\textbf{ABSTRACT}

\textbf{Context.} Water fountain stars are very young post-AGB stars with high velocity water maser jets. They are the best objects to study the onset of bipolar jets from evolved stars due to their young dynamical ages. However, none of them have been observed in any thermal lines.

\textbf{Aims.} Search for CO lines in the water fountain star IRAS 16342-3814 and investigate the properties of its thermal gas.

\textbf{Methods.} The proximity, peculiar stellar velocity and high Galactic latitude of IRAS 16342-3814 make a single dish observation possible. We use the Arizona Radio Observatory 10m telescope to observe the CO $J = 2\rightarrow 1$ line and compare the line parameters with that of masers.

\textbf{Results.} We report the detection of $^{12}$CO and $^{13}$CO $J = 2\rightarrow 1$ lines from IRAS 16342-3814. The inferred $^{12}$CO mass loss rate is an order of magnitude lower than the infrared and OH mass loss rates, indicating a very cold and thick O-rich circumstellar envelope around the star. We also find a $^{12}$CO expansion velocity of $V_{\exp} = 46 \pm 1$ km s$^{-1}$ that is too high for an AGB wind and confirm the systemic velocity of $44 \pm 1$ km/s. In addition we measure a very low $^{12}$CO/$^{13}$CO line ratio of 1.7.

\textbf{Conclusions.} The first detection of CO lines has provided a new way to investigate the water fountain stars. Given the high expansion velocity of the CO gas and its relation to maser velocities, we infer that the CO emission region is co-located with the OH mainline masers in the warm base of the optical bipolar lobes, while the high velocity OH 1612 MHz and H$_2$O masers are located in the side walls and at the farthest ends of the bipolar lobes, respectively. Further observations are highly desired to understand the very low $^{12}$CO/$^{13}$CO line ratio.

\textbf{Key words.} stars: AGB and post-AGB – (stars:) circumstellar matter – stars: evolution – stars: individual (IRAS 16342-3814) – stars: winds, outflows – radio lines: stars

1. Introduction

Water fountain stars are a group of rare objects that display a thick circumstellar envelope (CSE) that is typical for asymptotic giant branch (AGB) stars and also high velocity bipolar jets ($\geq 100$ km s$^{-1}$) detected via their H$_2$O masers. They could be stars near the end of AGB or post-AGB evolution stage when non-spherical circumstellar structures begin to develop inside the relic of the spherical AGB circumstellar envelope. Currently only about 10 such objects have been discovered through single dish and interferometry observations of their OH, H$_2$O and SiO masers (see the review by Imai 2007). However, none of them have ever been detected in a thermal molecular line. In this letter, we report the first detection of the $J = 2\rightarrow 1$ transition of $^{12}$CO and $^{13}$CO in the water fountain star IRAS 16342-3814.

IRAS 16342-3814 was discovered by Likkel & Morris (1988) to show H$_2$O masers with a line-of-sight expansion velocity up to 117 km s$^{-1}$, much higher than the typical speed of $\sim 15$ km s$^{-1}$ for a spherical AGB wind (see, e.g., Chen et al. 2001). They also found a progressive increase of expansion velocity in OH masers, from 36 km s$^{-1}$ (1665 MHz) through 42 km s$^{-1}$ (1667 MHz) to 58 km s$^{-1}$ (1612 MHz). The symmetrical H$_2$O maser velocities found by Likkel & Morris (1992) allowed them to determine a star velocity of $V_{sys} = 43.2 \pm 0.9$ km s$^{-1}$, which further constrained a higher line-of-sight H$_2$O maser expansion velocity of 130 km s$^{-1}$.

Optical and infrared imaging to this star has revealed striking structures in its CSE. The Hubble Space Telescope (HST) observations by Sahai et al. (1999) revealed a bipolar nebula. Corkscrew patterns were found in the bipolar lobes in follow-up infrared $L_p$ band imaging with the Keck telescope (Sahai et al. 2005), indicating that the bipolar lobes and the H$_2$O masers might be created by precessing jets. Infrared imaging in the 3.8 – 20$\mu$m range by Dijkstra et al. (2003) showed the variation of the CSE morphologies from bipolar at near infrared to spherical at middle infrared, demonstrating that the outer CSE ejected earlier was spherical and the star is currently undergoing CSE morphology transformation. Dijkstra et al. (2003) also found from the 2 – 200$\mu$m Infrared Space Observatory (ISO) spectra that the star is the only object known to show absorption in both amorphous and crystalline silicate features. The very red spectral energy distribution possibility indicates a very cold and thick dusty CSE with an AGB mass loss rate on the order of $10^{-3}$ $M_{\odot}$yr$^{-1}$ (Dijkstra et al. 2003).

Interferometric measurements of masers have supplied kinematic information. The mapping of OH masers in IRAS 16342-3814 by Sahai et al. (1999) and Zijlstra et al. (2001) showed linear increase of line-of-sight outflow velocity with projected dis-
tance from the central star. High-velocity OH maser spots are located around the optical bipolar lobes while low-velocity maser spots appear near a dark waist close to the central star. These facts are in accord with a wind interaction model of the bipolar structure (Zijlstra et al. 2001). However, the corkscrew pattern in the infrared images also suggests that precessing jets may play some role. Very Long Baseline Array (VLBA) mapping of H$_2$O masers by Morris et al. (2003) and Claussen et al. (2004) showed bipolar distribution of maser spot clusters with more than 2 degrees separation along the optical bipolar lobes and quasi-linear alignment of maser spots that delineates shock front of the jets. The interplay of the jets with magnetic field is still unclear, although extremely high degree of polarisation has been found in the OH masers (TeLintelHekkert et al. 1988; Szymczak & Gérard 2004).

The post-AGB nature of IRAS 16342-3814 has been critically investigated by Sahai et al. (1999). However the status of thermal gas in the CSE of this star is still unclear due to the lack of thermal molecular line observations. Unlike other known water fountain stars, IRAS 16342-3814 is the easiest object in which to search for its CO lines with a single dish telescope, because it is relatively near with a distance of 0.7 ~ 2 kpc (Sahai et al. 1999; Zijlstra et al. 2001), it has a high galactic latitude of 5.8 and a large line-of-sight velocity difference of at least 40 km s$^{-1}$ from that of nearby interstellar molecular clouds.

2. Observation and data reduction

The ALMA band-6 sideband separating receiver on the Arizona Radio Observatory 10 m submillimeter telescope (SMT) was used for the $^{12}$CO and $^{13}$CO J=2–1 observations towards IRAS 16342-3814 on 2008, May 09. Sky subtraction was made in a beam switch mode with 2 arcmin throw at 2.2 Hz in azimuth direction. The receiver temperature was about 100 K. Two filter bands (FFBs, 1 GHz width, 1024 channels) were used for the two polarisations of the $^{12}$CO line and two acousto-optical spectrometers (AOS’s, 972.8 MHz width, 2048 channels) were used for the two polarisations of the $^{13}$CO line. A 90 minute integration under a zero order baseline was removed from each spectrum, it has a high galactic latitude of 5.8 and a large line-of-sight velocity difference of at least 40 km s$^{-1}$ from that of nearby interstellar molecular clouds.

4. Discussion

4.1. The low $^{12}$CO mass loss rate

The detection of the $^{12}$CO J=2–1 line allows us to directly estimate the mass loss rate of IRAS 16342-3814. Using the $^{12}$CO J=2–1 formula scaled by Heske et al. (1990), we derive $M(12CO) = 0.7 \pm 0.6 \times 10^{-6} M_{\odot} yr^{-1}$ for a source distance of 0.7 ~ 2 kpc. As discussed in §4.2, the detected CO gas may not represent the spherical AGB wind. The true AGB wind CO mass loss rate, if also estimated with Heske’s formula, should be even lower than this value, because the CO gas emission from the slow AGB wind is not definitely detected yet, while the mass loss rate is $V_{exp}^2 T_{mb}(CO)$. However, the formula of Baud & Habing (1983) applied to an OH 1612 MHz maser peak flux of 9Jy (Likkul & Morris 1988) yields a much higher mass loss rate of $M(OH) = 1.7 \times 9.4 \times 10^{-6} M_{\odot} yr^{-1}$ (with $V_{exp} = 46$ km s$^{-1}$ from our $^{12}$CO line). Do et al. (2007) fitted the Spitzer MIPS 70µm images with a two shell model, and obtained $M(70\mu) = 0.4 \times 3 \times 10^{-6} M_{\odot} yr^{-1}$ for an inner smooth CSE and $M(Shell) = 0.4 \times 3 \times 10^{-6} M_{\odot} yr^{-1}$ for an outer extended dust shell (assuming a gas-to-dust mass ratio of 200 and $V_{exp} = 15$ km s$^{-1}$. Here we note that our measured $^{12}$CO expansion velocity of 46 km s$^{-1}$ may not be that of the dusty CSE, see the discussion in §4.2.4. The inner shell mass loss rate agrees with the OH mass loss rate. Due to its huge radius of 1.4 ~ 4 pc, the outer shell could be explained by sweep-up of interstellar material, as suggested by the recent hydrodynamic simulation of Wareing et al. (2007). To summarise, we suggest that IRAS 16342-3814, while located in a very extended and cold detached outer dust shell, has an inner CSE whose mass loss rate (estimated from IR and OH emission) is roughly an order of magnitude higher than its $^{12}$CO mass loss rate. The weakness of $^{12}$CO J=2–1 line could be interpreted by the coldness of the CO gas, as suggested for some other very red OH/IR stars by Heske et al. (1990).

4.2. The high $^{13}$CO expansion velocity

The $^{13}$CO expansion velocity $V_{exp}(^{13}CO) = 46$ km s$^{-1}$ is too high for a typical OH/IR star (typically ~ 15 ± 5 km s$^{-1}$ for long period OH/IR stars, see e.g., Chen et al. 2003). Another possible source of the broad $^{13}$CO emission is the swept-up bipolar bubble walls. According to a momentum driven wind-interaction model suggested by Zijlstra et al. (2001), the radial motion velocity of different parts of the bubble wall will be proportional to distance to the central star. This has been confirmed.
by the linear OH maser velocity offset-radius (V-r) relationship found by Sahai et al. (1999) and Zijlstra et al. (2001). Assuming that \( V_{\text{exp}}(^{12}\text{CO}) \) follows the same V-r relationship in Fig. 3 of Sahai et al. (1999), we find a rough angular radius of 0.5" for the CO emission region, similar to that of OH mainline masers. Further assuming a Gaussian source shape, a brightness temperature of the \(^{12}\text{CO} \rightarrow 2\) line can be estimated to be \( \sim 30\) K. Therefore, the \(^{12}\text{CO} \rightarrow 2\) line could be optically thin if the gas temperature is much higher than this.

Further insight can be gained by comparing the velocities of \(^{12}\text{CO} \rightarrow 2\) line, OH and H2O masers. We find several interesting facts by comparing the CO velocities with the V-r relationship of OH masers in the Fig. 3 of Sahai et al. (1999): 1) The 1612 MHz maser velocity offsets are all \( \gtrsim V_{\text{exp}}(^{12}\text{CO}) \), while most of the OH 1665/1667 MHz (mainline) maser velocity offsets \( \lesssim V_{\text{exp}}(^{12}\text{CO}) \); 2) The OH 1612 MHz masers show two components – a pair of bipolar high velocity clumps that tightly follow the linear V-r relation and a peculiar group of points with \( V_{\text{LSR}} \sim 0\) km s\(^{-1}\) but scattered in a large radius range (\( \sim 1.2\) ); 3) The position of the bipolar 1612 MHz maser component is not symmetrical with respect to the star position, perhaps due to 3D projection effect. The peculiar group of 1612 MHz masers are not only scattered in radius, but also scattered in position angle with respect to the central star in the VLA maps (see Fig. 1b and Fig. 9 of Sahai et al. 1999, Zijlstra et al. 2001, respectively). This is difficult to explain with a spherical expanding shell model in which masers should show an elliptical relation between line-of-sight velocity and projected radial distance. Taking away this peculiar 1612 MHz maser component, one can see a better V-r relationship among the rest 1612, 1665 and 1667 MHz masers. If we further take a velocity span of \( \sim 248\) km s\(^{-1}\) and a spatial separation of \( \sim 3\)" of H2O masers from (Morris et al. 2003) and overlap their symmetry center with that of OH masers, we can see that the H2O masers follow the same linear V-r relationship quite well. Upon these arguments, we can sketch a picture for the CSE as follows:

Both the OH mainline masers and the CO emission arise from the same region near the base of the bipolar outflow, the two clumps of high velocity OH 1612 maser spots are located on the farther and faster part of the bipolar lobe side walls, the H2O masers are stimulated by the shock fronts at the two farthest and fastest ends of the bipolar lobes, while the peculiar group of spatially scattered 1612 MHz maser spots are located in an independent structure that is blue-shifted by \( \sim -46\) km s\(^{-1}\) with respect to the star but not necessarily associated with the bipolar outflow. The dark waist and the slow AGB wind might be simply too cold to be detected in our CO \( \rightarrow 2\) line spectra. Actually, the pair of faint spikes on the top of the broad \(^{12}\text{CO} \rightarrow 2\) line profile near the line centre in Fig. 1 could be the emission from the slow AGB wind. If this is true, we may estimate a crude AGB wind speed of \( \sim 13\) km s\(^{-1}\), typical for an AGB star.

### 4.3. On the origin of the extremely low \(^{12}\text{CO}/^{13}\text{CO}\) ratio

The detection of the \(^{13}\text{CO} \rightarrow 2\) line yields an extremely small \(^{12}\text{CO}/^{13}\text{CO}\) peak flux ratio of 1.7. A range of \(^{12}\text{CO}/^{13}\text{CO}\) ratios have been found in PPNe and PNe by other researchers. Hasegawa & Kwok (2003) concluded from a survey of published \(^{13}\text{CO}\) observations of PNe (Palla et al. 2001, Balser et al. 2002, Bachiller et al. 1997, Josselin & Bachiller 2003) that the \(^{12}\text{CO}/^{13}\text{CO}\) ratios are about 10 to 30 in most PNe, but are \( 2 \sim 3 \) in a few and \( > 60 \) in a few others. Some examples of low ratios are: \(^{12}\text{CO}/^{13}\text{CO} \sim 4.6 \) in AFGL 618, \( \sim 2.2 \) in M 1-16 (Balser et al. 2002), \( \sim 3 \) in the PN NGC 6302 (Hasegawa & Kwok 2003), and \( \sim 3.2 \) in HD 17982 (Josselin & Lêbre 2001). Bachiller et al. (1997) pointed out that the \(^{12}\text{CO}/^{13}\text{CO}\) ratios in PPNe and PNe are affected by two competing effects: selective photodissociation of \(^{13}\text{CO}\) and isotopic fractionation of \(^{13}\text{C}\) in CO. Another issue is the opacity in the \(^{12}\text{CO}\) lines, e.g., the very low ratio in NGC 6302 was later found by interferometry work of Peretto et al. (2007) to be affected by opacity effects in a massive torus and the true \(^{12}\text{CO}/^{13}\text{CO}\) should be \( > 15 \). For an embedded dusty post-AGB star like IRAS 16342-3814, we do not need to worry about the selective photodissociation in the central region. If the detected CO emission does come from the accelerated bipolar bubble walls (see the discussion in § 4.2), neither isotopic fractionation nor \(^{12}\text{CO}\) line opacity should be an issue, since the dynamical age of the bipolar jets is short (\( \sim 100\) yr) and the high expansion velocity and high radial velocity gradient (according to wind interaction model) might render the \(^{12}\text{CO}\) emission not too optically thick. A rough but conservative calculation of the optical depth under an LVG approximation gives a value smaller than unity. However, better CO line data is required to confirm this. We also find that our \(^{12}\text{CO}/^{13}\text{CO}\) ratio is about 1.1 and 3.2 on the red and blue line wings (46 > \( |V_{\text{exp}}| > 15\) km s\(^{-1}\)) respectively, but the uncertainties are larger there. One more issue is that the \(^{12}\text{CO}\) and \(^{13}\text{CO}\) lines might come from different clumps of gas. Again, better CO line profiles and, better still, CO mapping data are needed to clarify this point and to constrain a reliable \(^{12}\text{CO}/^{13}\text{CO}\) ratio. Therefore, later in this section, we will discuss different opacity cases separately, using only the assumption that the \(^{12}\text{CO}\) and \(^{13}\text{CO}\) lines are co-located in the CSE.

A precise measurement of the \(^{12}\text{C}/^{13}\text{C}\) ratio has the potential to cast light on the evolutionary status of the star. Stellar models of low mass (\( M \lesssim 2.0\) M\(_{\odot}\)) and intermediate mass (\( 2.0\) M\(_{\odot} < M \lesssim 8.0\) M\(_{\odot}\)) stars (e.g., El Eid 1994, Straniero et al. 1997, Karakas & Lattanzio 2007) show that there are quite a few phases of evolution where this ratio is altered from the initial value (assumed to be solar at 89). The first occurs during the first dredge up (FDU) at the beginning of the Red Giant Branch (RGB). Here the ratio declines from the initial value to \( \sim 20\) as the convective envelope moves in and mixes up partially burnt material (we note that the second dredge-up has only a minor effect on the ratio). The second evolutionary phase that alters the \(^{12}\text{C}/^{13}\text{C}\) ratio is not predicted by stellar models. Observations have shown that the isotopic ratio reduces along the RGB in low-mass stars (\( M < 2.0\) M\(_{\odot}\)), via a process known as Deep Mixing (also known as \( \delta_{\text{mix}}\) mixing - see the recent theoretical models by Eggleton et al. 2008). This phenomenon reduces the ratio down to a value of \( \sim 15\) by the end of the RGB in Population I stars. The third phase that significantly alters the ratio actually increases it – the Third Dredge-Up (TDU). Here \(^{12}\text{C}\) is periodically mixed into the envelope during the thermally-pulsing AGB stage (TPAGB), raising the \(^{12}\text{C}/^{13}\text{C}\) ratio from the FDU value to values of \( \sim 60\) or more (see e.g., Lebzelter et al. 2008, for recent observations of this effect). The final phase to alter the ratio is Hot Bottom Burning (HBB). However this only occurs in stars more massive than \( \sim 4\) or \( 5\) M\(_{\odot}\) (at solar metallicity). HBB is active during the later phases of the TPAGB and acts to burn the carbon and nitrogen in the convective envelope via the CNO cycles. This results in the \(^{12}\text{C}/^{13}\text{C}\) ratio approaching the equilibrium value of \( \sim 3\) (see e.g., Plez et al. 1993, McSweeney et al. 2007, for some observational evidence of this phenomenon). The very low \(^{12}\text{C}/^{13}\text{C}\) ratio in some Galactic PNe, PPNe and extremely young post-AGB stars like IRAS 16342-3814 could be also indicative of the HBB process.
If IRAS 16342-3814 has a high $^{12}$C/$^{13}$C ratio close to the solar value of $89 \pm 50$ times larger than the $^{12}$CO/$^{13}$CO line ratio, e.g., as a $3 \mathrm{M}_\odot$ star experiencing TDU), the CO line optical depths can be derived from the observed $^{12}$CO/$^{13}$CO ratio ($\sim 1.7$) to be $\tau(\text{CO}) \sim 82$ and $\tau(\text{CO}) \sim 0.93$ (assuming $T_e \sim 1$ under the assumption of co-location of $^{12}$CO and $^{13}$CO gas and the same excitation temperature). However, the $^{12}$CO mass loss rate should also be raised by a factor of $\tau/(1-e^{-\tau}) = 82/5.7 \sim 45.9 \times 10^{-3} \mathrm{M}_\odot/\text{yr}$, which is significantly higher than the OH and IR mass loss rates.

If the true $^{12}$C/$^{13}$C ratio is an intermediate value of 20, i.e., a factor of $\sim 10$ higher than the $^{12}$CO/$^{13}$CO line ratio, the similarly determined opacities are $\tau(12\text{CO}) \sim 19$ and $\tau(12\text{CO}) \sim 0.93$. In this case, the $^{12}$CO mass loss rate is comparable to the OH and IR mass loss rates. Therefore, a low mass AGB star ($\sim 1.5 \mathrm{M}_\odot$) that didn’t experience TDU or HBB and thus retains its FDU plus Deep Mixing surface abundances would be a possible progenitor of IRAS 16342-3814.

If the $^{12}$CO-1 line is only slightly optically thick so that the $^{12}$C/$^{13}$C ratio is $\sim 3$ (the CNO equilibrium value), the CO line opacities are $\tau(12\text{CO}) \sim 2.3$ and $\tau(12\text{CO}) \sim 0.77$. In this case, we can see that the only process (to the best of our knowledge) that could have lowered the $^{12}$C/$^{13}$C ratio to such a value is HBB. Thus the inferred mass of the star that produced the material that we observe today would have been $> 4 \mathrm{M}_\odot$. Interestingly, the low $^{12}$CO/$^{13}$CO ratio, bipolar outflow, and the properties of the OH masers of IRAS 16342-3814 are reminiscent of the massive PPN IRAS 22036+5306 investigated by Sahai et al. (2003, 2006), although IRAS 16342-3814 is probably in an earlier phase of evolution due to the presence of the young ‘water fountain’. Alternatively, a binary system in which a massive AGB star had transferred low $^{12}$C/$^{13}$C matter to the current AGB star is also possible. We note that a low isotopic ratio is supported by our rough estimation of the small $^{12}$CO-2-1 opacity at the beginning of this section.

However, both the measured CO and H$_2$O maser systemic velocities ($\sim 44 \mathrm{km} \mathrm{s}^{-1}$, Likkel et al. 1992) confirm that the spatial motion of IRAS 16342-3814 is in the reverse direction of the Galactic disk rotation (interstellar CO cloud velocity near the same line of sight is $\sim -17 \mathrm{km} \mathrm{s}^{-1}$, Dame et al. 2001). The peculiar stellar motion lends weight to IRAS 16342-3814 being a low mass stars, although in rare cases kick-out of stars from the crowded galactic plane can give rise to peculiar velocities.

Given the preceding discussions it is obvious that further observations are highly desirable to investigate the different opacity possibilities. Molecular line interferometry and maser proper motion measurements (such as the work of Imai et al. 2007) are also needed to check the interstellar contamination, confirm the co-location of the $^{12}$CO and $^{13}$CO gas, and to locate the birthplace of the possibly escaped AGB progenitor on the Galactic plane.

Fig. 1. The observed $^{12}$CO and $^{13}$CO 2–1 line profiles. The spectra have been box smoothed to a resolution of about 3 MHz. The $^{13}$CO 2–1 line has been shifted upward by 0.06 K for clarity. The arrows mark $V_{\text{sys}} = 44$ km s$^{-1}$ that is derived from the $^{12}$CO line.
