ABSTRACT
Spectroscopic observations of distant quasars have resulted in the detection of molecular hydrogen in intervening damped Lyman-\textalpha{} absorption clouds (DLAs). We use observations compiled from different experimental groups to show that the molecular hydrogen abundance exhibits a dramatic increase over a cosmological time period corresponding to 13\% to 24\% of the age of the universe. We also tentatively show that the heavy element abundances in the same gas clouds exhibit a faster and more well-defined cosmological evolution compared to the general DLA population over the same time baseline. We argue that this latter point is unsurprising, because the general DLA population arises in a wide variety of galaxy types and environments, and thus a spans broad range of ISM gas-phases and abundances at the same cosmic time. DLAs exhibiting H\textsubscript{2} absorption may therefore circumvent this problem, efficiently identifying a narrower class of objects, and provide a more sensitive probe of cosmological chemical evolution.

Key words: line: identification – ISM: molecules – Galaxy: abundances – intergalactic medium – quasars: absorption lines – ultraviolet: general

1 INTRODUCTION
The detection of cosmological chemical evolution is a cornerstone of modern cosmology, providing empirical details about galaxy formation and evolution, and independent supporting evidence of the big bang. High-precision measurements of chemical abundances at early cosmological epochs come from damped Lyman-\textalpha{} absorption systems (DLAs), arising in distant galaxies which intersect the lines of sight to high-redshift quasars. DLAs are easily detected in quasar spectra due to their particularly high neutral hydrogen column densities $\log_{10} N(\text{H}1) \geq 20.3$ atoms cm$^{-2}$ by definition, though Voigt profile damping wings are seen at lower $N(\text{H}1))$. Generally, they comprise a clumpy distribution of clouds, spread typically over a few hundred km s$^{-1}$. Detection levels for heavy element transitions in DLAs are $\approx 7$ orders of magnitude below that for $N(\text{H}1)$. High resolution optical spectra reveal transitions from many redshifted UV species, allowing detailed heavy element abundance patterns to be studied. The metallicity of DLAs – defined as the heavy element abundance with respect to hydrogen, relative to that of the solar neighbourhood: $[\text{M/H}] \equiv \log_{10} \frac{N(\text{M})}{N(\text{H})} - \log_{10} \frac{N(\text{M})}{N(\text{H})}_{\odot}$ – ranges over 2 orders of magnitude and is usually $\approx 0.1$ solar or lower. The presence of dust in DLAs is revealed by the relative depletion of refractory elements (e.g. Fe) with respect to those thought not to readily deplete onto dust grains (e.g. Zn; Pettini et al. 1997), and by the suppression of blue light from the background quasar (e.g. Fall et al. 1985). These spectroscopic observations demonstrate that DLAs arise along lines of sight through distant galaxies but they do not disclose details such as the galaxy’s morphology, luminosity, mass or age.

Evidence for an increase in DLA metallicity with cosmic time has emerged only gradually over the past few years from a number of different studies (Pettini et al. 1995; Lu et al. 1996; Vladilo et al. 2000; Kulkarni & Fall 2002; Prochaska et al. 2003). The latter reference provides the most compelling statistical evidence so far since, using the full sample of 125 DLAs, one sees a strong anti-correlation between $[\text{M/H}]$ and absorption redshift, $z_{\text{abs}}$: Kendall’s $\tau = -0.32$ with an associated probability of $P(\tau) \lesssim 10^{-7}$. The need for such a large sample is due to the $\approx 2$ dex scatter in $[\text{M/H}]$ at a given epoch.

The types of galaxies responsible for DLAs can be investigated using direct imaging methods or comparison of spectroscopic data with models. The kinematics of optical resonance absorption transitions in low redshift DLAs appear consistent with 2-component models: a rotating disk plus an extended halo (Briggs et al. 1985). A recent detailed radio study of one particular DLA at $z_{\text{abs}} = 0.437$ clearly shows that at least some DLAs arise in the rotating disks of ordinary spiral galaxies (Briggs et al. 2001). High redshift ($z_{\text{abs}} \sim 3$) DLAs have been interpreted similarly, using detailed kinematic modeling to argue that they are rotating ensembles of clouds with further evidence for this interpretation coming from comparison of abundance ratios in DLAs and the thick component of our Galaxy’s disk (Prochaska & Wolfe 1997; Wolfe 2001).

On the other hand, direct imaging of DLAs at $z_{\text{abs}} < 1.5$ reveals the hosts to be a mix of irregulars, spirals and low surface-
brightness galaxies (LSBs; e.g. Le Brun et al. 1997; Rao et al. 2003), a result further borne out by a blind 21-cm emission survey at $z = 0$ (Ryan-Weber et al. 2003). The observed number of DLAs per unit redshift interval and the $N$(H$^1$) distribution suggest that DLAs at $z_{\text{abs}} < 2$ are a roughly equal mix of LSBs and spirals; at higher redshift they are more likely to be dwarfs (that subsequently merge) since there are too few precursors of present-day disk galaxies to explain the data (Boissier 2003; Boissier et al. 2003).

Fitting simple chemical evolution models to an observed $N$(H$^1$)–[Zn/H] distribution suggests that at redshifts $z_{\text{abs}} \sim 2.5$, about half of all DLAs are due to dwarf galaxies, while at $z_{\text{abs}} < 1$, giant galaxies may dominate the population (Baker et al. 2000). H I 21-cm absorption measurements also hint that dwarfs could dominate at high-$z$ (Kanekar & Chengalur 2003).

Further work is clearly needed to generate an accurate inventory of DLA host galaxy types as a function of cosmic epoch. Nevertheless, the evidence for a broad mix of galaxy types is already compelling, if not conclusive.

2 OUR CONJECTURE

It is well established from studies of local galaxies that chemical abundances depend on morphology, luminosity and location within a galaxy. The diversity and evolution of the DLA host population will further complicate and distort estimates of chemical evolution over cosmological timescales. The DLA data themselves thus suggest that we may derive greater insight by attempting to disentangle these different galaxy types of DLA absorbers, rather than assuming all DLAs can be classified into one sample. A more sensitive test, or at least complementary test, for chemical evolution may be arrived at if we can select a subset of DLAs which arise in a narrow range of physical conditions.

One possibility, which we suggest here, is to target those DLAs which exhibit molecular hydrogen absorption. There are currently 8 examples of such H$_2$-bearing DLAs at redshifts $z_{\text{abs}} > 1.9$. None of the absorbing galaxies have been identified directly through imaging, though hints at the galaxy types come from a comparison with our own Galaxy and its satellites. The mean molecular hydrogen fraction, $f \equiv 2N$(H$_2$)/[$2N$(H$_2$) + $N$(H$^1$)], seen along lines of sight through our Galaxy is $\log_{10} f \sim -1$, and for the SMC and LMC it is $\log_{10} f \sim -2$. DLA detections in the range from $-6 < \log_{10} f < -2$ (upper limits on non-detections are $-7 < \log_{10} f < -5$). Ledoux, Petitjean & Srianand 2003, hereafter LPS03) but 2/3 of the detections are in the range $-4 < \log_{10} f < -2$. As discussed in LPS03, >90% of the sightlines through our Galaxy (and through the SMC) intercept H$_2$ clouds. For the LMC, only 50% of sightlines contain H$_2$ at the same strength. DLAs exhibit H$_2$ absorption ~20% of the time. In this respect are more similar to the LMC. It is therefore possible that H$_2$-bearing DLAs may arise predominantly in dwarf galaxies rather than massive spirals. However, given the rapid apparent molecular fraction evolution in Fig. 1, this interpretation is speculative.

3 CURRENT OBSERVATIONAL EVIDENCE

3.1 The data

Table 1 summarizes the properties of the 8 H$_2$-bearing DLAs studied here. H$_2$ is detected in DLAs via the Lyman and Werner-band UV lines and H I is detected via the Lyman series. Observed transitions fall in the visible region for $z_{\text{abs}}$ larger than $\approx 1.9$. Column densities are measured from Voigt profile fits to absorption lines from each species. A compilation of results from H$_2$ searches in DLAs is given in Table 8 of LPS03, for which 7 DLAs have confirmed H$_2$ detections and metallicity measurements: 0013–004 ($z = 1.973$), 0347–383, 0405–443 ($z = 2.593$), 0528–250, 0551–366, 1232+082 and 1444+014. The $z = 1.973$ DLA towards 0013–004 has been studied in detail by Pettigrew et al. 2002: it comprises several absorbing components, of which 2 are dominant (their components c and d). These 2 components are distinguishable in H I but not in the saturated H I Lyman series. $N$(H$^1$) has thus been measured at the mean redshift of these 2 components and we use the mean $N$(H$_2$) in computing $f$ for this DLA. The error we use for $f$ is derived from the range in $N$(H$_2$) given in LPS03.

We include one further DLA, 0000–263. The H$_2$ detection was regarded as only tentative in LPS03 but has been carefully scrutinised in Levshakov et al. 2000, 2001 and relies on two H$_2$ absorption features, the L(4-0)R1 and W(2-0)Q(1) lines, the former appearing relatively free from Lyman-α forest blending. Since this is the highest redshift H$_2$-bearing DLA, the [M/H]–$z_{\text{abs}}$ and $f$–$z_{\text{abs}}$ correlations derived below rely on this point relatively heavily. Further confirmation or refutation of this H$_2$ detection is therefore desirable. A tentative H$_2$ detection at $z = 2.374$ towards 0841+129 has also been reported (Petitjean et al. 2000), though confirmation requires future data and/or analyses.

Here we omit the recent detection towards 0515–4414 (Reimers et al. 2003) since the local ionizing UV background may be relatively intense. See Murphy, Curran & Webb 2004 for an analysis including this system.

All metallicities are based on elements where depletion onto dust is expected to be small: 7 measurements are derived from [Zn/H], while the metallicity for 1232+082 is derived from [Si/H]. In most DLAs Si is observed to be slightly dust-depleted with respect to Zn so one might expect our conclusions below to be slightly strengthened if [Zn/H] could be used as a metallicity indicator for 1232+082.

Fig. 1 illustrates the distribution of [M/H] and $f$ for the 8 DLAs with detected H$_2$. The metallicity appears to change by $\sim 1.5$ dex over the range $1.9 < z_{\text{abs}} < 3.4$, while the molecular hydrogen fraction appears to change by $\sim 6$ dex. The scatter about the straight line fits is clearly larger than the statistical ($\sigma$) errors in both panels. The validity of any simple parametric fit is thus dubious. Straight-line fits were nevertheless derived by quadrature addition of the same constant to each statistical error such that the normalised $\chi^2 = 1$. Least-squares fits give similar slopes and intercepts but our procedure results in reasonable error estimates for these quantities.

3.2 Metallicity vs. Redshift

With this procedure, a fit of the form $[M/H] = A_8 + B_8 z_{\text{abs}}$ to the 8 [M/H] points in Fig. 1 gives $A_8 = 1.0 \pm 0.74$ and $B_8 = -0.77 \pm 0.29$. Using Kendall’s $\tau$ as a non-parametric correlation estimate gives $\tau = -0.50$ and $P(\tau) = 0.08$. That is, [M/H] and $z_{\text{abs}}$ are anti-correlated with 92% confidence. Compare these statistics with those derived using the 60 DLAs from Prochaska et al. 2003. In the redshift range $1.9 < z_{\text{abs}} < 3.4$ which have Zn, O, S or Si metallicities: $A = -0.75 \pm 0.41$, $B = -0.26 \pm 0.15$, $\tau = -0.13$ and $P(\tau) = 0.14$. The slope, $B$, also compares well
Table 1. Summary of QSO and absorption line measurements for the 8 H$_2$-bearing DLAs considered here. Measurements of neutral hydrogen column density [N(H$_1$)], H$_2$ column density [N(H$_2$)], relative iron abundance [Fe/H], and metallicity [M/H] are from Ledoux et al. (2003) (LPS03) unless otherwise noted. The QSO magnitudes are given approximate V-band values. ‘S/N (H$_2$)’ refers to approximate signal-to-noise ratio per ∼2 km s$^{-1}$ pixel for the continuum in the vicinity of the most clearly detected H$_2$ absorption lines. ‘M’ refers to the element used to calculate the metallicity.

| QSO     | z$_{em}$ | Mag. | z$_{abs}$ | log$_{10}$ [N(H$_1$) cm$^{-2}$] | log$_{10}$ [N(H$_2$) cm$^{-2}$] | log$_{10}$ f | S/N (H$_2$) | [Fe/H] | [M/H] | M    |

Notes: $^a$ A value for QSO258−250 is not available in LPS03 but reasonably high S/N is expected from the QSO magnitude, exposure time and z$_{abs}$.

References: Lu et al. (1996); Levshakov et al. (2000); Molaro et al. (2001); Pettine et al. (2002); Ledoux et al. (2002); Srikanth et al. (2002).

Figure 1. Upper panel: Metallicities for the 8 DLAs which exhibit H$_2$ absorption (shaded circles), derived from the abundance of Zn (Si for 1232+082). The relevant data are summarized in Table 1. The long-dashed line is a least-squares fit to the 8 points with expanded errors (see text). The dotted line is similar fit excluding 0000−263. Small hollow diamonds illustrate metallicity measurements for the 60 DLAs between 1.9 < z$_{abs}$ < 3.4 from Prochaska et al. (2003). The short-dashed line is fit to the hollow diamonds, also with expanded errors. Lower panel: Logarithmic molecular hydrogen fraction. The dotted line represents the typical non-detection levels found by Ledoux et al. (2003). The age of the universe is calculated using Ω$_m$ = 0.30, Ω$_Λ$ = 0.70, H$_0$ = 70 km s$^{-1}$ Mpc$^{-1}$.

Figure 2. As in the upper panel of Fig. 1 but for the distribution of relative iron abundance, [Fe/H].

would give good agreement between the slope for the remaining 6 points and the general DLA population, but the metallicity agreement would be somewhat worse (KS probability reduces to 0.8%). (ii) The [M/H]−z$_{abs}$ correlation appears to be tighter for the H$_2$-bearing DLAs compared to the general DLA population. To test this we subtract the linear fit to the data in each case and use an F-test to compare the variances of the residuals. The variance for the 60 general DLAs is 1.9 times that for the H$_2$-bearing DLAs, although the probability of this happening by chance is 39% given the sample sizes.

In summary, the H$_2$-bearing DLAs display a faster increase in metallicity with cosmic time compared to the general DLA population. Furthermore, this increase is more well-defined in the H$_2$-bearing sample and these DLAs seem to be chemically distinct from the general DLA population.

These latter two results are also supported by the distribution of relative iron abundance, [Fe/H], as shown in Fig. 2. Using [Fe/H] for the same 60 general DLAs from Prochaska et al. (2003) as before, the KS probability for the two samples being drawn from the same parent distribution is only 0.01%. The F-test reveals that the variance of the general DLA population is 2.1 times that of the H$_2$-bearing sample but, again, this has reasonably low statistical significance since we would expect a larger variance ratio 29% of the time by chance alone. Therefore, the H$_2$-bearing DLAs do seem to form a chemically distinct sub-class of the DLA population which may encompass a narrower range of physical condi-
tions and environments. We note in passing that the slope of the \([\text{Fe/H}]–z_{\text{abs}}\) relation for the \(H_2\)-bearing DLAs, in contrast to the \([\text{M/H}]–z_{\text{abs}}\) relation, is not significantly steeper than for the general DLA population. With the same fitting procedure above we find \(A_f = -0.78 \pm 0.61\) and the slope \(B_f = -0.30 \pm 0.24\) with Kendall’s \(\tau = -0.21\) and \(P(\tau) = 0.46\) for the \(H_2\)-bearing DLAs. The general DLA population gives \(A = -1.3 \pm 0.36\), \(B = -0.17 \pm 0.14\), \(\tau = -0.10\) and \(P(\tau) = 0.24\). These shallower slopes are expected if dust depletion increases in importance with decreasing redshift, as implied by the \(f–z_{\text{abs}}\) relation discussed below (Section 3.3). We explicitly treat the evolution of the dust depletion factor in Murphy et al. (2004).

Finally, it was earlier mentioned that the above conclusions rely relatively heavily on the highest redshift \(H_2\) detection towards 0000–263. If we remove this point, the straight-line fits to the \([\text{M/H}]–z_{\text{abs}}\) relation give \(A_f = 0.11 \pm 0.81\) and the slope \(B_f = -0.38 \pm 0.33\) with a non-parametric correlation estimate given by Kendall’s \(\tau = -0.33\) with \(P(\tau) = 0.29\). Thus, the negative \([\text{M/H}]–z_{\text{abs}}\) correlation is not as steep, nor as robust when the 0000–263 data point is removed. However, note that the evidence supporting the hypothesis that the \(H_2\)-bearing DLAs form a chemically distinct population with a potentially narrower range of physical conditions is relatively independent of the 0000–263 \(H_2\) detection. Comparing the 7 remaining \(H_2\)-bearing DLAs with the 49 general DLAs between 1.9 < \(z_{\text{abs}}\) < 3.1 from Prochaska et al. (2003) gives a KS probability of 0.8% and the F-test gives a ratio of variances of 2.6 which occurs 23% of the time by chance alone.

3.3 Molecular fraction vs. Redshift

Turning to the lower panel of Fig. 1, we proceed as above and derive a straight-line fit for the \(f–z_{\text{abs}}\) relation: \(A_f = 5.1 \pm 2.4, B_f = -3.4 \pm 0.9\). Kendall’s \(\tau = -0.50\) with \(P(\tau) = 0.08\). Thus, there is reasonable statistical evidence that the molecular hydrogen fraction increases dramatically with cosmic time. Previous studies do not explicitly identify this trend. In particular, although LPS03 plot \(f\) versus \(z_{\text{abs}}\) for their sample of DLAs (their figure 16) they do not point out this apparently rapid evolution of \(f\) with \(z_{\text{abs}}\).

Again, removing 0000–263 from consideration weakens the statistical significance of the \(f–z_{\text{abs}}\) correlation but the slope remains quite steep: the new fits with 0000–263 removed give \(A_f = 3.0 \pm 3.0, B_f = -2.4 \pm 1.2\) with Kendall’s \(\tau = -0.33\) and \(P(\tau) = 0.29\). However, we again stress the apparent reliability of the \(H_2\) detection towards 0000–263 made by Levshakov et al. (2004, 2001) and point out that H$_2$ systems with high-\(z_{\text{abs}}\) and high-\(f\) (or, indeed, low-\(z_{\text{abs}}\) and low-\(f\)) will need to be detected to show this correlation to be spurious.

Below we consider possible interpretations of the \(f–z_{\text{abs}}\) trend but first discuss some systematic effects and biases.

4 OBSERVATIONAL BIASES AND POSSIBLE SYSTEMATIC EFFECTS

Could the strikingly steep apparent evolution of \(f\) with \(z_{\text{abs}}\) be significantly affected by observational selection effects? We consider some possibilities for both the \([\text{M/H}]–f\) and \(f–z_{\text{abs}}\) correlations below.

Firstly, the \(H_2\) sample is inhomogeneous since the quasar spectra do not all have similar S/N and since the \(H_2\) detection methods and criteria were not uniform. Indeed, the weak \(H_2\) lines detected towards 0000–263 and 0347–383 are at the same level as the many non-detections listed by LPS03 (their figure 16). Typically, these fall in the region illustrated in Fig. 1 by the light dotted line. The \(f–z_{\text{abs}}\) correlation we report is therefore only tentative. However, it seems surprising that no high-\(z_{\text{abs}}\)/high-\(f\) or low-\(z_{\text{abs}}\)/low-\(f\) detections of \(H_2\) have been made. Secondly, the \(H_2\) detection limit will change with redshift: observed line widths increase as \((1+z)^2\), making higher-\(z\) lines more detectable, but the Lyman-\(\alpha\) forest density increases roughly as \((1+z)^2\), making higher-\(z\) lines harder to detect due to increased blending. This will be further complicated by higher order Lyman series forest lines for DLAs at low redshift compared to their corresponding QSO. Quantification of these competing effects requires numerical simulations which mimic the (unknown and, likely, non-uniform) techniques used to detect the \(H_2\) systems studied in Fig. 1.

The \([\text{M/H}]\) and \(f\) values in Fig. 1 are not specific to the \(H_2\)-bearing components because \(N(\text{H}_1)\) is determined from the damped Lyman-\(\alpha\) line profile. The relative abundances of refractory (e.g. Fe) and non-refractory (e.g. Si) elements are generally found to be uniform across the absorption profiles of most DLAs (Prochaska 2003), indicating that \([\text{M/H}]\) is also likely to be uniform. The notable exceptions to this rule are the \(H_2\)-bearing components where large dust depletion factors are found (e.g. LPS03 and the [Si/Fe] profile of 0347–383 in Prochaska 2003). These components usually dominate the non-refractory metal-line profiles and so, although the derived \([\text{M/H}]\) and \(f\) measurements will be systematically underestimated, the effect will not be large. Though the fitted slopes in Fig. 1 are likely to be reasonably robust against this effect, a larger sample and more detailed study of the metal-line and Lyman series profiles is required.

Selection effects related to dust obscuration of quasars may also be present. In the \(H_2\) systems, \(f\) is somewhat correlated with dust depletion factor [Za/Fe] LPS03, providing evidence that the \(H_2\) is formed on dust grains, a view supported by theory (Cazaux & Tiels 2003; Glover 2003; cf. Liszt 2002). However, DLAs containing large amounts of dust (i.e. those with high \(f\)) could suppress detection of their background quasars and may therefore be ‘missing’ from our sample (Fall et al. 1989). Since metallicity and dust depletion are also strongly correlated LPS03, this effect is likely to suppress, rather than create, the correlations in Fig. 1. Further to this, Boisse et al. (1998) and Prantzos & Boissier (2004) have found an anti-correlation between [Zn/H] and \(N(\text{H}_1)\) in DLAs. For the 8 \(H_2\) systems studied here, there exists a mild correlation between \(N(\text{H}_1)\) and \(z_{\text{abs}}\). If the latter is not simply fortuitous, it should have resulted in a correlation between \(f\) and \(z_{\text{abs}}\), opposite to that observed.

The above implies that dust obscuration bias may somewhat suppress the observed \(f–z_{\text{abs}}\) correlation. However, several empirical studies suggest this bias is small. For example, DLAs surveys using radio-selected quasars should not be subject to this bias. Recent work (Ellison et al. 2001) indicates that the number of DLAs per unit redshift interval found in previous optical DLAs surveys is not significantly biased, suggesting the number of ‘missing’ DLAs is at most a factor of 2 below the radio-selected result. Nevertheless, we note 2 studies which tentatively suggest strong enhancements in the incidence of absorption towards radio-loud BL Lac objects (Stocke & Rector 1997) and optically red quasars (Carilli et al. 1998). In the former case, many of the emission redshifts are not known and, if intrinsic absorption occurs more frequently in BL Lacs, the comparison with Ellison et al. (2001) is not useful. For the red quasars of Carilli et al. (1998), only absorption close to the quasar redshifts was searched for and so, again, the comparison with Ellison et al. (2001) is tentative. Clearly these
possible discrepancies should be resolved observationally in future work.

5 INTERPRETATIONS

By selecting those DLAs exhibiting H$_2$ absorption, one may focus on systems with a narrower range of physical conditions than the general DLA population. Tentative support for this conjecture lies in the tighter metallicity–$z_{\text{abs}}$ anti-correlation observed for the 8 H$_2$ DLAs studied here. Hou et al. (2001) recently presented detailed chemical evolution models which give a slope for the metallicity–$z_{\text{abs}}$ relation of $\approx -0.6$ dex. They correct this predicted slope for various observational biases to achieve the shallower slope observed for the general DLA population. However, the steep slope observed for 8 H$_2$ systems may be less affected by these biases and may therefore be more comparable to the uncorrected model slopes. H$_2$-bearing DLAs could therefore provide an important probe of cosmological chemical evolution.

That there exists such a large range ($\approx 6$ dex) in the values of $f$ in Fig. 1 may not be surprising. For example, Schaye (2001) describes a photo-ionization model for clouds in local hydrostatic equilibrium with a representative incident UV background flux, [M/H] and dust-to-metals ratio. The molecular fraction in this model shows a sudden increase of $\approx 4$ dex for only a small increase in the total hydrogen density. Therefore, the very steep $f$–$z_{\text{abs}}$ correlation in Fig. 1 could be achieved with a modest increase in dust content at lower redshifts, consistent with the [M/H]–$z_{\text{abs}}$ correlation. Within the Schaye model, one also expects an anti-correlation between the intensity of the UV background and $f$. However, the behaviour of the UV background flux with redshift over the range $z = 2-3$ is still a matter of considerable uncertainty. The strong decrease in $f$ at high $z_{\text{abs}}$ may also be consistent with recent H$_2$ 21-cm absorption measurements in DLAs (Kanekar & Chengalur 2003), where a generally higher spin temperature is found at $z > 2.5$. With an increased sample size and more detailed analyses, the $f$–$z_{\text{abs}}$ correlation, if real, may provide complementary constraints on these problems.

ACKNOWLEDGMENTS

We enjoyed and benefitted from discussions with Ed Jenkins, Charley Lineweaver, Mark Whittle and Max Pettini. We thank the anonymous referee for critical comments which improved the manuscript. SJC gratefully acknowledges receipt of a UNSW NS Global Fellowship and MTM is grateful to PPARC for support at the IoA under the observational rolling grant. This research has made use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.
