Twistless KAM tori.

Giovanni Gallavotti

F-13288 Marseille"

Abstract: A self-contained proof of the KAM theorem in the Thirring model is discussed.

Keywords: KAM, invariant tori, classical mechanics, perturbation theory, chaos

I shall particularize the Eliasson method, [E], for KAM tori to a special model, of great interest, whose relevance for the KAM problem was pointed out by Thirring, [T] (see [G] for a short discussion of the model). The idea of exposing Eliasson’s method through simple particular cases appears in [V], where results of the type of the ones discussed here, and more general ones, are announced.

The connection between the methods of [E] and the tree expansions in the renormalization group approaches to quantum field theory and many body theory can be found also in [G]. The connection between the tree expansions and the breakdown of invariant tori is discussed in [PV].

The Thirring model is a system of rotators interacting via a potential. It is described by the Hamiltonian

\[ H = \sum_{l=1}^{d} \left( \sum_{j=1}^{d} \omega_{j, l} + \epsilon \sum_{j=1}^{d} \cos \beta_{j} \cdot \alpha_{j} \right) \]

where \( J \) is the (diagonal) matrix of the inertia moments, \( \vec{A} = (A_{1}, \ldots, A_{d}) \in R^{d} \) are their angular momenta and \( \vec{\alpha} = (\alpha_{1}, \ldots, \alpha_{l}) \in R^{l} \) are the angles describing their positions: the matrix \( J \) will be supposed non singular; but we only suppose that \( \min_{j=1,\ldots,l} J_{j} = J_{0} > 0 \), and no assumption is made on the size of the twist rate \( T = \min J^{-1} \); the results will be uniform in \( T \) (hence the name “twistless”: this is not a contradiction with the necessity of a twist rate in the general problems, see problems 1, 16, 17 in §5.11 of [G2] and [G]). We suppose \( f \) to be an even trigonometric polynomial of degree \( N \):

\[ f(t) = \sum_{0 < |\beta| \leq N} f_{|\beta|} \cos \beta \cdot \vec{\alpha}, \quad f_{|\beta|} = f_{-|\beta|} \]

We shall consider a “rotation vector” \( \vec{\omega}_{0} = (\omega_{1}, \ldots, \omega_{l}) \in R^{l} \) verifying a strongly diophantine property (see, however, the final comments) with diophantine constants \( C_{0}, \tau, \gamma, c \); this means that:

1) \( C_{0}|\vec{\omega}_{0} \cdot \vec{\beta}| \geq |\vec{\beta}|^{-\tau}, \quad \vec{\beta} \neq \vec{0} \in Z^{d} \)

2) \( \min_{0 \leq |\beta| \leq N} |C_{0}|\vec{\omega}_{0} \cdot \vec{\beta}| - \gamma^{P} \leq \gamma^{n+1} \) if \( n \leq 0, 0 < |\vec{\beta}| \leq (\gamma^{n+c})^{-\tau^{-1}} \)

and it is easy to see that the strongly diophantine vectors have full measure in \( R^{d} \) if \( \gamma > 1 \) and \( c \) are fixed and if \( \tau \) is fixed \( \tau > l - 1 \): we take \( \gamma = 2, c = 3 \) for simplicity; note that 2) is empty if \( n > -3 \) or \( p < n + 3 \).

We shall set \( \vec{A}_{0} = J \vec{\omega}_{0} \). And a special example can be the model \( f_{0}(\vec{\alpha}) = J_{0} \vec{\omega}_{0} \cos(\alpha_{1} + \cos(\alpha_{1} + \alpha_{2})) \).

We look for an \( \epsilon \)-analytic family of motions starting at \( \vec{\alpha} = \vec{0} \) having the form:

\[ \vec{A} = \vec{A}_{0} + \vec{H}(\vec{\omega}_{0}; \epsilon), \quad \vec{\alpha} = \vec{\omega}_{0} + \vec{h}(\vec{\omega}_{0}; \epsilon) \]

with \( \vec{H}(\vec{\psi}; \epsilon), \vec{h}(\vec{\psi}; \epsilon) \) analytic in \( \vec{\psi} \in T^{d} \) and in \( \epsilon \) close to 0. We shall prove that such functions exist and are analytic for \( |\text{Im} \psi_{j}| < \xi \) for \( |\epsilon| < \epsilon_{0} \) with:

\[ \epsilon_{0}^{-1} = bJ_{0}^{-1}C_{0}^{2} \epsilon N^{2} + \epsilon N \]

where \(b, c\) are \(l\)-dependent positive constants, \(f_0 = \max_{\varphi} |f_{\varphi}|\). This means that the set \(\bar{A} = \bar{A}_0 + \bar{H}(\bar{\psi}; \varepsilon), \bar{\alpha} = \bar{\psi} + \bar{h}(\bar{\psi}; \varepsilon)\) described as \(\bar{\psi}\) varies in \(T^1\) is, for \(\varepsilon\) small enough, an invariant torus for (1), which is run quasi periodically with angular velocity vector \(\bar{\omega}_0\). It is a family of invariant tori coinciding, for \(\varepsilon = 0\), with the torus \(\bar{A} = \bar{A}_0, \bar{\alpha} = \bar{\psi} \in T^1\). One recognizes a version of the KAM theorem. The proof that follows simplifies the one reported in [G].

Supposing \(J_0 \equiv J_1 < J_2\) the uniformity in \(J_2\) (i.e. what we call the twistless property) implies that the same \(\varepsilon_0\) can be used as an estimate of the radius of convergence in \(\varepsilon\) of the power series describing the KAM tori with rotation vector \(\bar{\omega}_0 = (\omega_1, \omega_2)\) in the system \((2J_l^{-1}A_l^2 + \omega_2A_2 + \varepsilon f_0(\alpha_l, \alpha_2),\) which is one of the most studied hamiltonian systems. The estimate can be improved. Note that a careful analysis of the proof of the KAM theorem also shows the uniformity in the twist rate in the case (1).

Calling \(\bar{H}^{(k)}(\bar{\psi}), \bar{h}^{(k)}(\bar{\psi})\) the \(k\)-th order coefficients of the Taylor expansion of \(\bar{H}, \bar{h}\) in powers of \(\varepsilon\) and writing the equation of motion as \(\dot{\bar{\alpha}} = \bar{\omega}_0 + J^{-1}\bar{A}\) and \(\bar{A} = -\varepsilon \partial_{\bar{\alpha}} f(\bar{\alpha})\) we get immediately recursion relations for \(\bar{H}^{(k)}, \bar{h}^{(k)}\). Namely \(\bar{\omega}_0 \cdot \bar{\theta} h_j^{(k)} = J_j^{-1} H_j^{(k)}\) and:

\[
\bar{\omega}_0 \cdot \bar{\theta} H_j^{(k)} = - \sum_{m_1, \ldots, m_j > 0} \frac{1}{\prod_{s=1}^j m_s} \partial_{x_j} \bar{H}^{(m_1, \ldots, m_j)} \bar{h}^{(k)}(\bar{\omega}_0 t) \cdot \sum_{s=1}^j \prod_{j=1}^s h_s^{(k_j)}(\bar{\omega}_0 t)
\]

where the \(\sum^*\) denotes summation over the integers \(k_j \geq 1\) with: \(\sum_{s=1}^j \sum_{j=1}^k k_j = k - 1\).

The trigonometric polynomial \(\bar{h}^{(k)}(\bar{\psi})\) will be completely determined (if possible at all) by requiring it to have \(\bar{\theta}\) average over \(\bar{\psi}\), (note that \(\bar{H}\) has to have zero average over \(\bar{\psi}\)). For \(k = 1\) one easily finds:

\[
\bar{h}^{(1)}(\bar{\psi}) = - \sum_{\bar{\psi} \neq 0} \frac{J^{-1}_{\bar{\psi}} \bar{\omega}_0 f_{\bar{\psi}}}{(2\pi)^2 \bar{\psi}} e^{i\bar{\theta} \bar{\psi}}
\]

Suppose that \(\bar{h}^{(k)}(\bar{\psi})\) is a trigonometric polynomial of degree \(\leq kN\), odd in \(t\), for \(1 \leq k < k_0\). Then we see immediately that the r.h.s. of (6) is odd in \(t\). This means that the r.h.s. of (6) has zero average in \(t\), hence in \(\bar{\psi}\), and the second of (6) can be solved for \(k = k_0\). It yields an even function \(\bar{H}^{(k_0)}(\bar{\psi})\) which is defined up to a constant which, however, must be taken such that \(\bar{H}^{(k_0)}(\bar{\psi})\) has zero average, to make \(\bar{\omega} \cdot \bar{\theta} h_j^{(k)} = J_j^{-1} H_j^{(k)}\) soluble. Hence the equation for \(\bar{h}^{(k)}\) can be solved (because the r.h.s. has zero average) and its solution is a trigonometric polynomial in \(\bar{\psi}\), odd if \(\bar{h}^{(k)}\) is determined by imposing that its average over \(\bar{\psi}\) vanishes.

Hence the (7) provide an algorithm to evaluate a formal power series solution to our problem. It has been remarked, [E], [V], see also [G], that (6) yields a diagrammatic expansion of \(\bar{h}^{(k)}\). We simply "iterate" it until only \(\bar{h}^{(1)}\), given by (7), appears.

Let \(\vartheta\) be a tree diagram: it will consist of a family of "lines" (i.e. segments) numbered from 1 to \(k\) arranged to form a (rooted) tree diagram as in the figure:

![Tree Diagram](image)

**fig. 1**: A tree diagram \(\vartheta\) with \(m_{v_0} = 2, m_{v_1} = 2, m_{v_2} = 3, m_{v_3} = 2, m_{v_4} = 2\) and \(m = 12, \prod m_v! = 2^4 \cdot 6,\) and some decorations. The line numbers, distinguishing the lines, are not shown.
To each vertex $v$ we attach a "mode label" $\vec{\nu}_v \in \mathbb{Z}^l$, $|\vec{\nu}_v| \leq N$ and to each branch leading to $v$ we attach a "branch label" $j_v = 1, \ldots, l$. The order of the diagram will be $k = \text{number of vertices} = \text{number of branches}$ (the tree root will not be regarded as a vertex).

We imagine that all the diagram lines have the same length (even though they are drawn with arbitrary length in fig. 1). A group acts on the set of diagrams, generated by the permutations of the subdiagrams having the same vertex as root. Two diagrams that can be superposed by the action of a transformation of the group will be regarded as identical (recall however that the diagram lines are numbered, i.e. are regarded as distinct, and the superposition has to be such that all the decorations of the diagram match). Trees diagrams are regarded as partially ordered sets of vertices (or lines) with a minimal element given by the root (or the root line). We shall imagine that each branch carries also an arrow pointing to the root ("gravity" direction, opposite to the order).

We define the "momentum" entering $v$ as $\vec{\nu}(v) = \sum_{w \in \partial v} \vec{\nu}_w$. If from a vertex $v$ emerge $m_1$ lines carrying a label $j = 1, m_2$ lines carrying $j = 2, \ldots$, it follows that (6) can be rewritten:

$$
\tilde{F}_{j_k}^{(k)} = \frac{1}{k!} \sum_{v \in \partial} \prod_{v \in \partial} (iJ^{-1}\vec{\nu}_v)_{j_v} f_{\tau_j} \prod_{s=1}^{l} (i\vec{\nu}_s)^{m_s} \prod_{v \in \partial} (i\vec{\omega}_0 \cdot \vec{\nu}(v))^{2} \tag{8}
$$

with the sum running over the diagrams $\partial$ of order $k$ and with $\vec{\nu}(v_0) = \vec{\nu}_0$ and the combinatorics can be checked from (6), by taking into account that we regard the diagram lines as all different (to fix the factorials).

The * recalls that the diagram $\partial$ can and will be supposed such that $\vec{\nu}(v) \neq \vec{0}$ for all $v \in \partial$ (by the above remarked parity properties). Note that (8) is implied by the corresponding (6.23) of [G]: one can check that the two formulae coincide (by summing over what in [G] are called the "fruit values"). The theory in [G] is in fact a little more general, although it is really applied to the same Thirring model.

There are other diagrams, however, which we would like to eliminate. They are the diagrams with nodes $v', v$, with $v' < v$, not necessarily nearest neighbours, such that $\vec{\nu}(v) = \vec{\nu}(v')$. Such diagrams are, according to Eliasson's terminology, *in resonance*.

To see this, for the purpose of illustration, we shall first restrict the sum in (8) to a sum over diagrams such that:

I) $\vec{\nu}(v) \neq \vec{0}$ if $v$ is any vertex.

II) $\vec{\nu}(v) \neq \vec{\nu}(v')$ for all pairs of comparable vertices $v', v$, (not necessarily next to each other in the diagram order, however), with $v \geq v_0$.

There are at most $2^{2k}k!$ diagrams and the labels $j$ can be at most $k^l$ while the $\vec{\nu}_v$ can be chosen in a number of ways bounded by $(2N+1)^{k} < (3N)^{k}$. Therefore, if $f_0 = \max_{\partial} |f_{\partial}|$:

$$
|h_{j_k}^{(k)}| \leq N(3N)^{k_0 2^{2k}k!} \frac{k^l}{k!} \frac{C_0^2 k_0}{\bar{f}_0} N^{2k} \max_{\partial} \prod_{v \in \partial} (C_0 \vec{\omega}_0 \cdot \vec{\nu}(v))^{-2} \leq (f_0 C_0^2 J_0^{-1})^k N^{(l+2)k+1} (23)^k M \tag{9}
$$

where the maximum is over the diagrams $\partial$ verifying the I),II) above. Hence the whole problem is reduced to estimating the maximum with $M$.

Let $q(q) \equiv (3N^\tau q^\tau)^{-1}$, where $\tau$ is the diophantine constant in (3): then $C_0 |\vec{\omega}_0 \cdot \vec{\nu}| \geq 3q(q)$ if $0 < |\vec{\nu}| \leq q$: we can say that $\vec{\nu} \in \mathbb{Z}^l$ is "$q$-singular" if $|\vec{\omega}_0 \cdot \vec{\nu}| < \zeta(q)$. Then the following (extension) of a lemma by Brijuno, see [P], holds for diagrams of degree $k$ verifying I),II) above. Fixed $q \geq 1$ let $N(k)$ be the number of $q$–resonant harmonics, among the vertex momenta $\vec{\nu}(v)$ of the vertices $v \in \partial$. Then $N(k) \leq 2 q^{\frac{k}{\tau}}$.

Assuming the above claim true (we shall not use it outside the present heuristic argument), we fix an exponentially decreasing sequence $\gamma^n$: the choice $\gamma = 2$ recommends itself. The number of $q = \gamma^{-n}$–singular harmonics which are not $q = \gamma^{-n+1}$–singular is bounded by $2k \gamma^{-n}$, (being trivially bounded by the number of $\gamma^{-n}$–singular harmonics!). Hence:

$$
\prod_{v \in \partial} \left( \frac{1}{(C_0 \vec{\omega}_0 \cdot \vec{\nu}(v))^2} \right) \leq \prod_{n=-\infty}^{-1} \zeta(\gamma(n-1))^{-4k\gamma^n} \leq \exp 4k \sum_{n \geq 1} 2^{-n} \log(3 \cdot 2^{(n-1)} N^\tau) = M \tag{10}
$$

therefore the series for the approximation to $\tilde{h}_{\vec{\nu}}^{(k)}$, that we are considering because of the extra restriction in the sum (8), has radius of convergence in $\varepsilon$ bounded below.
However there are resonant diagrams. The key remark is that they cancel almost exactly. The reason is very simple: imagine to detach from a diagram \( \vartheta \) the subdiagram \( \vartheta_2 \) with first node \( v \). Then attach it to all the remaining vertices \( w \geq v', w \in \vartheta/\vartheta_2 \). We obtain a family of diagrams whose contributions to \( h^{(k)} \) differ because:

1) some of the branches above \( v' \) have changed total momentum by the amount \( \vec{v}(v) \): this means that some of the denominators \( (\vec{\omega} \cdot \vec{v}(v))^{-2} \) have become \( (\vec{\omega} \cdot \vec{v}(v) \pm \epsilon)^{-2} \) if \( \epsilon \equiv \vec{\omega}_0 \cdot \vec{v}(v) \); and:

2) because there is one of the vertex factors which changes by taking successively the values \( \nu_{w_j}, j \) being the line label of the line leading to \( v \), and \( w \in \vartheta/\vartheta_2 \) is the vertex to which such line is reattached.

Hence if \( \vec{\omega} \cdot \vec{v} = \epsilon = 0 \) we would build in this resummation a quantity proportional to: \( \sum \vec{v}_w = \vec{v}(v) - \vec{v}(v') \) which is zero, because \( \vec{v}(v) = \vec{v}(v') \) means that the sum of the \( \vec{v}_w \)'s vanishes. Since \( \vec{\omega} \cdot \vec{v} = \epsilon \neq 0 \) we can expect to see a sum of order \( \epsilon^2 \), if we sum as well on a overall change of sign of the \( \vec{v}_w \) values (which sum up to \( \vec{0} \)).

But this can be true only if \( \epsilon \ll \vec{\omega} \cdot \vec{v}' \), for any line momentum \( \vec{v}' \) of a line in \( \vartheta/\vartheta_2 \). If the latter property is not true this means that \( \vec{\omega} \cdot \vec{v}' \) is small and that there are many vertices in \( \vartheta/\vartheta_2 \) of order of the amount needed to create a momentum with small divisors of order \( \epsilon \).

Examining carefully the proof of Brjuno’s lemma one sees that such extreme case would be essentially also treatable. Therefore the problem is to show that the two regimes just envisaged (and their “combinations”) do exhaust all possibilities.

Such problems are very common in renormalization theory and are called “overlapping divergences”. Their systematic analysis is made through the renormalization group methods. We argue here that Eliasson’s method can be interpreted in the same way.

The above introduced diagrams will play the role of Feynman diagrams; and they will be plagued by overlapping divergences. They will therefore be collected into another family of graphs, that we shall call trees, on which the bounds are easy. The \( (\vec{\omega} \cdot \vec{v})^{-2} \) are the propagators, in our analogy.

We fix an scaling parameter \( \gamma \), which we take \( \gamma = 2 \) for consistency with (3), and we also define \( \vec{\omega} \equiv C_0 \vec{\omega}_n \): it is an adimensional frequency. Then we say that a propagator \( (\vec{\omega} \cdot \vec{v})^{-2} \) is on scale \( n \) if \( 2^{n-1} \leq |\vec{\omega} \cdot \vec{v}| \leq 2^n \), for \( n \leq 0 \), and we set \( n = 1 \) if \( 1 < |\vec{\omega} \cdot \vec{v}| \).

Proceeding as in quantum field theory, see [G3], given a diagram \( \vartheta \) we can attach a scale label to each line \( v' v \) in (8) (with \( v' \) being the vertex preceding \( v \)): it is equal to \( n \) if \( n \) is the scale of the line propagator. Note that the labels thus attached to a diagram are uniquely determined by the diagram: they will have only the function of helping to visualize the orders of magnitude of the various diagram lines.

Looking at such labels we identify the connected clusters \( T \) of vertices that are linked by a continuous path of lines with the same scale label \( n_T \) or a higher one. We shall say that the cluster \( T \) has scale \( n_T \).

Among the clusters we consider the ones with the property that there is only one diagram line entering them and only one exiting and both carry the same momentum. Here we use that the diagram lines carry an arrow pointing to the root: this gives a meaning to the words “incoming” and “outgoing”.

If \( V \) is one such cluster we denote \( \lambda_V \) the incoming line: the line scale \( n = n_{\lambda_V} \) is smaller than the smallest scale \( n' = n_T \) of the lines inside \( V \). We call \( w_1 \) the vertex into which the line \( \lambda_V \) ends, inside \( V \). We say that such a \( V \) is a resonance if the number of lines contained in \( V \) is \( \leq E 2^{-m_v} \), where \( n = n_{\lambda_V} \), and \( E, \varepsilon \) are defined by: \( E \equiv 2^{-3 \varepsilon} N^{-1}, \varepsilon = \tau^{-1} \). We shall say that \( n_{\lambda_V} \) is the resonance scale.

Let us consider a diagram \( \vartheta \) and its clusters. We wish to estimate the number \( N_n \) of lines with scale \( n \leq 0 \) in it, assuming \( N_n > 0 \).

Denoting \( T \) a cluster of scale \( n \) let \( m_T \) be the number of resonances of scale \( n \) contained in \( T \) (i.e. with incoming lines of scale \( n \)), we have the following inequality, valid for any diagram \( \vartheta \):

\[
N_n \leq \frac{3k}{E 2^{-\varepsilon n}} + \sum_{T, n_T = n} (-1 + m_T)
\]

with \( E = N^{-1} 2^{-3\varepsilon} \varepsilon = \tau^{-1} \). This is a version of Brjuno’s lemma: a proof is in appendix.

Consider a diagram \( \vartheta^1 \) we define the family \( F(\vartheta^1) \) generated by \( \vartheta^1 \) as follows. Given a resonance \( V \) of \( \vartheta^1 \) we detach the part of \( \vartheta^1 \) above \( \lambda_V \) and attach it successively to the points \( w \in V \), where \( V \) is the set of vertices of \( V \) (including the endpoint \( w_1 \) of \( \lambda_V \) contained in \( V \)) outside the resonances contained in \( V \). Note that all the lines \( \lambda \) in \( V \) have a scale \( n_{\lambda} \geq n_V \).

For each resonance \( V \) of \( \vartheta^1 \) we shall call \( M_V \) the number of vertices in \( V \). To the just defined set of diagrams we add the diagrams obtained by reversing simultaneously the signs of the vertex modes \( \vec{v}_w \), for \( w \in V \): the
In fact, large being inside the resonances: the reason is simply that inside a resonance $\lambda$ of scale $\lambda$ pairwise disjoint families of diagrams. We shall sum all the contributions to $\vartheta$ are attached to generally distinct vertices inside the resonances: the identity of the lines is here defined by the vertex to which the line entering $F$ members of each family. This is the $\vartheta$ in the sense of the line arrows, but contained in $V$; and $\vartheta = 0, \pm 1$.

Therefore not only $|\vec{\omega} \cdot \vec{p}_\lambda| \geq 2^{n+3}$ (because $\vec{p}_\lambda$ is a sum of $\leq N_n$ vertex modes, so that $|\vec{p}_\lambda| \leq N N_n$) but $\vec{\omega} \cdot \vec{p}_\lambda$ is "in the middle" of the diadic interval containing it and by (3) does not get out of it if we add a quantity bounded by $2^{n+1}$ (like $\sigma_\lambda \vec{\omega} \cdot \vec{p}_\lambda$). Hence no line changes scale as $\vartheta$ varies in $\mathcal{F}(\vartheta^1)$, if $\vec{\omega}_0$ verifies (3).

This implies, by the strong diophantine hypothesis on $\vec{\omega}_0$, (3), that the resonant clusters of the diagrams in $\mathcal{F}(\vartheta^1)$ all contain the same sets of lines, and the same lines go in or out of each resonance (although they are attached to generally distinct vertices inside the resonances: the identity of the lines is here defined by the number label that each of them carries in $\vartheta^1$). Furthermore the resonance scales and the scales of the resonant clusters, and of all the lines, do not change.

Let $\vartheta^2$ be a diagram not in $\mathcal{F}(\vartheta^1)$ and construct $\mathcal{F}(\vartheta^2)$, etc. We define a collection $\{\mathcal{F}(\vartheta^i)\}_{i=1,2,\ldots}$ of pairwise disjoint families of diagrams. We shall sum all the contributions to $\tilde{h}^{(k)}$ coming from the individual members of each family. This is the Eliasson’s resummation.

We call $\varepsilon_V$ the quantity $\vec{\omega} \cdot \vec{p}_\lambda$ associated with the resonance $V$. If $\lambda$ is a line with both extremes in $V$ we can imagine to write the quantity $\vec{\omega} \cdot \vec{p}_\lambda$ as $\vec{\omega} \cdot \vec{p}_\lambda + \sigma_\lambda \varepsilon_V$, with $\sigma_\lambda = 0, \pm 1$. Since $|\vec{\omega} \cdot \vec{p}_\lambda| > 2^{n+1}$

we see that the product of the propagators is holomorphic in $\varepsilon_V$ for $|\varepsilon_V| < 2^{n+3}$. While $\varepsilon_V$ varies in such complex disk the quantity $|\vec{\omega} \cdot \vec{p}_\lambda|$ does not become smaller than $2^{n+1} - 2^{n+3} \geq 2^{n+2}$. Note the main point here: the quantity $2^{n+3}$ will usually be $\geq 2^{n+3}$ which is the value $\varepsilon_V$ actually can reach in every diagram in $\mathcal{F}(\vartheta^1)$: this can be exploited in applying the maximum principle, as done below.

It follows that, calling $n_\lambda$ the scale of the line $\lambda$ in $\vartheta^1$, each of the $\Pi \lambda \leq 2^{2(k-2)} K \Pi \lambda \leq 2^{2(k-2)} M$, if regarded as a function of the quantities $\varepsilon_V = \vec{\omega} \cdot \vec{p}_\lambda$, for $|\varepsilon_V| \leq 2^{n-3}$, associated with the resonant clusters $V$. This even holds if the $\varepsilon_V$ are regarded as independent complex parameters.

By construction it is clear that the sum of the $\Pi \lambda \leq 2^{2(k-2)} K \Pi \lambda \leq 2^{2(k-2)} M$, terms, giving the contribution to $\tilde{h}^{(k)}$ from the trees in $\mathcal{F}(\vartheta^1)$, vanishes to second order in the $\varepsilon_V$ parameters (by the approximate cancellation discussed above). Hence by the maximum principle, and recalling that each of the scalar products in (8) can be bounded by $N^2$, we can bound the contribution from the family $\mathcal{F}(\vartheta^1)$ by:

$$\left[ \frac{1}{k! N_n^2} \left( \frac{\beta C_0^2 N_n^2}{J_0} \right)^k 2^{2k} e^{2k} \prod_{n \leq 0} 2^{2n N_n} \right] \left[ \prod_{n \leq 0 T_n \sigma_T} \prod_{n \leq 0 T_n} 2^{2(n-n+1)} \right]$$

where:

1) $N_n$ is the number of propagators of scale $n$ in $\vartheta^1$ ($n = 1$ does not appear as $|\vec{\omega} \cdot \vec{p}| \geq 1$ in such cases),

2) the first square bracket is the bound on the product of individual elements in the family $\mathcal{F}(\vartheta^1)$ times the bound $e^{2k}$ on their number,

3) The second term is the part coming from the maximum principle, applied to bound the resummations, and is explained as follows.

i) the dependence on the variables $\varepsilon_{V_i} \equiv \varepsilon_i$ relative to resonances $V_i \subset T$ with scale $n_{\lambda_{V_i}} = n$ is holomorphic for $|\varepsilon_i| < 2^{n-3}$ if $n_i = n_{V_i}$, provided $n_i > n + 3$ (see above).

ii) The resummation says that the dependence on the $\varepsilon_i$’s has a second order zero in each. Hence the maximum principle tells us that we can improve the bound given by the first factor in (12) by the product of factors

$$|\vec{\omega} \cdot \vec{p}_\lambda| \geq 2^{n+3} \text{ because } V \text{ is a resonance; therefore } |\vec{\omega} \cdot \vec{p}_\lambda| \geq 2^{n+3} - 2^{n+1} \geq 2^{n+2} \text{ so that } n_V \geq n + 3.$$

On the other hand note that $|\vec{\omega} \cdot \vec{p}_\lambda| > 2^{n-1} - 2^{n+1}$ so that $|\vec{\omega} \cdot \vec{p}_\lambda + \sigma_\lambda \varepsilon_V| \geq 2^{n-1} - 2^{n+1} - 2^{n-3} \geq 2^{n-3}$, for $|\varepsilon_V| < 2^{n-3}$. 

(\varepsilon_i 2^{-n_i+3})^2 \text{ if } n_i > n + 3. \text{ If } n_i \leq n + 3 \text{ we cannot gain anything: but since the contribution to the bound from such terms in (12) is } > 1 \text{ we can leave them in it to simplify the notation, (of course this means that the gain factor can be important only when } \ll 1). 

Hence substituting (11) into (12) we see that the \( m_T \) is taken away by the first factor in \( 2^{2n} 2^{-2n_i} \), while the remaining \( 2^{-2n_i} \) are compensated by the \( -1 \) before the \(+ m_T \) in (11), taken from the factors with \( T = V_i \), (note that there are always enough \(-1\)'s).

Hence the product (12) is bounded by:

\[
\frac{1}{k!} N (C_0 J_0^{-1} f_0 N^2)^k e^{2k 2^{4k} 2^{6k}} \prod_n 2^{-6nk E^{-1} 2^n} \leq \frac{1}{k!} N B_0^k
\]

with: \( B_0 = 2^{10} e^2 C_0^2 f_0 N^2 \exp[N (2^{2+2\tau-1} \log 2) \sum_{p=1}^\infty b 2^{-p\tau-1}] \).

To sum over the trees we note that, fixed \( \vartheta \) the collection of clusters is fixed. Therefore we only have to multiply (13) by the number of diagram shapes for \( \vartheta \), \( \leq 2^{2k!} \), by the number of ways of attaching mode labels, \( \leq (3N)^{4k} \), so that we can bound \(|h^{(k)}|\) by (5).

Comments.

The strong diophantine condition is quite unpleasant as it seems to put an extra requirement on \( \omega_0 \): I think that in fact such condition is not necessary. Given \( \bar{\omega}_0 \) verifying the first of (3) with some constant \( \bar{C}_0 \) and some \( \tau \) we can imagine to define \( C_0 \equiv 2^{*} \bar{C}_0 \): this leaves the first of (3) still valid. One should then note that the \( 0 < \| \bar{\nu} \| \leq (2^{n+3})^{-\tau} \) will imply that if \( 0 < \| \bar{\nu} \| \leq (2^{n+3})^{-\tau} \) the numbers \( |\bar{\omega} \cdot \bar{\nu}| \) are spaced by at least \( (2 (2^{2n+3})^{-\tau})^{-1} \). Hence we can find a sequence \( \gamma_n \) such that \( 1 < \gamma_n 2^{-n} \leq 2 \) and \( |\bar{\omega} \cdot \bar{\nu}| - \gamma_p \geq 2^{n+2} \) for \( 0 \geq p \geq n \). Defining a propagator \( x^{-2} \) to have "scale \( n \)" if \( \gamma_{n-1} < |x| \leq \gamma_n \) it should be possible to perform the proof without the second assumption in (3). This will be interesting to check if it really works as it would be fully constructive, given \( \bar{\omega}_0 \) verifying the first of (3), and as it would cover the most studied cases like the case \( l = 2 \) and \( \bar{\omega} = (\omega_1, \omega_2) = (1, \omega) \) with \( \omega \) a quadratic irrational, or a number with uniformly bounded continued fraction entries. It has also the conceptual advantage that the sequence of scales \( \gamma_n \) is not "prescribed a priori" but it is determined by the arithmetic properties of the rotation vector \( \omega_0 \).

Appendix A1: Resonant Siegel-Brjuno bound.

Calling \( N^*_n \) the number of non resonant lines carrying a scale label \( \leq n \). We shall prove first that \( N^*_n \leq 2k (E 2^{-en})^{-1} \) if \( N^*_n > 0 \).

If \( \vartheta \) has the root line with scale \( > n \) then calling \( \vartheta_1, \vartheta_2, \ldots, \vartheta_m \) the subdiagrams of \( \vartheta \) emerging from the first vertex of \( \vartheta \) and with \( k_j > E 2^{-en} \) lines, it is \( N^*(\vartheta) = N^*(\vartheta_1) + \ldots + N^*(\vartheta_m) \) and the statement is inductively implied from its validity for \( k' < k \) provided it is true that \( N^*(\vartheta) = 0 \) if \( k < E 2^{-en} \), which is is certainly the case if \( E \) is chosen as in (11).

In the other case it is \( N^*_n \leq 1 + \sum_{i=1}^m N^*(\vartheta_i) \), and if \( m = 0 \) the statement is trivial, or if \( m \geq 2 \) the statement is again inductively implied by its validity for \( k' < k \).

If \( m = 1 \) we once more have a trivial case unless the order \( k_1 \) of \( \vartheta_1 \) is \( k_1 > k - \frac{1}{2} E 2^{-en} \). Finally, and this is the real problem as the analysis of a few examples shows, we claim that in the latter case the root line is either a resonance or it has scale \( > n \).

Accepting the last statement it will be: \( N^*(\vartheta) = 1 + N^*(\vartheta_1) = 1 + N^*(\vartheta'_1) + \ldots + N^*(\vartheta'_m) \), with \( \vartheta'_j \) being the \( m' \) subdiagrams emerging from the first node of \( \vartheta'_1 \) with orders \( k'_j > E 2^{-en} \): this is so because the root line of \( \vartheta_1 \) will not contribute its unit to \( N^*(\vartheta_1) \). Going once more through the analysis the only non trivial case is if \( m' = 1 \) and in that case \( N(\vartheta'_1) = N(\vartheta''_1) + \ldots + N(\vartheta''_{m'}) \), etc, until we reach a trivial case or a diagram of order \( \leq k - \frac{1}{2} E 2^{-en} \).

It remains to check that if \( k_1 > k - \frac{1}{2} E 2^{-en} \) then the root line of \( \vartheta_1 \) has scale \( > n \), unless it is entering a resonance.

\[3\] Note that if \( k \leq E 2^{-en} \) it is, for all momenta \( \vec{\nu} \) of the lines, \( |\vec{\nu}| \leq NE 2^{-en} \), i.e. \( |\bar{\omega} \cdot \vec{\nu}| \geq (NE 2^{-en})^{-\tau} = 2^3 2^n \) so that there are no clusters \( T \) with \( n_T = n \) and \( N^* = 0 \). The choice \( E = N^{-1} 2^{-3c} \) is convenient: but this, as well as the whole lemma, remains true if \( 3 \) is replaced by any number larger than \( 1 \). The choice of \( 3 \) is made only to simplify some of the arguments based on the resonance concept.
Suppose that the root line of $\vartheta_1$ is not entering a resonance. Note that $|\vec{\omega} \cdot \vec{\vartheta}(v_0)| \leq 2^n, |\vec{\omega} \cdot \vec{\vartheta}(v)| \leq 2^n$, if $v_0, v_1$ are the first vertices of $\vartheta$ and $\vartheta_1$ respectively. Hence $\delta \equiv |(\vec{\omega} \cdot (\vec{\vartheta}(v_0) - \vec{\vartheta}(v_1)))| \leq 22^n$ and the diophantine assumption implies that $|\vec{\vartheta}(v_0) - \vec{\vartheta}(v_1)| \leq (2^{2n})^{-1}$, or $\vec{\vartheta}(v_0) = \vec{\vartheta}(v_1)$. The latter case being discarded as $k - k_1 < \frac{1}{2} E 2^{-\varepsilon n}$ (and we are not considering the resonances), it follows that $k - k_1 < \frac{1}{2} E 2^{-\varepsilon n}$ is inconsistent: it would in fact imply that $\vec{\vartheta}(v_0) - \vec{\vartheta}(v_1)$ is a sum of $k - k_1$ vertex modes and therefore $|\vec{\vartheta}(v_0) - \vec{\vartheta}(v_1)| < \frac{1}{2} NE 2^{-\varepsilon n}$ hence $\delta > 2^{\varepsilon 2^n}$ which is contradictory with the above opposite inequality.

A similar, far easier, induction can be used to prove that if $N_n^* > 0$ then the number $p$ of clusters of scale $n$ verifies the bound $p < k (E 2^{-\varepsilon n})^{-1} - 1$. Thus (11) is proved.

Remark: the above argument is a minor adaptation of Brjuno’s proof of Siegel’s theorem, as remarkably exposed by Pöschel, [P].

Acknowledgements: I am indebted to J. Bricmont and M. Vittot for many clarifying discussions; and in particular to S. Miracle-Solé for the same reasons and for his interest and suggestions.
