Supercritical Carbon Dioxide Extraction of *Nicotiana tabacum* Leaves: Optimization of Extraction Yield and Nicotine Content

Nina Djapic

Technical Faculty “Miha¡jo Pupin”, University of Novi Sad, Djure Djakovica bb, 23000 Zrenjanin, Serbia; nina.djapic@tfzr.rs

**Highlights:**

Nicotine was extracted from varieties Samsun and Virginia tobacco leaves using supercritical CO₂ extraction.

Response surface methodology was used to find factors that influence the supercritical CO₂ extraction of tobacco leaves.

The highest nicotine relative amount was at lower pressure (15 MPa), temperature of 50 °C and during 90 min extraction time.

The quantity of nicotine and phytochemical composition in different tobacco varieties is specific.

**Abstract:** The employment of supercritical carbon dioxide extraction for obtaining the chemical compounds from *N. tabacum* leaves, especially nicotine, is advancing. The supercritical carbon dioxide extraction of dried *N. tabacum* cv. Samsun and *N. tabacum* cv. Virginia at different process parameters was performed to obtain the highest extraction yield and nicotine relative amount. The optimal extraction conditions concerning the highest extraction yield and nicotine relative amount were determined by response surface methodology. The highest extraction yield for *N. tabacum* cv. Samsun was 2.99% and for *N. tabacum* cv. Virginia 2.33% at 23.41 MPa, 50 °C and 90 min of extraction time. The highest nicotine relative amount in *N. tabacum* cv. Samsun and *N. tabacum* cv. Virginia was at 15 MPa, 50 °C and 90 min extraction time and was 242.1 mg per 100 g of plant material and 32.4 mg per 100 g of plant material, respectively. The pressure, temperature and time influenced the extraction yield and nicotine relative amount recovery in *N. tabacum* cv. Samsun and *N. tabacum* cv. Virginia. A general inclusive concept in respect to pressure, temperature and time of the supercritical carbon dioxide extraction and a report on phytochemicals present in two *N. tabacum* varieties is presented.

**Keywords:** *Nicotiana tabacum*; nicotine; supercritical CO₂ extraction

1. Introduction

*Nicotiana tabacum* L., Solanaceae is the most common tobacco with approximately 152 cultivated varieties [1]. The main cultivated tobacco species are Burley, Virginia, and Oriental [2,3]. The Oriental tobacco, which includes several hundred varieties, has four primary groups: Samsun, Smyrna, Kavalla, and Xanthi [2]. The chemical constituents of tobacco leaf and differences among tobacco types are well described [4]. *N. tabacum* leaves are the source of nicotine [4,5]. Nicotine can range in concentrations from 0.5 to 8% in cultivated tobacco species [4]. Nicotine is soluble in alcohol, chloroform, ether, petroleum ether, kerosene, and water [6,7]. Various solvents can be used to isolate nicotine from tobacco leaves using the solvent extraction method [6,7]. The separation of nicotine from tobacco leaves can be performed with supercritical carbon dioxide (SC CO₂) [8]. In the single-stage process at the pressure of approximately 30 MPa and the temperatures between the critical temperature of the gas and 100 °C, the dissolved nicotine is separated by reducing the temperature or by changing the temperature or is bound by adsorption onto suitable sorbents [8]. The residual nicotine content as a function of processing time...
for Burley, Virginia and Oriental tobacco leaves is different [8]. Tobaccos of different origin behave differently under the SC CO\textsubscript{2} extraction [9,10]. The supercritical fluid extraction was used for the extraction of \textit{N. tabacum} leaves and apart from nicotine and solanesol, in those extracts, \(\alpha\)-tocopherol was detected [11,12]. The SC CO\textsubscript{2} is used in the tobacco processing industry for removing nicotine and producing low-nicotine tobacco. The reduction in nicotine content in tobacco is completed in several stages [10]. After the selective removal of aroma with the SC CO\textsubscript{2}, the obtained aroma is used to impregnate a previous batch from which the nicotine and aroma have been removed [10]. This is completed by allowing the SC phase to expand into the batch [10]. The de-aromatized tobacco is moistened, and the nicotine is removed in an isobaric and isothermal recycling operation involving a selective sorbent, indicating that the moisture is the essential in the extraction of nicotine [10]. After all the stages, the nicotine content of the tobacco is reduced to \(~95\)% [10]. The mixture of tobacco varieties, in form of 32.5\% flue-cured, 19.9\% Burley, 1.2\% Maryland, 11.1\% Oriental and 27.1\% reconstituted, has been used for the SC CO\textsubscript{2} extraction of nicotine under the pressure of 26 MPa and temperature of 70 °C [10]. The influence of particle size, cell geometry and packing of the extraction cell was investigated for the extraction of nicotine from the tobacco using cosolvent, 12 cm\(^3\) MeOH:41.2 mM KH\textsubscript{2}PO\textsubscript{4} = 2:3, under the pressure of 13.7 MPa, temperature of 100 °C for 35 min [13]. Tobacco waste, derived from tobacco leaves and obtained during tobacco processing, has been used for the extraction of nicotine by SC CO\textsubscript{2} extraction [14]. The SC CO\textsubscript{2} extraction conditions were at the pressure from 15 to 30 MPa, time was from 180 to 300 min and temperature was from 50 to 70 °C [14].

Many factors influence the SC CO\textsubscript{2} extraction, and it is important to screen the factors that influence the SC CO\textsubscript{2} process to find the responses. The response surface methodology (RSM) and central composite rotatable design (CCRD) are appropriate to find the important factors influencing the process. This optimization design permits finding the optimal levels of chosen factors that influence the process in SC CO\textsubscript{2} [15]. The RSM is useful for modeling and analysis of factors where a response of interest is influenced by several variables [16,17]. The present research aims to optimize the pressure, temperature and time for the production of high extraction yield and nicotine content of two \textit{N. tabacum} varieties. From the Oriental tobacco leaves, chosen was the variety Samsun grown in Shuakhevi, Adjara, Georgia, and the other variety was Virginia, which is the most commonly grown of all plants in the genus \textit{Nicotiana}; the leaves grown to be processed into tobacco were grown in Kukujevci, Srem, Serbia.

Starting from the assumption that Oriental and flue-cured tobacco leaves have different aroma, chosen were \textit{N. tabacum} cv. Samsun and \textit{N. tabacum} cv. Virginia leaves for this research. The aim of the work was to investigate the (1) influence of process parameters, pressure, temperature, and time on SC CO\textsubscript{2} extraction of dried \textit{N. tabacum} cv. Samsun and \textit{N. tabacum} cv. Virginia on the total extraction yield; (2) chemical profile of extracts analyzed by GC–MS; and (3) influence of process parameters, pressure, temperature, and time on SC CO\textsubscript{2} extraction of dried \textit{N. tabacum} cv. Samsun and \textit{N. tabacum} cv. Virginia on the relative amount of nicotine analyzed by GC–MS. In addition, the aim was also to (4) determine optimal extraction conditions by RSM.

2. Results
Optimization of SC CO\textsubscript{2} Extraction of \textit{N. tabacum} cv. Samsun and \textit{N. tabacum} cv. Virginia Leaves

The CCRD was used to optimize the operating variables, pressure, temperature, and time of the SC CO\textsubscript{2} extraction to achieve the highest extraction yield and higher relative amount of nicotine from the \textit{N. tabacum} cv. Samsun and \textit{N. tabacum} cv. Virginia leaves. The design matrix indicating the coded variables is depicted in Table 1.

The CCRD was completed with 20 experiments where six replicates were for the central point (Table 2).

The effects of linear, square, and two-way interaction coefficients on the response were tested for the significance by the analysis of variance (ANOVA). Regression coefficients of constant, linear, square and interaction terms of the model were obtained using the least square method. The degree of significance is determined by the \(p\)-value (Table 3).
Table 1. The uncoded and coded levels of independent variables used in the RSM.

| Levels                     | Independent Variables | Symbol | −1.414 | −1 | 0 | +1 | +1.414 |
|----------------------------|-----------------------|--------|--------|----|---|-----|--------|
| Pressure [MPa]             | X₁                    | 8      | 10     | 15 | 20| 22  |
| Temperature [°C]           | X₂                    | 36     | 40     | 50 | 60| 64  |
| Time [min]                 | X₃                    | 39.55  | 60     | 90 | 120| 140.45 |

Table 2. The CCRD experimental design and results for the *N. tabacum* cv. Samsun and *N. tabacum* cv. Virginia leaves total extraction yield [%] for the response surface analysis.

| No. | Pressure [MPa] | Temperature [°C] | Time [min] | Extraction Yield *N. tabacum* cv. Samsun [%] | Extraction Yield *N. tabacum* cv. Virginia [%] |

The surface response plots for the effect of independent variables on the *N. tabacum* cv. Samsun leaves total extraction yield [%] are depicted in Figure 1.

![Figure 1](a) Surface response plots for the *N. tabacum* cv. Samsun leaves extraction yield in a function of extraction: (a) pressure and temperature; (b) pressure and time and (c) temperature and time.

The surface response plots for the effect of independent variables on the *N. tabacum* cv. Virginia leaves total extraction yield [%] are depicted in Figure 2.

The CCRD was used to optimize the extraction pressure, temperature and time to achieve the highest relative amount of nicotine. The chemical profiles of *N. tabacum* cv. Samsun and *N. tabacum* cv. Virginia leaves’ extracts analyzed by GC–MS and their relative amount are depicted in Tables 5 and 6, respectively.
The ANOVA was used for the calculation of regression coefficients of constant, linear, square and interaction terms of the nicotine relative amount model for *N. tabacum* cv. Samsun and *N. tabacum* cv. Virginia leaves' extracts (Table 7).
Table 7. The response surface regression coefficients of the polynomial function for the *N. tabacum* cv. Samsun and *N. tabacum* cv. Virginia leaves’ nicotine relative amount (mg nicotine equivalents per 100 g of plant material).

\textbf{3. Discussion}

The extraction yield of \textit{N. tabacum} cv. Samsun leaves varied from 0.11% to 2.99% under applied process parameters (Table 2). The lowest yield was at the pressure of 10 MPa, temperature of 60 °C and 60 min extraction time. The highest yield was at the pressure of 23.41 MPa, temperature of 50 °C and 90 min extraction time. The extraction yield of \textit{N. tabacum} cv. Virginia was from 0.08% to 2.33% (Table 2). The extraction yield, for both plant systems analyzed, increased with the increase in pressure. The linear term of pressure, temperature and time, the square term of pressure, temperature and time, and two-way interaction factor of pressure and temperature exhibited the most statistically significant influence \((p < 0.05)\) on the extraction yield in both plant systems (Table 3). The two-way interaction factors of pressure and time and temperature and time did not have a significant influence on the extraction process for the total extraction yield in both plant systems analyzed. The visual effects of independent on dependent variables are depicted on the surface response plots of the proposed model in Figures 1 and 2. From the surface response plots, it can be seen that the extraction yield increases with the extraction time. The similar shape of response plots 1a and 2a, 1b and 2b, and 1c and 2c indicate that the influence of process parameters is almost the same on the total extraction yield in both plant varieties analyzed.

The obtained SC CO\textsubscript{2} extracts were characterized by gas chromatography-mass spectrometry (GC–MS). The main compound in Samsun tobacco leaves was nicotine, and different extraction parameters influenced its relative amount in the extracts (Table 5).
Nicotine is the major alkaloid in tobacco leaves [4]. Its quantity depends on the variety, climate conditions, cultivation, and processing methods [4]. Neophytadiene is present in Samsun tobacco leaves in quantities from 17.25 to 38.29 mg expressed as nicotine equivalents per 100g of plant material. Its quantities are the highest in Burley tobacco leaves [18]. The main compound in Virginia tobacco leaves was 8,13-epoxy-14-labden-12-ol, a tricyclic diterpenoid, also identified in *N. tabacum* Oriental type tobacco leaves Yaka and Prilep, and semi Oriental type Otlja [19]. The main compounds in Virginia tobacco leaves, apart from a tricyclic diterpenoid were nicotine, a primary alcohol solanesol, neophytadiene, a sesquiterpenoid farnesol, unsaturated ketone solanone and a diketone norsolanadione (Table 6). Other compounds identified in Virginia tobacco leaves were present only under some extraction parameters (Table 6). The compounds detected in both plant varieties leaves were nicotine, neophytadiene, sesquiterpenoid 3-oxo-α-ionol, a monocyclic diterpene alcohol thunbergol, and sesquiterpene lactone sclareolide (Table 6).

Different SC CO₂ extraction parameters influence the abundance of compounds present in the SC CO₂ extracts. The effects of linear, square, and two-way interaction on the nicotine relative amount in Samsun and Virginia tobacco leaves are depicted in Tables 7 and 8, respectively. The regression coefficients of intercept, linear, square, and two-way interaction terms of the model were determined by the least square method. The degree of significance of every factor is represented with *p*-factor. For both systems analyzed, the linear term of pressure and time and all square terms showed the most significant influence. The linear term of temperature and the two-way interactions did not exhibit a statistically significant influence on any of the investigated responses (Table 7). The coefficient of determination *R*² was 0.9659 for Samsun and 0.9514 for Virginia, indicating that the model was made with satisfactory coefficients of determination. The data obtained were used to create the three-dimensional graphs of the response surface (Figures 3 and 4). The similar shape of the response plots 3a and 4a, 3b and 4b, and 3c and 4c indicated the same influence of process parameters on the extraction of nicotine relative amount. The SC CO₂ extraction has been used for removing nicotine [20]. It was proposed that the moisture and compounds present in plant material influence the extraction yield of nicotine [13].

The results obtained indicated that the pressure has a significant influence on nicotine yield [11,14,21]. The extraction yield of nicotine from tobacco waste, which also contains leaves’ particles, increases with the increase in pressure and at the temperatures between 50 and 60 °C [14]. At temperatures above 60 °C, the extraction yield of nicotine decreases [14]. The optimal temperature for Samsun and Virginia leaves was 50.51 °C, indicating the accordance with previous investigations [14]. The extraction at higher temperatures yields extracts with high nicotine content, while extractions at lower temperatures yield extracts with high solanesol content [11]. One investigation suggested that for the extraction of nicotine from tobacco leaves, higher pressures are favorable due to the selectivity and high extraction yield [14]. For Samsun leaves, the optimal pressure was 17.80 MPa and for Virginia, it was 17.29 MPa for obtaining the high nicotine relative amount. In previous investigations, the highest nicotine relative content in *N. tabacum* leaves was obtained at pressure of 15 MPa and at the temperature of 50 °C [11]. The lowest nicotine relative content was, in one investigation, at 8 MPa and temperature of 25 °C, indicating that the lower temperatures influenced the relative nicotine content in the extract [11]. The study on nicotine content in *N. tabacum* L. leaves was in one investigation 19.34% (15 MPa and 28 °C) and 23.70% (15 MPa and 60 °C); 12.29% (17 MPa and 60 °C) and 22.50% (17 MPa and 80 °C); and 47.40% (12 MPa and 60 °C) and 25.87% (12 MPa and 80 °C) [12]. The highest extraction yield was at lower pressure, the pressure of 12 MPa and temperature of 60 °C [12]. The lowest nicotine content was obtained at 17 MPa and at the temperature of 60 °C, indicating that the increase in pressure at the same temperature decreases the nicotine content [12]. This suggested explanation that with the increase in pressure, the dissolving power of nicotine decreases.

The application of the optimal parameters leads to the highest extraction yield. The predicted optimum parameters for the highest extraction yield for the *N. tabacum* cv. Samsun
were at 23.41 MPa, at 56.62 °C and 125.1 min extraction time and for the \textit{N. tabacum cv. Virginia} were at 21.03 MPa, at 50.51 °C and 124.1 min extraction time. The SC CO\textsubscript{2} extraction of \textit{N. tabacum cv. Samsun} and \textit{N. tabacum cv. Virginia} at their predicted optimal parameters for obtaining the highest extraction yield was performed three times. The extraction yield under the predicted optimal conditions yielded for Samsun tobacco leaves 3.07 % ± 0.11 and for Virginia tobacco leaves 2.52 % ± 0.10. The results obtained were compatible with the theoretical model value. The goal of the RSM was to develop the method that can be used for the simulation of the extraction that yields the highest nicotine relative amount. By applying appropriate pressure, temperature, and extraction time, the optimal conditions for obtaining the highest extraction nicotine relative amount in \textit{N. tabacum cv. Samsun} was at the pressure of 17.80 MPa, the temperature of 50.51 °C and 104.5 min extraction time and in \textit{N. tabacum cv. Virginia}, it was at 17.29 MPa, at 50.51 °C and 105.5 min extraction time. The extractions for obtaining the highest nicotine relative amount were completed three times, and it was determined for the Samsun tobacco leaves to be 242.80 ± 0.07 and for Virginia tobacco leaves 32.27 ± 0.13 mg per 100 g of plant material. These values are close to the value of the ideal case. A general inclusive concept revealed that the optimum extraction time was longer compared to previous reports. The phytochemical profile of two \textit{N. tabacum} varieties revealed that the variety Samsun is the best for the recovery of nicotine.

4. Materials and Methods

4.1. Chemicals

The CO\textsubscript{2} used for the extraction was 99.97% pure (Messer, Tehnogas AD, Rakovica, Serbia). Nicotine standard (99% purity) was purchased from Sigma-Aldrich Chemie GmbH (Taufkirchen, Germany). All other solvents used were of analytical reagent grade.

4.2. Plant Material

\textit{N. tabacum cv. Samsun} was purchased from a local producer in November 2021, Shuakhevi, Adjara, Georgia and \textit{N. tabacum cv. Virginia} from a local producer in Kukujevci, Srem, Serbia. The leaves were air-cured in a well-ventilated barn for three months. Cured tobacco leaves were grounded and sieved for 15 min using a vertical vibratory sieve shaker (Labortechnik GmbH, Ilmenau, Germany). The average particle size was 0.352 mm ± 0.043 for Samsun tobacco leaves and 0.361 mm ± 0.037 for Virginia tobacco leaves. The water content of grounded tobacco leaves was determined according to AOAC Official Method 925.40 and was 2.86 ± 0.11% for Samsun tobacco leaves and 2.37 ± 0.09% for the Virginia tobacco leaves. All measurements were performed in triplicate. The Samsun tobacco leaves and Virginia tobacco leaves powder obtained were used for the SC CO\textsubscript{2} extractions.

4.3. Extraction Procedure

The experiments were completed in a SC CO\textsubscript{2} system described previously [22]. Here, 50 g of plant material powder was used for each extraction. The extractions were performed at different extractions conditions determined by CCRD. For all extractions, the CO\textsubscript{2} mass flow rate was 1.94 kg/h.

4.4. Experimental Design

For determining the optimal process parameters of pressure, temperature and time, the CCRD was used [23]. The extraction pressure (X\textsubscript{1}), temperature (X\textsubscript{2}), and time (X\textsubscript{3}) were independent variables studied to optimize the extraction process in terms of obtaining a higher total extraction yield and nicotine relative amount. Investigated factors and levels tested are depicted in Table 1.
Experimental data were fitted with the second-order response surface model with the following equation:

$$Y = \beta_0 + \sum_{j=1}^{k} \beta_j X_j + \sum_{j=1}^{k} \beta_{jj} X_j^2 + \sum_{i<j} \beta_{ij} X_i X_j$$  \hspace{1cm} (1)

where $Y$ is the response variable, $\beta_0$ is a constant, $\beta_j$, $\beta_{jj}$ and $\beta_{ij}$ are regression coefficients of the model, and $X_j$ and $X_i$ are the independent variables in coded values. The statistical analysis of experimental data and three-dimensional response surface plots were generated using Minitab LLC®, 2021. The test of statistical difference was based on the total error criteria with the confidence level of 95.0%.

4.5. GC–MS Analysis

The samples obtained were dissolved in $n$-hexane. The GC–MS analyses were carried out on Agilent 7890B GC fitted with a mass selective detector 5977A (Agilent Technologies, Palo Alto, CA, USA). The capillary column was HP-5MS (5% phenyl-methyl polysiloxane, 30m × 250 µm × 0.25 µm). Helium was the carrier gas at 1 mL·min$^{-1}$. The injection port temperature was 250 °C. The HP-5MS column temperature was programmed at 70 °C isothermal for 2 min and then increased to 200 °C·min$^{-1}$ at the rate of 3 °C·min$^{-1}$ and held isothermal for 20 min. The split ratio was 1:50. The ionization voltage was 70 eV. The ion source temperature was 230 °C. The mass scan range was 60–650 mass units. The injected sample volume was 1 µL. The identification of components was carried out based on computer matching with the NIST 2008 MS library. The percentage composition was calculated from the GC peak areas using the normalization method. The quantitative analysis was completed using calibration curves. Standard compound was dissolved in $n$-hexane, and prepared were six different concentrations of nicotine. The $R^2$ for the calibration curve was 0.999. All analyses were performed in triplicate.

5. Conclusions

The research presents the optimization of SC CO$_2$ extraction of dried $N$. tabacum cv. Samsun and $N$. tabacum cv. Virginia leaves. The results of the statistical assays showed that the pressure, temperature, and time have a significant effect on the total extraction yield and pressure and time on nicotine relative amount. The differences in nicotine relative amount indicated that the quantity depends on the variety. The two varieties have different phytochemical compounds, indicating that the abundance of phytochemical compounds depends on the variety. The optimal temperature for the SC CO$_2$ extraction for the highest nicotine relative amount is the same and the optimal pressure and time are slightly different. Further investigations can give a better understanding of parameters influencing the total extraction yield and nicotine relative amount in $N$. tabacum varieties.
