Abstract

Quantifying simulation uncertainties is a critical component of rigorous predictive simulation. A key component of this is forward propagation of uncertainties in simulation input data to output quantities of interest. Typical approaches involve repeated sampling of the simulation over the uncertain input data, and can require numerous samples when accurately propagating uncertainties from large numbers of sources. Often simulation processes from sample to sample are similar and much of the data generated from each sample evaluation could be reused. We explore a new method for implementing sampling methods that simultaneously propagates groups of samples together in an embedded fashion, which we call embedded ensemble propagation. We show how this approach takes advantage of properties of modern computer architectures to improve performance by enabling reuse between samples, reducing memory bandwidth requirements, improving memory access patterns, improving opportunities for fine-grained parallelization, and reducing communication costs. We describe a software technique for implementing embedded

ensemble propagation based on the use of C++ templates and describe its integration with various scientific computing libraries within Trilinos. We demonstrate improved performance, portability and scalability for the approach applied to the simulation of partial differential equations on a variety of CPU, GPU, and accelerator architectures, including up to 131,072 cores on a Cray XK7 (Titan).

1 Introduction

As computing power continues to increase there is an increasing desire to leverage computational simulation to predict physical, biological, and other scientific phenomena. However for predictions based on simulation to be rigorously justified, all errors arising in the simulation must be accurately accounted for. All simulations involve input data, such as physical properties, initial conditions, boundary conditions, and geometries, that are rarely known precisely. Characterizing the error, or uncertainty, in these data, propagating this uncertainty to the simulation results, and understanding its implications on predictions is generally called uncertainty quantification. Often uncertainty in input data is represented through bounds on the data or random variables/stochastic processes with prescribed probability distribution functions. Numerous approaches for propagating this uncertainty through computational simulations have been investigated in the literature, including random sampling [9, 15, 23, 24, 25], stochastic collocation [1, 26, 27, 35], and stochastic Galerkin [12, 13, 36], many of which involve sampling the simulation over the range of uncertain data. While the accuracy and scalability properties of numerical uncertainty propagation schemes vary, they all suffer from the basic challenge that accurately resolving discontinuous and localized behavior over high-dimension uncertain input spaces can require a tremendous number of samples. Since each sample evaluation is independent, it is trivial to parallelize sampling-based uncertainty propagation schemes in a coarse-grained manner by executing each sample on a disjoint set of compute nodes (and evaluation of the simulation at each sample typically involves the bulk of the computational cost). However, most uncertainty quantification problems of scientific and engineering interest involve high-fidelity simulations that require for each sample a significant fraction of the available computational resources, and therefore it is often possible to execute only a small fraction of the total number of samples needed in parallel with the remaining fraction executed sequentially. This leads to very high computational cost, making many uncertainty quantification problems applied to high-fidelity simulations intractable.

In this work, we investigate whether the aggregate computational cost for propagating uncertainties can be reduced by propagating multiple samples, which we call ensembles, together through simulations. We discuss an embedded approach for propagating ensembles, whereby scalars within the simulation code are replaced by ensemble arrays, and apply the technique to the solution of partial differential equations on unstructured meshes. We demonstrate that
the approach, *embedded ensemble propagation*, results in improved performance, portability, and scalability on contemporary multicore and manycore computational architectures by sharing sample-independent data and calculations across the ensemble (reducing floating-point operations and/or memory bandwidth requirements), improving memory access patterns by replacing sparse gather/scatter operations with packed loads/stores, improving opportunities for fine-grained vector (SIMD/SIMT) parallelization, and reducing aggregate communication costs arising from latency.

The paper is organized as follows. We discuss the mathematical formulation of ensemble propagation and its impact on iterative linear solvers in Sect. 2. In Sect. 3, we describe a software implementation of the technique leveraging C++ templates and operator overloading, focusing on its integration with the performance portability package Kokkos [7, 8] and with sparse linear algebra tools available in Trilinos [16, 17]. While the performance portability of Kokkos has been demonstrated in small mini-applications and graph algorithms [7, 8, 33], Sect. 3 details how the ensemble propagation approach is embedded into the Trilinos solver stack, from linear algebra kernels to iterative solvers and multigrid preconditioners. Then in Sect. 4 we demonstrate performance improvements for the approach compared to traditional one-at-a-time sample propagation on a variety of contemporary computational architectures, including weak-scaling results on a Cray XK7 (Titan) with up to 131,072 processor cores. Finally in Sect. 5 we summarize our work.

The idea of propagating multiple samples together has been proposed previously [14]. However, in this work we describe a unique approach for implementing the technique in a portable fashion that results in performant code in three different architectures (CPU, GPU and Xeon Phi). We also study its relevance to sparse linear algebra, partial differential equations, fine-grained hardware parallelism, and coarse-grained message-passing parallelism.

## 2 Ensemble Propagation

In this section we formalize ensemble propagation and illustrate its effect on a ubiquitous computational kernel in the simulation of partial differential equations (PDEs), the sparse matrix-vector product. For simplicity and brevity, we only consider steady-state problems here as the extension to transient problems is straightforward. Consider a steady-state, finite-dimensional, nonlinear system

\[
f(u, y) = 0, \quad u \in \mathbb{R}^n, \quad y \in \mathbb{R}^m, \quad f : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n.
\]

For the simulation of PDEs, we assume the equations have been spatially discretized by some suitable method (e.g., finite element, finite volume, finite difference), in which case \(u\) would represent the nodal vector of unknowns, and \(f\) the discretized PDE residual equations. Here \(y\) is a set of problem inputs, and we are interested in sampling the solution \(u\) for numerous values of \(y\). Given some number \(s\), consider computing \(u\) for \(s\) values of \(y\): \(y_1, \ldots, y_s\) (we assume \(s\) is small and in what follows will be a small multiple of the natural vector...
Figure 1: (a) Block diagonal structure of Kronecker product system (2). The number of blocks is determined by the ensemble size $s$, and each block has the sparsity structure for $\partial f/\partial u$. (b) Block structure of Kronecker product system (3). The outer structure is determined by $\partial f/\partial u$ where each nonzero is replaced by an $s \times s$ diagonal matrix.

Formally this can be represented by the Kronecker product system:

$$F(U, Y) = \sum_{i=1}^{s} e_i \otimes f(u_i, y_i) = 0,$$

$$U = \sum_{i=1}^{s} e_i \otimes u_i, \quad Y = \sum_{i=1}^{s} e_i \otimes y_i,$$

where $e_i \in \mathbb{R}^s$ is the $i$th column of the $s \times s$ identity matrix. In this system, the solution vector $U$ is a block vector where all $n$ unknowns for each sample are ordered consecutively. Furthermore, the Jacobian matrix $\frac{\partial F}{\partial U} = \sum_{i=1}^{s} e_i e_i^T \otimes \partial f/\partial u_i$ has a block diagonal structure, an example of which is shown in Fig. 1(a).

The choice of ordering for the unknowns in $U$ is arbitrary, and in particular the unknowns can be ordered so that all sample values are stored consecutively for each spatial degree of freedom in $u$. Formally, this amounts to commuting the terms in the Kronecker product system:

$$F_c(U_c, Y_c) = \sum_{i=1}^{s} f(u_i, y_i) \otimes e_i = 0,$$

$$U_c = \sum_{i=1}^{s} u_i \otimes e_i, \quad Y_c = \sum_{i=1}^{s} y_i \otimes e_i.$$

The Jacobian matrix $\frac{\partial F_c}{\partial U_c} = \sum_{i=1}^{s} \partial f/\partial u_i \otimes e_i e_i^T$ also has a block structure where each scalar nonzero in the original matrix $\partial f/\partial u$ is replaced by an $s \times s$ diagonal matrix, an example of which is shown in Fig. 1(b).

To understand the performance aspects of the commuted ensemble system (3), we will describe its impact on a ubiquitous kernel in the simulation of PDEs, the sparse matrix-vector product. In Fig. 2, a data structure for storing a matrix $A$ in the compressed row storage (CRS) format is displayed, along with a routine for computing matrix-vector products $z = Ax$ in this format.
// Matrix stored in compressed row storage for an arbitrary floating-point type T

```cpp
template <typename T>
struct CrsMatrix {
    int num_rows; // number of rows
    int num_entries; // number of nonzeros
    int *row_map; // starting index of each row
    int *col_entry; // column index for each nonzero
    T *values; // matrix values of type T
};
```

// CRS matrix-vector product z = A*x for arbitrary floating-point type T

```cpp
template <typename T>
void crs_mat_vec (const CrsMatrix<T>& A, const T *x, T *z) {
    for (int row =0; row <A.num_rows; ++row) {
        const int entry_begin = A.row_map[row];
        const int entry_end = A.row_map[row+1];
        T sum = 0.0;
        for (int entry = entry_begin; entry < entry_end; ++entry) {
            const int col = A.col_entry[entry];
            sum += A.values[entry] * x[col];
        }
        z[row] = sum;
    }
}
```

![Figure 2: CRS matrix data structure and corresponding matrix-vector product routine.](image)

Both the data structure and the matrix-vector product routine are templated to allow computations with any floating point scalar type.

Matrices and vectors for the ensemble system (2) can be stored in exactly the same format as in Fig. 2. Only modifications for the matrix-vector product routine are required to add an additional outer loop over the samples within the ensemble and adjustment of the indexing into A.values, x and z as shown in Fig. 3. Here the ensemble size s is controlled through a compile-time constant template parameter. This approach reduces memory requirements slightly since the row-offsets (A.row_map) and column-index (A.col_entry) arrays are only stored once for all matrices in the ensemble. However for large matrices it is unlikely these arrays will fit in a low-level cache, and therefore these values are re-read for each sample within the ensemble. Thus one would expect little improvement in performance.

For the commuted Kronecker product system (3) however, the ensemble loop is inside the row and column loops as is shown in Fig. 4. There are several things to note. First, any sample-dependent intermediate variables in the computation, such as sum, are replaced by length-s arrays. Second, sample independent data, such as the row-offsets and column-index arrays discussed above, are read once per ensemble reducing aggregate memory bandwidth requirements. Third, a common approach for exploiting SIMD/SIMT vector parallelism within the matrix-vector product calculation is to block the inner entry loop by some multiple of the vector width and replace the multiply-add with the corresponding parallel instruction. This requires a sparse gather for x based on the indices within A.col_entry. The effectiveness of this depends on the
Figure 3: Matrix vector product routine for ensemble matrix and vectors in original layout.

number of nonzeros per row in the matrix, how these nonzeros are distributed across the matrix columns, and the capabilities of the computer architecture. For the commuted ensemble system however, $s$ contiguous entries of $x$ are accessed consecutively from a common column offset $\text{col} \cdot s$. Thus the ensemble loop around the multiply-add can be parallelized by SIMD/SIMT where the scalar sparse gather is replaced by a packed/coalesced load. Furthermore, the ensemble loop is the inner-most loop, with a compile-time known trip-count and no dependencies between loop iterations, and thus is simple for the compiler to auto-vectorize. Thus the effectiveness of applying SIMD/SIMT parallelism to the ensemble matrix-vector product routine effectively becomes independent of the matrix structure and the architecture’s capabilities (assuming the ensemble size is chosen appropriately). Finally, while not shown explicitly in Figs. 2-4, the traditional approach for exploiting distributed-memory parallelism (e.g., MPI) within the matrix-vector product calculation is to distribute the rows of $A$, $x$ and $z$ across processors, where each processor computes the rows of $z$ it owns. Based on the sparsity structure of $A$, this requires communicating entries of $x$ between processors so that all needed entries of $x$ are available to each processor, commonly referred to as the halo exchange. When propagating one sample at a time, a halo exchange must occur for each matrix-vector product call, for each sample. However for the ensemble system, only one halo exchange is necessary per ensemble, reducing the latency cost of this communication by a factor of $s$.

In short, the commuted Kronecker product system results in reduced aggregate bandwidth, packed loads/stores (instead of sparse gather/scatter), better vector parallelization and reduced latency costs. For this approach to be effective, one must choose the ensemble size $s$ appropriately for each architecture. For effective SIMD/SIMT parallelism, it should be made a multiple of the natural vector width. Increasing $s$ generally improves reuse and use of SIMD/SIMT hardware, at the expense of increased aggregate memory usage, cache pressure,
// Ensemble matrix-vector product for commuted layout

```cpp
template <typename T, int s>
void ensemble_crs_mat_vec(const CrsMatrix<T>& A, const T* x, T* z) {
    for (int row=0; i<A.num_rows; ++row) {
        const int entry_begin = A.row_map[row];
        const int entry_end = A.row_map[row+1];
        T sum[s];
        for (int e=0; e<s; ++e) sum[e] = 0.0;
        for (int entry=entry_begin; entry<entry_end; ++entry) {
            const int col = A.col_entry[entry];
            for (int e=0; e<s; ++e) {
                sum[e] += A.values[entry*s + e] * x[col*s + e];
            }
        }
        for (int e=0; e<s; ++e) z[row*m + e] = sum[e];
    }
}
```

Figure 4: Matrix vector product routine for ensemble matrix and vectors in commuted layout.

and interconnect bandwidth pressure. The effects of ensemble size choice for several architectures will be studied in Sect. 4.

The literature extensively discusses blocking solver algorithms to improve performance. In particular, authors have explored approaches for exploiting block matrix structure in sparse matrix-vector product algorithms to reduce memory bandwidth and increase instruction throughput on superscalar architectures [19]. Similarly, matrix-vector product kernels have been developed for solving linear systems with multiple right-hand sides that leverage reuse of the matrix graph and values across right-hand sides as well as row-wise column ordering to apply SIMD/SIMT parallelism across right-hand-side columns [19]. The approach described here is distinct in that it groups together normally independent linear systems (each with a distinct right-hand side), and forms a block solver algorithm from the constituent matrices and right-hand sides. It does not rely on any block structure within each matrix, and can be viewed as an extension of the multiple right-hand side approach to also include multiple left-hand sides. Furthermore, the necessary row-wise layout occurs naturally through the commuted Kronecker product ordering.

3 Embedded Implementation

In this section we discuss an *embedded* approach for implementing ensemble propagation in general scientific simulation codes, based on C++ templates and operator overloading. From this point on, we are only concerned with the commuted ensemble system (3), henceforth referred to as the “ensemble system.” We first describe a new ensemble scalar type and a systematic approach for incorporating it into computer codes. We then describe its integration with the manycore performance portability library Kokkos, and our solution to challenges
3.1 Ensemble Scalar Type

Converting the matrix-vector product routine to propagate ensembles of values requires two fundamental steps: replace each sample-dependent variable with a length-s array, and replace each sample-dependent arithmetic operation with a length-s loop. Implementing such a change by hand is possible, but tedious and error prone. Furthermore, this is only one of many computational kernels and numerical algorithms that preconditioned iterative linear solvers need. Others have explored using source-to-source transformation to automate this conversion [14]. In this work we describe an approach based on compile-time polymorphism, using C++ templates and operator overloading. The idea is to write application code and solvers that are parametrized (“templated”) on the data type, and then replace the customary floating-point data type (e.g., double) with one that propagates ensembles.

We begin by defining the Ensemble C++ class that stores an ensemble of values. Fig. 5 displays a portion of it. The Ensemble class, along with support-
ing utilities, is provided by the Stokhos package\textsuperscript{1} [31] within Trilinos [16, 17]. It implements all of the necessary operations for making objects of this type act like standard floating-point data types, and for making them work with Trilinos’ data structures and solvers. These operations fall into four categories:

1. Arithmetic and basic mathematical functions
2. Input and output (C++ stream operations $\ll$ and $\gg$)
3. What Kokkos needs for reductions and atomic updates
4. What Tpetra needs to tell MPI how to communicate ensemble values

The first category of operations make Ensemble objects act like a C++ built-in floating-point type. They include:

- Copy constructors and assignment operators from ensemble values as well as scalar values (that is, for objects of type $\text{Ensemble}<T,s>$, values of any type $U$ convertible to $T$)
- Arithmetic operations ($+$, $-$, $\times$, $/$) and arithmetic-assignment operators ($+=, -=, \times=, /=$) from ensemble and scalar values
- Comparison operations $>$, $<$, $\leq$, $\geq$, and $==$ between ensembles and scalar values, which base the result on the first entry in the ensemble
- Overloads of basic mathematical functions declared in \texttt{cmath}, such as $\sin()$, $\cos()$, $\exp()$, as well as other common operations such as $\min()$ and $\max()$

The third category of operations lets Kokkos produce ensemble values as the result of a parallel reduction or scan, and ensures that if threads update the same ensemble value concurrently, those updates are correct (assuming that order does not matter). Kokkos needs overloads of the above operations for ensemble values declared \texttt{volatile}, and an implementation of Kokkos’ atomic updates for ensemble values. Sect. 3.4 will discuss the fourth category of operations.

$\text{Ensemble}<T,s>$ meets the C++ requirements for a \textit{plain old data} type. The template parameter $s$ fixes its size at compile time; it does no dynamic memory allocation inside. Furthermore, it has default implementations of the default constructor, copy constructor, assignment operator, and destructor. This implies that arrays of ensemble values can be allocated with no more initialization cost than built-in scalars. Ensemble objects can be easily serialized for parallel communication and input / output, since all such objects have the same size on all parallel processes.

Our ensemble scalar type employs expression templates [34] to avoid creation of temporaries and fuse loops within expressions, thus reducing overhead. Since the ensemble loop is always the lowest-level loop, it has a fixed trip count and no

\textsuperscript{1}For expository purposes, we have simplified the \texttt{Ensemble} class described here. Stokhos’ actual ensemble class differs in both interface and implementation.
iteration dependencies. This means that the compiler can easily auto-vectorize each arithmetic operation, including insertion of packed load/store instructions. However, difficulties do arise when mapping GPU threads to ensemble components for GPU SIMT parallelization. We discuss our GPU optimizations in Sect. 3.3.

Since the original CRS matrix-vector multiply routine in Fig. 2 is already templated on the scalar type, instantiating this code on the ensemble scalar type, \texttt{crs\_mat\_vec< Ensemble<T,s> \ }; \texttt{>()} results precisely in the ensemble matrix-vector multiply routine in Fig. 4.

3.2 Incorporating the Ensemble Type in Complex Codes

Replacing the floating-point scalar type with the ensemble types accomplishes both steps of replacing sample-dependent variables with ensemble arrays and arithmetic operations with ensemble loops. We generally advocate the use of C++ templates to facilitate this type change, whereby the floating-point type is replaced by a general template parameter. This allows the original code to be recovered by instantiating the template code on the original floating-point type, and the ensemble code through the ensemble scalar type. Furthermore, other scalar types can be used as well, such as automatic differentiation types for computing derivatives. We refer to the process of using C++ templates and a variety of scalar types to implement different forms of analysis as \textit{template-based generic programming} [29, 30]. This has been shown to be effective for supporting analyses such as ensemble propagation in complex simulation codes.

The most challenging part of incorporating the ensemble scalar type in complex code bases is its conversion to code templated on the scalar type. Developers must analyze the code to determine which values depend (directly or indirectly) on the input data that will be sampled, and therefore should be converted to ensembles by replacing the types of those values with a template parameter. While this is admittedly tedious, it is generally straightforward to accomplish. Furthermore, the compiler helps in this process since the ensemble scalar type does not allow direct conversions of ensemble values to scalar values. This prevents accidentally breaking the chain of dependencies from input data to simulation outputs. It is possible to implement this conversion through a helper function, which takes the first entry in the ensemble to initialize the resulting scalar. Therefore one can incrementally convert a code to use ensembles by manually converting ensembles to scalars whenever ensemble code calls code that has not yet been converted. Note that scalars can be automatically converted to ensemble values by the compiler, which implies it is possible to incorrectly replace code that does not depend on the input data with ensembles. This can only be discovered through programmer analysis and optimization of the code.

Once all necessary scalar values have been replaced by ensembles in the simulation code, the ensemble propagation occurs automatically by “evaluating” the resulting ensemble code. This requires adding suitable initialization and finalization code to initialize ensemble values for input data and extracting en-
semble values for simulation results (using various ensemble constructors and coefficient access routines). Sample independent data are not replaced by ensembles, and therefore reuse happens naturally through the normal compiler optimization process and overloaded operators that take a mixture of scalars and ensembles as arguments.

3.3 Kokkos Performance Portability

Kokkos [7, 8] is a programming model and C++ library that enables applications and domain libraries to implement thread scalable algorithms that are performance portable across diverse manycore architectures such as multicore CPU, Intel Xeon Phi, and NVIDIA GPU. Kokkos’ design strategy is to define algorithms with parallel patterns (for-each, reduction, scan, task-dag) and their code bodies invoked within these patterns, and with multidimensional arrays of their “scalar” data types. Performance portability is realized through the integrated mapping of patterns, code bodies, multidimensional arrays, and datum onto the underlying manycore architecture.

This mapping has three components. First, code is mapped onto the target architecture’s best performing threading mechanism; e.g., pthreads or OpenMP on CPUs and CUDA on NVIDIA GPUs. Second, parallel execution is mapped with architecture-appropriate scheduling; e.g., each CPU thread is given a contiguous range of the parallel iteration space while each GPU thread is given a thread-block-strided range of the parallel iteration space. Third, multidimensional arrays are given an architecture-appropriate layout; e.g., on CPUs arrays have a row-major or “array of structs” layout and on GPUs arrays have a column-major or “struct of arrays” layout. While this polymorphic multidimensional array abstraction has conceptual similarities to Boost.MultiArray [11], Kokkos’ abstractions for explicit dimensions and layout specializations provides greater opportunities for performance optimizations.

When scalar types are replaced with ensemble types in a Kokkos multidimensional array, the layout is specialized so that operations on ensemble types may exploit the lowest level of hierarchical parallelism. Hierarchical thread parallelism can be viewed as “vector” parallelism nested within thread parallelism. The mechanism to which Kokkos maps “vector” parallelism is architecture dependent. On CPUs this level is mapped to vector instructions, typically through the compiler’s optimization algorithms. On GPUs this level is mapped to threads within a GPU warp, and then Kokkos’ thread abstraction is remapped to the entire warp. Thus on the GPU architecture ensemble operations are, transparent to the user code, performed in parallel by a warp of threads.

The specialized layout integrates the ensemble dimension into the multidimensional array such that the ensemble’s values remain contiguous in memory on any architecture. This contiguity is necessary to obtain the best “vector” level parallel performance for computations on irregular data structures; such as sparse matrices and unstructured finite elements. These data structures typically impede performance by requiring non-contiguous scalar values to be
gathered into contiguous memory (vector registers), processed with vector instructions, and then results scattered back to non-contiguous scalar values. On CPU architectures these gather/scatter operations might be automatically generated by a compiler that recognizes the indirection patterns of irregular data structures. When the scalar type is an ensemble each indirect access that previously referenced a single scalar value instead references the ensemble types’ contiguous set of values (recall Fig. 5). As such, gather/scatter operations are no longer needed for vector instructions, and compilers can more easily generate vectorized operations.

On NVIDIA GPU architectures, warp-level gather/scatter operations are generated by hardware, removing the need for sophisticated indirection-pattern recognition by the compiler. However, memory accesses are still non-coalesced gather/scatter operations thus reducing performance. When the scalar type is an ensemble, indirect access patterns lead to coalesced reads and writes of contiguous ensemble values, resulting in improved performance.

In summary, replacing scalar types with ensemble types in computations on irregular data structures enables improved utilization of hierarchical parallel hardware such as multicore CPUs with vector instructions and GPUs. To realize this improvement (1) Kokkos multidimensional array layouts are specialized to insure ensemble values are contiguous in memory and (2) ensemble operations are mapped to the “vector” level of Kokkos’ hierarchical thread-vector parallelism. On CPU architectures, this mapping happens automatically through the normal compiler vectorization process when applied to the ensemble loops. For GPU architectures however, this mapping occurs by creating a strided subview within the ensemble dimension of the multidimensional array for each GPU thread within a warp. These two mappings insure that CPU vector instructions or GPU warp operations are performed on contiguous memory.

3.4 Linear Algebra and Iterative Solvers

The ensemble scalar type and Kokkos library described above have both been incorporated into the Tpetra linear algebra package [3, 18] within Trilinos. Tpetra implements parallel linear algebra data structures, computational kernels, data distributions, and communication patterns. “Parallel” includes both MPI (the Message Passing Interface) for distributed-memory parallelism, and Kokkos for shared-memory parallelism within an MPI process. Supported data structures include vectors, “multivectors” that represent groups of vectors with the same parallel distribution, sparse graphs, sparse matrices, and “block” sparse matrices (where each block is a small dense matrix). Tpetra’s computational kernels include vector arithmetic, sparse matrix-vector products, sparse triangular solve, and sparse matrix-matrix multiply. It lets users represent arbitrary distributions of data over MPI processes, and communicate data between those distributions.

Tpetra is templated on the “scalar” type, the type of each entry in the matrix or vector. In theory, this lets Tpetra work with any type that “looks like” one of the C++ built-in floating-point types. Tpetra uses this flexibility to provide
built-in support for both single- and double-precision real and complex floating-point values, as well as 128-bit real floating-point arithmetic if the compiler supports it. In practice, in order to support an arbitrary scalar type, Tpetra needs it to implement all of the operations described in Sect. 3.1. In particular, Tpetra needs to tell MPI how to communicate scalars. This means that Tpetra either needs to know the MPI\texttt{Datatype} corresponding to the scalar type, or how to pack and unpack scalars into byte arrays. The scalar type tells Tpetra this by implementing a C++ traits class specialization. Tpetra in turn provides a type-generic MPI interface, both for itself and for users.

The Belos package\cite{4} in Trilinos builds upon Tpetra data structures to provide parallel iterative linear solvers such as CG and GMRES. It is also templated on the scalar type, allowing ensembles to be propagated through these linear solver algorithms. Iterative solver algorithms do not directly access matrix and vector entries. They only need to know the results of inner product and norm calculations, and only deal with matrices and vectors as abstractions. Furthermore, viewing the ensemble system as the Kronecker product system (3), inner products and norms of ensemble vectors should be scalars and not ensembles. That is, given two ensemble vectors $U_c = \sum_{i=1}^{s} u_i \otimes e_i$ and $V_c = \sum_{i=1}^{s} v_i \otimes e_i$,

$$U_c^T V_c = \sum_{i=1}^{s} u_i^T v_j \otimes e_i^T e_j = \sum_{i=1}^{s} u_i^T v_i.$$  

Tpetra assists Belos by defining a traits class that defines the proper data type for the result of inner product and norm calculations, and exposing these types to solvers and application code as public typedefs. First

$$\sum_{i=1}^{s} u_i^T v_i \otimes e_i$$

is computed, which naturally arises when propagating the ensemble scalar type through the inner product code. The final inner product value is then computed by adding together each ensemble component. Thus, Belos does not directly generate or access ensemble values; they only appear internally within the matrix and vector data structures. Belos only needs one implementation for Tpetra objects of all scalar types, with no significant abstraction overhead.

### 3.5 Multigrid Preconditioners

Multigrid is a provably optimal linear solution method in work per digit of accuracy for systems arising from elliptic PDEs. Multigrid works by accelerating the solution of a linear system of interest, $A^0 x^0 = b^0$, through a sequence or hierarchy of increasingly smaller linear systems $A^i x^i = b^i, i > 0$. The purpose of each system or level is to reduce particular ranges of errors in the $i = 0$ problem. Any errors that are not quickly damped by a particular system should be handled by a coarser problem.

The main components of a multigrid solver are smoothers, which are solvers that operate only on particular levels, and transfer operators to migrate data
Algorithm 1 V-cycle multigrid with $N$ levels to approximate solution $Ax = b$.

$A^0 = A$

function $VCycle(A^k, b, x, k)$

// Solve $A^k x = b$ (k is current grid level)
$x = S^k_1(A^k, b, x)$

if ($k \neq N - 1$) then
  $r^{k+1} = R^k(b - A^k x)$
  $A^{k+1} = R^k A^k P^k$
  $z = 0$
  $VCycle(A^{k+1}, r^{k+1}, z, k + 1)$
  $x = x + P^k z$
  $x = S^k_2(A^k, b, x)$
else
  $x = S^c(A^{N-1}, x, b)$
end if
end function

between levels. The transfer from level $i + 1$ to $i$ is called a \textit{prolongator} and denoted $P^i$. The transfer from level $i$ to $i + 1$ is the \textit{restrictor} and denoted $R^i$. A typical schedule for visiting the levels, called a V-\textit{cycle}, is given in Algorithm 1. In practice, this algorithm is divided into two phases: the setup phase where all of the matrix data used at each level is generated (e.g., $R^k, P^k, A^k, S^k_1, S^k_2$ and $S^c$), and the solve phase where given $b$ and the data from the setup phase, $x$ is computed.

Multigrid algorithms such as this have been implemented in the MueLu package within Trilinos [32]. MueLu’s performance with traditional scalar types on very large core counts has been studied before [20, 21]. This library builds upon the templated Tpetra data structures and algorithms described above, with all of the functionality used in setup (such as the matrix-matrix multiply $R^k A^k P^k$) and application of the V-cycle in Algorithm 1 (such as the smoothers $S^k_1$ and $S^k_2$) templated on the scalar type. Furthermore, the V-cycle algorithm in MueLu is encapsulated within an operator $z = M x$ allowing it to serve as a preconditioner for the Krylov methods in Belos. In this work, the restriction and prolongation operators $R^k$ and $P^k$ are generated from the graph of $A^k$ at each level, without any thresholding or dropping. This implies that given matrices $A_1, \ldots, A_s$ corresponding to $s$ samples within an ensemble, and corresponding multigrid preconditioners $M_1, \ldots, M_s$ generated for each matrix individually, then the corresponding ensemble preconditioner $M_c$ is equivalent to

$$M_c = \sum_{i=0}^{s} M_i \otimes e_i e_i^T.$$  \hspace{1cm} (6)

In the experiments described below, we use order-2 Chebyshev polynomial smoothers ($S^k_1$, $S^k_2$) and continue to generate levels in the multigrid hierarchy until the number of matrix rows falls below 500. For the coarse-grid solve $S^c$, 

a simple sparse-direct solver that is built into Trilinos, called Basker, is used. Note that in the current version of the code, the preconditioner setup and coarse grid solver do not leverage Kokkos directly and thus are thread-serial (but are MPI-parallel). Furthermore, for the GPU architecture, the coarse-grid solve is executed on the host using recent Unified Virtual Memory (UVM) features to automatically transfer data between the host and GPU. All other aspects of the V-cycle solve phase are fully thread-parallel using Kokkos.

A major concern in parallel multigrid is the relative cost of communication to computation for levels \( i > 0 \). For a good-performing multigrid method, matrix \( A^{i+1} \) can typically have 10–30 times fewer rows than \( A^i \), with only a modest increase in the number of nonzeros per row. Practically, this means that the ratio of communication to computation can increase by an order of magnitude per level. In MueLu, this issue is addressed by moving data to a subset of processes for coarser levels. Once, the number of processes for a coarser level is determined, a new binning of the matrix rows (weighted by the number of nonzeros per row) is found using the multi-jagged algorithm [6] from the Zoltan2 library [5]. Each bin is assigned to a process so that data movement is restricted in the coarser level to fewer processes. This improves scalability of the preconditioner, particularly with large numbers of processes. Propagating ensembles through the preconditioner further reduces communication costs by amortizing communication latency across the ensemble.

### 3.6 Build times and library sizes

Some developers worry that extensive use of C++ templates may increase compilation times and library sizes. The issue is that plugging each scalar type into templated linear algebra and solver packages results in an entirely new version of the solver to build. The compiler sees a matrix-vector multiply with double as distinct code from a matrix-vector multiply of \( \text{Ensemble<T,s>} \), for example. More versions of code means longer compile times and larger libraries. This is not particular to C++ templates; the same would occur when implementing ensemble computations automatically using source-to-source translation with Fortran or C, with manual translation, or with some other language’s flavor of compile-time polymorphism.

A second issue is particular to C++. Most C++ compilers by default must re-build templated code from scratch in each source file that uses it. Furthermore, deeply nested “stacks” of solver code do not actually get compiled until an application source file uses them with a specific scalar type. For example, MueLu is templated and depends on many Trilinos packages that are also templated, so using MueLu means that the application must build code from many different Trilinos packages. In practice, this shows up as long application build times, or even running out of memory during compilation.

Trilinos fixes this with its option to use what it calls explicit template instantiation (ETI). This “pre-builds” heavyweight templated code so applications do not have to build it from scratch each time. ETI corresponds to the second option in Section 7.5 of the GCC Manual [10], where Trilinos manually instanti-
Figure 6: Example of ensemble divergence due to conditional evaluation resulting in multiple code branches. Here Scalar is a general template parameter that could be double for single-point evaluation or Ensemble for ensemble evaluation.
// Base template definition of EnsembleTrait that is empty.
// It must be specialized for each scalar type T
template <typename T> struct EnsembleTrait {};

// Specialization of EnsembleTrait for T = double
template <> struct EnsembleTrait<double> {
    typedef double value_type;
    static const int ensemble_size = 1;
    static double& coeff(const double& x, const int i) { return x; }
    static double& coeff(double& x, const int i) { return x; }
};

// Specialization of EnsembleTrait for T = Ensemble
template <typename T, int s> struct EnsembleTrait<Ensemble<T,s> > {
    typedef T value_type;
    static const int ensemble_size = s;
    static T& coeff(const Ensemble<T,s>& x, const int i) { return x.val[i]; }
    static T& coeff(Ensemble<T,s>& x, const int i) { return x.val[i]; }
};

// ...
typedef EnsembleTrait<Scalar> ET;
typedef typename ET::value_type ScalarValue;
const int s = ET::ensemble_size;
Scalar x = ...
Scalar y;
for (int i=0; i<s; ++i) {
    const ScalarValue & xi = ET::coeff(x,i);
    ScalarValue & yi = ET::coeff(y,i);
    if (xi > 0) {
        ScalarValue z = xi*xi;
        yi = xi + z;
    } else {
        yi = xi;
    }
// ...
}

Figure 7: Handling ensemble divergence through the EnsembleTrait type trait which enables loops over ensemble components in a type-generic fashion.

inates the architectural benefits of ensemble propagation through the body of the loop, and therefore should only be applied to small portions of the code where the bodies of the conditional branches are small.

Divergence may also occur at high levels within the simulation code. Examples include iterative linear and nonlinear solver algorithms that require a different number of solver iterations for each sample, and adaptive time stepping and meshing schemes that dynamically adjust the temporal and spatial discretizations based on error estimates computed for previous time steps or solutions. While adding an ensemble loop around these calculations is certainly feasible, it defeats the original intent of incorporating ensemble propagation.

Alternately, recall that the use of an ensemble scalar type is merely a vehicle for implementing the Kronecker product system (3). As we discussed
in Sect. 3.4, the norm and inner product calculations that drive convergence decisions for iterative solver algorithms as well as adaptivity decisions for time-stepping and meshing do not produce ensemble values. Instead, they produce traditional floating-point values, which are the results of norms and inner products over entire ensemble vectors. This effectively couples all of the ensemble systems together, resulting in a single convergence or adaptivity decision for the entire ensemble system. Thus divergence is handled in these cases through proper definition of the types used for magnitudes and inner products, with associated traits classes for computing these quantities in a type-generic fashion. The resulting coupled linear solver algorithm is analogous to block Krylov subspace methods [28]. First, it couples the linear systems together algorithmically, not just computationally. Second, our approach opens up opportunities for increasing spatial locality and reuse in computational kernels, just as block Krylov methods do. (See, for example, [2]). Just as with block Krylov methods, however, coupling the component systems comprising the ensemble system means that the solves are no longer algorithmically equivalent to uncoupled solves. This means that the choice of the ensemble size $s$, as well as which samples are grouped together within each ensemble, will affect the performance of the resulting simulation algorithms. Therefore, the solution to managing high-level solver divergence across ensemble values is group samples together in ensembles that minimize this divergence.

For example, the convergence of iterative linear solvers (or its number of iterations) for each sample depends on several factors. Among these, the most important are the condition number of the matrix associated with $\partial f / \partial u$ and the spatial variation and magnitude of the sample-dependent parameters. When the ensemble system $F_e$ is formed, the solver’s convergence is always poorer than the solver applied to each sample individually. This happens because the spectrum of the ensemble matrix is the union of the matrix spectra of the samples that comprise it; this likely increases the condition number and hence the number of iterations. For this reason, it is convenient to have a grouping strategy that gathers samples requiring a similar number of iterations in the same ensemble. Since this information is not known a priori, quantities such as those mentioned above can be used to predict which samples feature a similar number of iterations. Preliminary studies show that the variation of the sample-dependent parameters over the computational domain may induce a grouping very similar to the one based on the number of iterations. Algorithmic ideas along these lines will be explored in a future paper. In the computational studies below however, we assume the matrix spectra for all samples are similar so that the number of iterations of the ensemble system is constant with regards to grouping.

4 Computational Results

We now investigate the performance improvements possible for the ensemble propagation approach described above. We consider the simple nonlinear
advection-diffusion system
\[-\nabla \cdot (\kappa(x,y)\nabla u) + \alpha v \cdot \nabla u + \beta u^2 = 0, \quad x \in D = [0,1]^3.\] (7)
The diffusion coefficient \(\kappa\) is treated as uncertain and is represented by a truncated Karhunen-Loève expansion [13]:
\[\kappa(x,y) = \kappa_0 + \sigma \sum_{i=1}^{m} \kappa_i(x)y_i, \quad x \in D, \quad y \in \Gamma = [-1,1]^m,\] (8)
where each \(y_i\) is a uniform random variable over \([-1,1]\), \(\kappa_0\) is the mean of the diffusion coefficient, \(\sigma\) its standard deviation, the \(\kappa_i\) are eigenfunctions of the exponential covariance function
\[C(x,x') = \sigma^2 e^{-\frac{\|x-x'\|}{L}}, \quad x,x' \in D,\] (9)
and \(L\) is the correlation length (in this case, the \(\kappa_i\) are tensor products of sines and cosines with frequencies that grow with \(i\) [13]).

We assemble and solve Eq. 10 via a hybrid distributed-shared memory parallel approach where given the number of MPI ranks \(p\), the spatial domain \(D\) is divided into \(p\) disjoint subdomains resulting in a partitioning of Eq. 10 into \(p\) disjoint sets of rows. The processors associated with each MPI rank then assemble and solve the equations belonging to them using a shared-memory parallel approach implemented by Kokkos described below.

A pseudocode description of the assembly portion of the calculation is presented in Algorithm 2. Given values for \(u\) and \(y\), the residual \(f(u,y)\) and Jacobian \(\partial f/\partial u = A\) are evaluated. Here \(N_{\text{mesh}}\) is the number of mesh cells for a given MPI rank, \(N_{\text{node}} = 8\) is the number of finite element basis functions/vertices per cell, and \(N_{\text{qp}} = 8\) is the number of quadrature points per cell. First entries of \(u\) owned by other MPI ranks that are needed within each MPI rank’s assembly are imported in the halo exchange. This communication pattern is precisely the same as needed in sparse matrix-vector products involving \(A\). Then each element (cell) in the mesh belonging to the given MPI rank is visited, where local contributions to the global residual and Jacobian are computed. This loop is executed in parallel by Kokkos, where each cell is assigned a unique thread. A mapping from mesh nodes to global degree-of-freedom indices (NodeIndex) is used to initialize the local element solution vector \(u_e\). The element residual and Jacobian are computed through a numerical integration which requires evaluating the finite element basis functions, their gradients, the corresponding solution vector \(u_e\), the gradient of the solution vector \(\nabla u_e\), and...
Algorithm 2 Pseudo-code description of PDE assembly algorithm.

```plaintext
function ResidualJacobianAssembly(A, f, u, y)
    // Import needed off-processor elements of u
    halo_exchange(u)
    // Thread-parallel for loop over mesh cells
    for e = 0 to Nmesh do
        // Sparse gather of element solution vector
        for i = 0 to Nnode do
            I = NodeIndex(e,i)
            ue(i) = u(I)
        end for
        // Evaluate element residual fe and Jacobian Ae
        for qp = 0 to Nqp do
            // Evaluate basis functions, gradients, and
            // transformation from reference cell at
            // quadrature point qp
            // Evaluate element solution ue and
            // gradient ∇ue at quadrature point
            // Evaluate diffusion, advection, source terms
            // and sum into element residual/Jacobian
        end for
        // Sparse scatter into global residual/Jacobian
        for i = 0 to Nnode do
            I = NodeIndex(e,i)
            atomic_add(f(I), fe(i))
            for j = 0 to Nnode do
                J = ElemGraph(e,i,j)
                atomic_add(A(I,J), Ae(i,j))
            end for
        end for
    end for
end function
```
the PDE diffusion, advection, and source terms at each quadrature point (not shown for brevity). The results of these calculations are accumulated into the local residual and Jacobian. Finally the element residual and Jacobian contributions are accumulated into the global residual and Jacobian data structures using the NodeIndex mapping as well as a second mapping of element Jacobian columns to global matrix columns (ElemGraph). Since multiple cells contribute to the same residual/Jacobian row, these contributions must use atomic instructions to prevent thread race conditions. The C++ code implementing the assembly algorithm (2) is templated on the scalar type as described above, using templated Tpetra matrix and vector data structures for storing $f$ and $A$. This allows reuse of the same templated code base for both scalar (single sample value) and ensemble systems.

In the experiments below, we choose $\alpha = \beta = 0$, in which case the resulting discrete equations are linear, symmetric, and positive-definite. Thus only a single iteration of Newton’s method is required, and the Newton system Eq. 10 is solved by CG preconditioned by multigrid as described in Sect. 3.5. We also choose $m = 5$, $\kappa_0 = 1$, $\sigma = 0.1$, and $L = 1$, in which case the diffusion coefficient varies smoothly with respect to both $x$ and $y$, the number of CG iterations is very nearly constant with respect to samples of $y$, and the number of CG iterations does not vary with $s$.

Given an ensemble size $s$, we measure speed-up of the ensemble approach for assembling and solving Eq. 10 for $s$ values of $y$ simultaneously over the scalar approach of assembling and solving this system $s$ time sequentially, by measuring

Table 1: Computational architectures studied.
the timings of the two approaches implemented on the parallel architectures\textsuperscript{2} displayed in Table 1. Here speed-up is defined as
\begin{equation}
\text{Speed-Up} = \frac{s \times \text{Time for single sample}}{\text{Time for ensemble}}. \tag{11}
\end{equation}

First in Fig. 8 we display the measured speed-up for the ensemble propagation approach applied to the sparse matrix-vector product kernel discussed above for the matrix $A$ generated on a $64 \times 64 \times 64$ spatial mesh, for a single compute node of each architecture in Table 1.\textsuperscript{3} For reference, we display in Table 2 the measured sparse matrix-vector product floating-point throughput for each architecture, as well as optimistic and pessimistic bounds for this throughput based on bandwidth considerations. Assuming storage of $8$ B per matrix value, $4$ B per matrix column entry, and $8$ B per vector value, these bounds are given by
\begin{align}
\text{Scalar Optimistic} &= \text{Bandwidth} \times \frac{2 \text{ FLOPS}}{12 \text{ B}} \\
\text{Scalar Pessimistic} &= \text{Bandwidth} \times \frac{2 \text{ FLOPS}}{20 \text{ B}} \\
\text{Ensemble Optimistic} &= \text{Bandwidth} \times \frac{2 \text{ FLOPS}}{8 \text{ B}} \\
\text{Ensemble Pessimistic} &= \text{Bandwidth} \times \frac{2 \text{ FLOPS}}{16 \text{ B}} \tag{12}
\end{align}

where the optimistic bounds assume vector entries are read from a fast cache, and the pessimistic bound assumes they are read from main memory. The bounds listed in Table 2 are based on bandwidth measured by the STREAM Triad benchmark\textsuperscript{22}. For the Sandy Bridge and Cray XK7 architectures with multiple NUMA regions per node, the bandwidth measurements, bounds, and matrix-vector product timings are based on a single NUMA region ($8/16$ and $8/8$ cores/threads respectively). One can see from Fig. 8 that significant improvements in matrix-vector product throughput are achievable by the ensemble approach (even for the relatively well-structured finite element matrix used in this example). On the CPU architectures, performance of which is better modeled by the optimistic bounds due to their large caches, most of this improvement derives from the $33\%$ reduction in bandwidth arising from reuse of the matrix graph. However the speed-ups are larger for the GPU and accelerator architectures where coalesced/packed memory access patterns are required to achieve full bandwidth.

\textsuperscript{2}Due to insufficient support for the C++98 standard by the native IBM compilers, the GNU compilers were used on the Blue Gene/Q architecture, disallowing the use of vector instructions. At the time of this writing, performance issues associated with the CUDA toolkit available for the Cray XK7 prohibited generating computational results with this code base on the GPU. Therefore GPU results were obtained on a small cluster. Also, only a single Intel Xeon Phi accelerator card is available to the authors.

\textsuperscript{3}The scalar kernel used in these experiments is a custom matrix-vector product kernel provided by Kokkos that has been optimized for these architectures. The ensemble kernel is identical to the one described Fig. 4, but with an additional specialization for CUDA that loads the sparse graph into shared memory to facilitate reuse.
Table 2: Measured and expected sparse matrix-vector product throughput (in GFLOP/s) for the scalar and ensemble matrix-vector product (for $s = 32$) on each architecture. Optimistic and pessimistic bounds are based on the main-memory bandwidth as measured by the STREAM Triad benchmark [22].

| Name          | Bandwidth (GB/s) | Scalar Mat-Vec | Ensemble Mat-Vec |
|---------------|------------------|----------------|------------------|
|               | Measured         | Optimistic     | Measured         | Optimistic     |
|               |                  | Pessimistic    | Bound            | Pessimistic    |
| Sandy Bridge  | 36.2             | 5.9            | 6.0              | 3.6            |
| Blue Gene/Q   | 28.5             | 3.5            | 4.8              | 2.9            |

| Accelerator   | 147              | 12.2           | 24.5             | 14.7           |

Figure 8: Ensemble matrix-vector product performance.

We next perform a similar experiment comparing the performance of scalar and ensemble assembly for $A$ and $f$ in Eq. 10 in Fig. 9 (again using only a single NUMA region for the Sandy Bridge and Cray architectures). As is clear from Algorithm 2 the assembly process involves substantially more operations than the matrix-vector product kernel, with significantly more reuse of data from sample to sample (such as the NodeIndex and ElemGather mappings, and basis function evaluations) and more opportunities for vectorization. This reuse and vectorization generally results in substantially improved assembly performance for the ensemble approach except for the GPU architecture. Because of the large operation count, assembly performance is less sensitive to coalesced memory accesses in the sparse gather operation than the matrix-vector product kernel. Furthermore there is little captured reuse of sample-independent data since reuse can only occur by communicating values between CUDA threads using shared-memory (which for portability reasons is not included in this implementation).
Next we measure the performance of MPI communication through the halo exchange that is needed for each sparse matrix-vector product and linear system assembly on both the Cray XK7 and Blue Gene/Q architectures. In Figs. 10(a) and 10(c) we display the total ensemble halo exchange time (in milliseconds) for varying node counts and ensemble sizes, and in Figs. 10(b) and 10(d) the corresponding ensemble speed-up. It is reasonable to assume both halo exchange message latency and bandwidth are roughly constant with regards to message size over the limited range of ensemble sizes considered, and thus the total exchange time can be approximated by

$$T_{halo}(s) = a + bs,$$  \hspace{1cm} (13)

where $a$ and $b$ are related to the interconnect latency and bandwidth respectively. Included in Figs. 10(a) and 10(c) is a plot of Eq. 13 based on a linear regression for approximating $a$ and $b$ for each architecture (black curve). Based on Eq. 13 the speed-up for the ensemble halo exchange is approximately

$$\text{Speed-up} = \frac{sT_{halo}(1)}{T_{halo}(s)} = \frac{s(a + b)}{a + bs}.$$  \hspace{1cm} (14)

Also included in Figs. 10(b) and 10(d) is a plot of Eq. 14 based on the above regression analysis (black curve), which matches the measured data well. Thus the reduction in total halo exchange time for propagating $s$ samples using the ensemble approach is due to the factor $as$ reduction in communication latency.

Finally, we investigate the performance of our ensemble approach with multi-grid preconditioned CG solves of Eq. 10 for both the Cray XK7 and Blue Gene/Q architectures, as well as 64 nodes of a Sandy Bridge cluster, 8 nodes of a K20X cluster, and a single Xeon Phi 7120P accelerator. In Figs. 11(a) and 11(b) we show preconditioned CG solve time relative to the time for a single node of each architecture for the scalar and ensemble systems respectively, with the spatial mesh size fixed at $64^3$ cells per compute node as the number of compute nodes is increased (weak scaling). For the ensemble system, we use $s = 32$. In Fig. 12
Figure 10: Ensemble halo exchange performance on Cray XK7 (a)-(b) and Blue Gene/Q (c)-(d) architectures, including a linear fit (black curves) of the exchange time (Eq. 13) and resulting ensemble speed-up (Eq. 14).
Figure 11: Time for multigrid preconditioned CG solve of scalar system (a) and ensemble system (b) relative to time for a single compute node (weak scaling).

Figure 12: Ensemble preconditioned linear solver speed-up relative to scalar solve.

we display the resulting ensemble solve speed-up. The cost of the preconditioned CG solves is dominated by applications of the multigrid preconditioner, which are in turn dominated by the matrix-vector products within the Chebyshev smoothers and transfer operators. This leads to improved single-node performance for all architectures, particularly so for the GPU and Accelerator architectures, deriving from the results in Fig. 8. We also see substantially improved weak-scaling due primarily to the reduced MPI communication costs for the smoothers and transfer operators, particularly for the GPU architecture where communication costs are much higher even at small node counts.

5 Conclusions

In this work we described an approach for improving uncertainty propagation performance for sampling-based uncertainty quantification methods based on
propagating multiple samples together through scientific simulations. We argued this should lead to improved aggregate performance by enabling reuse of sample-independent data, improving memory access patterns by replacing sparse gather/scatter instructions with packed/coalesced loads/stores, improving opportunities for fine-grained SIMD/SIMT parallelism, and reducing latency costs associated with message passing. We described a C++ template and operator overloading approach for incorporating the ensemble propagation approach in general scientific simulation codes, and discussed how tools implementing this technique have been incorporated into a variety of libraries within Trilinos, including the Kokkos manycore performance portability library. Furthermore, we argued how the approach improves portability by providing uniform access to fine-grained vector parallelism independent of the simulation code’s ability to exploit those hardware capabilities. Finally, we demonstrated performance and scalability improvements for the approach by applying it to the solution of a simple PDE.

Practical application of these ideas for uncertainty quantification requires grouping samples generated by the uncertainty quantification algorithm into sets of ensembles of a size most appropriate for the architecture. In the experiments covered in this paper, we found an ensemble size of 32 generally works well for all architectures considered. Grouping samples appropriately is critical for the approach to be effective for real scientific and engineering problems, where the simulation process should be as similar as possible for all samples within an ensemble. For example, the spectra of matrices used in the solution of linear/nonlinear systems should be similar to prevent growth in solver iterations. Furthermore, the code-paths required for samples within an ensemble need to be similar to achieve effective speed-ups. Work exploring algorithmic grouping approaches is underway and will be discussed in a subsequent publication. However, once samples have been grouped, each ensemble can be propagated independently using the traditional coarse-grained distributed memory approach.
