1},$$

it is easily shown that

$$F^{TT}_{\ell_1 \ell_2} = \sum_{m_1, m_2} |I_{m_1 m_2 m_3}^{\ell_1 \ell_2}|^2 \quad (A20)$$

For the second term, one makes use of Eqs. (A16) and (A17) to show that

$$\sum_{m_3} J_{m_3 m_3 m_3}^{\ell \ell_3 \ell_3} = -\frac{1}{2} \frac{\ell_3 + 1}{4\pi} \frac{2\ell_3 + 1}{4\pi} \left[ \frac{\ell_3 + 1}{4\pi} \right]$$

where the orthonormality of spherical harmonics has been used to derive the second line of the above equation. This leads to

$$R^T = \sum_{\ell_3} C^{\phi\phi}_{\ell_3} \sum_{m_3} \text{Re} \left[ I_{m_3 m_3 m_3}^{\ell_3 \ell_3} \right] \quad (A23)$$

3. Temperature-polarization power spectrum

We focus on the case of the $TB$ cross-correlation. This calculation is then easily adapted to the case of $TE$ by first, replacing $(C^{TB}_\ell)$ by $(C^{TE}_\ell)$, and, second, replacing $(C^{TB}_\ell)$ by $(-C^{TB}_\ell)$. Let us first notice that

$$\tilde C^{TB}_\ell = \langle T_{\ell m} B^*_{\ell m} \rangle + \langle T^{(1)}_{\ell m} B^{(1)*}_{\ell m} \rangle \quad (A24)$$

Each of this term are given by

$$\langle T_{\ell m} B^*_{\ell m} \rangle = C^{TB}_\ell, \quad (A25)$$

$$\langle T^{(1)}_{\ell m} B^{(1)*}_{\ell m} \rangle = \frac{1}{2} \sum_{\ell_1, \ell_2} C^{\phi\phi}_{\ell_1} \left\{ C^{TB}_\ell \sum_{m_1, m_2} \text{Re} \left[ I_{m_1 m_2 m_3}^{\ell_1 \ell_2} \right] + C^{TE}_\ell \sum_{m_1, m_2} \text{Im} \left[ I_{m_1 m_2 m_3}^{\ell_1 \ell_2} \right] \right\} \quad (A26)$$

$$\langle T^{(2)}_{\ell m} B^{(2)*}_{\ell m} \rangle = \frac{1}{4} C^{TB}_\ell \sum_{\ell_3} C^{\phi\phi}_{\ell_3} \sum_{m_3} \text{Re} \left[ J_{m_3 m_3 m_3}^{\ell_3 \ell_3} \right] + \frac{1}{4} C^{TE}_\ell \sum_{\ell_3} C^{\phi\phi}_{\ell_3} \sum_{m_3} \text{Im} \left[ J_{m_3 m_3 m_3}^{\ell_3 \ell_3} \right] \quad (A27)$$

The above expressions can be simplified using the properties of the $I, (\pm) J$ and $J, (\pm) J$ kernels. First, the second line of Eq. (A26) proportional to $C^{TE}_\ell$ is zero. This is a consequence of the first and the third properties: for
any triplet \((\ell, \ell_1, \ell_2)\), either \(I^{\ell_1 \ell_2}_{m m_1 m_2}\) or \((-I^{\ell_1 \ell_2}_{m m_1 m_2})\) is zero and the product of the two is always vanishing. In other word, primary \(TE\) does not contribute to \(\langle \pi_1 B_{1m}^{(1)} \rangle\), in perfect agreement with the analogous case of pseudospectrum estimators. (This is for that very same reason that \(TE\) is not leaking into \(TB\) in pseudospectrum estimator.) Second, the second line of Eq. (A27) proportional to \(C^{TE}_{\ell m}\) is also vanishing as a result of the fourth property. This means that even at second order, the primary \(TE\) correlations do not contribute to the lensed \(C^{TB}_{\ell m}\) correlations.

The same strategy is adopted for the \(TE\) angular power spectrum, and, similarly to \(TB\), it appears that the primary \(C^{TB}_{\ell m}\) does not contribute to the lensed \(C^{TE}_{\ell m}\). Gathering all the terms, one finally obtains

\[
\tilde{C}^{TE}_{\ell m} = [1 + R^{X}] C^{TE}_{\ell m} + \sum_{\ell_1, \ell_2} F^{X}_{\ell_1 \ell_2} C^{\phi \phi}_{\ell_1} C^{TE}_{\ell_2}, \quad (A29)
\]

\[
\tilde{C}^{TB}_{\ell m} = [1 + R^{X}] C^{TB}_{\ell m} + \sum_{\ell_1, \ell_2} F^{X}_{\ell_1 \ell_2} C^{\phi \phi}_{\ell_1} C^{TB}_{\ell_2}, \quad (A30)
\]

with

\[
F^{X}_{\ell_1 \ell_2} = \frac{1}{2} \sum_{m_1, m_2} \text{Re} [i^{\ell_1 \ell_2}_{m m_1 m_2} + i^{\ell_1 \ell_2}_{m m_1 m_2}^*] \quad (A31)
\]

\[
R^{X} = \frac{1}{4} \sum_{\ell_3} C^{\phi \phi}_{\ell_3} \left\{ 2 \text{Re} \left[ i^{\ell_3 \ell_3}_{m m_3 m_3} \right] \right\} + \text{Re} \left[ (+i^{\ell_3 \ell_3}_{m m_3 m_3}) \right]. \quad (A32)
\]

The first quantity is easily computed starting from the expressions of \(i^{\ell_1 \ell_2}_{m m_1 m_2}\) and \((+i^{\ell_1 \ell_2}_{m m_1 m_2})\) as functions of the Wigner-3j and using Eq. (A20) to get

\[
F^{X}_{\ell_1 \ell_2} = \frac{1}{8} \left[ \ell_1 (\ell_1 + 1) + \ell_2 (\ell_2 + 1) - \ell (\ell + 1) \right]^2 \times \frac{(2\ell + 1)(2\ell + 1)}{4\pi} \left( \begin{array}{ccc} \ell & \ell_1 & \ell_2 \\ 0 & 0 & 0 \end{array} \right) \times \left[ \left( \begin{array}{ccc} \ell & \ell_1 & \ell_2 \\ 2 & 0 & -2 \end{array} \right) \pm \left( \begin{array}{ccc} \ell & \ell_1 & \ell_2 \\ -2 & 0 & 2 \end{array} \right) \right]. \quad (A33)
\]

Using Eqs. (A16) and (A17) and the orthonormality of spin-(\pm 2) spherical harmonics, it is proved that

\[
\sum_{m_3} (+i^{\ell_3 \ell_3}_{m m_3 m_3}) = -\ell_3 (\ell_3 + 1) [\ell (\ell + 1) - 4] \frac{2\ell_3 + 1}{4\pi}. \quad (A34)
\]

This finally leads to

\[
R^{X} = -\frac{1}{2} [\ell (\ell + 2)] \sum_{\ell_3} \ell_3 (\ell_3 + 1) \frac{2\ell_3 + 1}{4\pi} C^{\phi \phi}_{\ell_3}. \quad (A35)
\]

4. Polarization power spectra

For the case of polarized angular power spectra, we detailed our derivation of the lensed \(EB\) cross-correlation which can then easily be adapted to the case of \(EE\) and \(BB\) angular power spectra. Following the same steps as the ones used for \(C^{TB}_{\ell m}\), we first note that

\[
\tilde{C}^{EB}_{\ell m} = \text{Re} \left[ \langle E_{\ell m} B^{*}_{\ell m} \rangle \right] + \text{Re} \left[ \langle E_{\ell m} (B^{(1)}_{\ell m})^* \rangle \right]. \quad (A36)
\]

Each of this term are given by

\[
\text{Re} \left[ \langle E_{\ell m} B^{*}_{\ell m} \rangle \right] = C^{EB}_{\ell m}, \quad (A37)
\]

\[
\text{Re} \left[ \langle E_{\ell m} (B^{(1)}_{\ell m})^* \rangle \right] = \frac{1}{4} \sum_{\ell_1, \ell_2} C^{EB}_{\ell_1 \ell_2} C^{\phi \phi}_{\ell_1} \sum_{m_1, m_2} \left( (+i^{\ell_1 \ell_2}_{m m_1 m_2})^2 - (-i^{\ell_1 \ell_2}_{m m_1 m_2})^2 \right), \quad (A38)
\]

\[
\text{Re} \left[ \langle E_{\ell m} (B^{(2)}_{\ell m})^* \rangle \right] = \frac{1}{4} C^{EB}_{\ell} \sum_{\ell_3} C^{\phi \phi}_{\ell_3} \sum_{m_3} \text{Re} [ (+i^{\ell_3 \ell_3}_{m m_3 m_3}) + \frac{1}{4} C^{EB}_{\ell} \sum_{\ell_3} C^{\phi \phi}_{\ell_3} \sum_{m_3} \text{Im} [ (-i^{\ell_3 \ell_3}_{m m_3 m_3})] \quad (A39)
\]

\[
\text{Re} \left[ \langle E_{\ell m} B^{(2)}_{\ell m} \rangle \right] = \frac{1}{4} C^{EB}_{\ell} \sum_{\ell_3} C^{\phi \phi}_{\ell_3} \sum_{m_3} \text{Re} [ (+i^{\ell_3 \ell_3}_{m m_3 m_3}) \sum_{m_3} \text{Im} [ (-i^{\ell_3 \ell_3}_{m m_3 m_3})]. \quad (A40)
\]
From the fourth property, the second term in the right-hand side of the equations (A39) and (A40) are vanishing. Similarly, the second term in the right-hand side of Eq. (A38) is equal to zero as a result of the second and third properties. Therefore, both the primary EE spectrum and the primary BB spectrum does not contribute to the lensed EB angular power spectrum.

An identical conclusion is easily derived for the case of the lensed EE and BB spectrum as the primary EB power spectrum does not contribute to the lensed EE and BB spectra, since any contribution of power spectrum does not contribute to the lensed BBs spectrum. Therefore, both the primary EE (A38) is equal to zero as a result of the second and third properties. The computation of an identical conclusion is easily derived for the case of the lensed EE and BB spectra, since any contribution of power spectrum does not contribute to the lensed BBs spectrum. Therefore, both the primary EE (A38) is equal to zero as a result of the second and third properties.

The computation of $\mathbf{R}_P$ directly follows from the computation of $\mathbf{R}^{TB}$ and gives

$$R_P = \frac{1}{2} \left[ \ell(\ell + 1) - 4 \right] \sum_{\ell_3(\ell_2+1)} 2 \ell_3 + 1 \sum_{\ell_3} \left[ \pm J_{\ell_1, \ell_2}^{m_1, m_2} \right].$$

(A46)

Using the expressions of $(\pm) J_{\ell_1, \ell_2}^{m_1, m_2}$ as functions of the Wigner-3j’s and the summation rule for the product of two such symbols, one easily derive that

$$F_{\ell_1, \ell_2}^{(\pm)} = \left[ \pm J_{\ell_1, \ell_2}^{m_1, m_2} \right] = \left[ \pm J_{\ell_1, \ell_2}^{m_1, m_2} \right] = \left[ \pm J_{\ell_1, \ell_2}^{m_1, m_2} \right].$$

(A47)

The instrumental noise, and,

$$\mathbf{R}(2\Delta \psi) = \begin{pmatrix} 1 & 0 \\ 0 & \cos(2\Delta \psi) & -\sin(2\Delta \psi) \\ 0 & \sin(2\Delta \psi) & \cos(2\Delta \psi) \end{pmatrix}$$

(B6)

a rotation matrix modeling the impact of miscalibration. Being a rotation matrix, it satisfies $\mathbf{R}^T(2\Delta \psi) = \mathbf{R}(-2\Delta \psi) = \mathbf{R}^{-1}(2\Delta \psi) = \mathbf{R}^{-1}(2\Delta \psi)$.

On defining $C_{\ell m} = \left\{ a_{\ell m} \right\}$ and $\mathbf{N}_{\ell m} = \left\{ n_{\ell m} \right\}$, both assumed to be block diagonal – which is only true for homogeneous noise – it is easily shown that

$$C_{\ell m}^{(obs)} = \mathbf{R}(2\Delta \psi) C_{\ell m} \mathbf{R}^{-1}(2\Delta \psi) + \mathbf{N}_{\ell m}.$$  

(B7)

Assuming finally that we are in such an experimental set-ups where sampling variance is dominating, then one can neglect noise leading to $C_{\ell m}^{(obs)} = \mathbf{R} C_{\ell m} \mathbf{R}^{-1}$ and

$$C_{\ell m}^{(obs)} = \mathbf{R} C_{\ell m} \mathbf{R}^{-1}.$$  

It is straightforward to show that the Fisher matrix for $r(\pm)$ reduces to:

$$\mathbf{F}[\ell, m] = \begin{pmatrix} f_{sky}^2 & \sum_{\ell, m} \left[ \frac{\partial C_{\ell m}^{(obs)}}{\partial r(\pm)} \right] C_{\ell m}^{-1} \mathbf{C}_{\ell m} \mathbf{C}_{\ell m}^{-1} \end{pmatrix}. $$

(B8)
This simply means that for an experiment only limited by cosmic variance, the block $r(\pm)$ of the Fisher information matrix is exactly the same as if there were no rotation.

Let us now consider the off-diagonal terms amounting for the correlations between $r(\pm)$ and $\Delta \psi$, i.e.

$$\begin{align*}
[F]_{r(\pm)\Delta \psi} &= \frac{f_{\text{sky}}}{2} \sum_{\ell, m} \text{Tr} \left( \frac{\partial R}{\partial \Delta \psi} C_{\ell m} R^{-1} + RC_{\ell m} \frac{\partial R^{-1}}{\partial \Delta \psi} \right) \\
&\quad \times RC_{\ell m}^{-1} \frac{\partial C_{\ell m}}{\partial r(\pm)} C_{\ell m}^{-1} R^{-1}. 
\end{align*}$$

(B9)

Using the fact we are considering the trace and $M^{-1}(\partial M) + (\partial M^{-1}) M = 0$, the above expression gives:

$$\begin{align*}
[F]_{r(\pm)\Delta \psi} &= \frac{f_{\text{sky}}}{2} \sum_{\ell, m} \text{Tr} \left[ R^{-1} \frac{\partial R}{\partial \Delta \psi} \right] (B10) \\
&\quad \times \left( \frac{\partial C_{\ell m}}{\partial r(\pm)} - C_{\ell m}^{-1} \frac{\partial C_{\ell m}}{\partial r(\pm)} \right),
\end{align*}$$

Because $\left( \frac{\partial C_{\ell m}}{\partial r(\pm)} C_{\ell m}^{-1} - C_{\ell m}^{-1} \frac{\partial C_{\ell m}}{\partial r(\pm)} \right)$ does not depend on $\Delta \psi$, this means that the correlations between parameters $r(\pm)$ and $\Delta \psi$ are independent of the value of $\Delta \psi$.
