Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Pneumonia in children admitted to the national referral hospital in Bhutan: A prospective cohort study

A B S T R A C T

Objectives: The study aim was to describe the etiological profile and clinical characteristics of pneumonia among children hospitalized in Thimphu, Bhutan.

Methods: This prospective study enrolled children aged 2–59 months admitted to the Jigme Dorji Wangchuck National Referral Hospital with World Health Organization (WHO)-defined clinical pneumonia. Demographic and clinico-radiological data were collected through questionnaires, physical examination, and chest radiography. Blood samples and nasopharyngeal washing were collected for microbiological analysis including culture and molecular methods.

Results: From July 2017 to June 2018, 189 children were enrolled, of which 53.4% were infants. Pneumonia-related admissions were less frequent over the winter. Chest radiographies were obtained in 149 children; endpoints included pneumonia in 39 cases (26.2%), other infiltrates in 31 (20.8%), and were normal in 79 children (53.0%). Non-contaminated bacterial growth was detected in 8/152 (5.3%) blood cultures, with only two cases of Streptococcus pneumoniae. Viral detection in upper respiratory secretions was common, with at least one virus detected in 103/115 (89.6%). The three most-commonly isolated viruses were respiratory syncytial virus (52/115; 45.2%), rhinovirus (42/115; 36.5%), and human parainfluenza virus (19/115; 16.5%). A third of patients with viral infections showed mixed infections. Case fatality rate was 3.2% (6/189).

Conclusion: Respiratory viral infections predominated among this cohort of WHO-defined clinical pneumonia cases, whereas bacterial aetiologies were uncommon, highlighting the epidemiologic transition that Bhutan seems to have reached.

Background

Pneumonia is the single largest cause of mortality in children aged under five years, causing an estimated 15.5% of all deaths in children under five years of age, and over 800,000 paediatric deaths annually (Liu et al., 2016; UN IGME, 2018). Most of these lives could be saved through more effective and equitable health system interventions, combining prevention, early and accurate diagnosis, and treatment (Walker et al., 2013; Rambaud-Althaus et al., 2015). The main pneumonia burden remains disproportionately concentrated in low- and middle-income countries (LMICs) in Southeast Asia and sub-Saharan Africa (Walker et al., 2013). Pneumonia deaths are decreasing, but more slowly than for other major causes of mortality, and too slowly to achieve the Sustainable Development Goal ambition of “ending preventable child deaths” by 2030 (United Nations, 2018).

Risk factors and causative pathogens of childhood pneumonia differ across the world. Obtaining reliable local data, including the burden of the disease, epidemiological trends, and the determinants of the main pathogens involved, is imperative to help develop targeted interventions. Therefore, adequate surveillance systems are required to monitor the effectiveness of national strategies implemented towards the reduction of the disease burden. However, the lack of local data and weak surveillance systems in many LMICs hamper an adequate knowledge of the epidemiology and etiology of childhood pneumonia in those settings where reliable data are most needed.

One country that exemplifies the dearth of data regarding childhood pneumonia is the Kingdom of Bhutan (Jullien et al., 2020), a small country locked in the Himalayas, with an estimated population of 779,666 in 2017 (Department of Information Technology, 2016; Ministry of Health, 2018). In this predominantly mountainous country, elevation rises from around 100 m in the southern foothills to over 7500 m in the northern Himalayan range, with the capital, Thimphu, standing at 2334 m (Central Intelligence Agency, 2019). The climate varies with the altitude, from tropical in the southern plains to alpine with very cold winters in the North. In Thimphu, the temperature ranges from –3 °C in winter to 22 °C in summer on average, coinciding with the monsoon that brings precipitations of around 350 mm in July (Climate-data org, 2019). Bhutan is classified as a lower-middle income country as of 2020 (The World Bank, 2020). Essential health services in both modern and traditional medicines are free for Bhutanese citizens, based on a primary healthcare approach (World Health Organization, 2017).

We conducted this prospective hospital-based observational study to describe the epidemiology, aetiology, and clinical and radiological presentation of World Health Organization (WHO)-defined pneumonia among children aged between 2 and 59 months admitted to the Jigme Dorji Wangchuck National Referral Hospital in Thimphu.

Methods

Study design and participants

This was a prospective hospital-based study conducted for 12 consecutive months at the Jigme Dorji Wangchuck National Referral Hospital (JDWNRH) in Thimphu. The hospital has 38 paediatric beds, including five in the paediatric intensive care unit (PICU).

All children aged 2–59 months hospitalized with WHO-defined pneumonia (irrespective of severity) were eligible for recruitment (World Health Organization, 2014) (see Box 1). Children admitted in the preceding seven days or with evidence of a foreign body in the respiratory tract were excluded. Potential participants were identified during day and night by the study co-investigators with the collaboration of paediatricians, paediatric residents, and nurses from the outpatient department, the emergency room, the PICU, and the paediatric ward. If an eligible participant was missed during the night, the child was assessed and recruited the following morning. All eligible children were recruited provided parent(s) or guardian(s) consented to study participation.

Data collection

On study admission, a study identification number was assigned and a comprehensive physical examination was performed, including anthropometric measurements, vital signs, axillary temperature, and peripheral oxygen saturation in room air. Demographic and clinical data were collected from the medical records and through family interviews. Sample collection upon enrolment, or as soon as possible after enrolment, included blood samples and nasopharyngeal washing (NPW). All the nurses in the PICU and paediatric ward were trained at the beginning of the study by the lead investigator on how to collect these samples. When a child was identified for recruitment but blood had already been collected, no further blood sampling was conducted. However, if another blood analysis was clinically indicated, additional blood was obtained for the specific purpose of the study. Fluid from pleural effusion was collected when clinically indicated. All recruited patients underwent a postero-anterior chest radiography upon admission. Additional information of potential diagnostic interest, such as computed tomography scans, ultrasound, or cerebrospinal fluid investigation available throughout admission, was also collected. Children were clinically managed and discharged as per existing hospital protocols and discretion of the treating paediatricians, and were followed-up by one study investigator in terms of outcome determination. All data were collected using digitalized and standardized forms (see Supplementary material for clinical definitions and details of variables measured).

Chest radiograph interpretation

The WHO protocol used in clinical trials of pneumococcal conjugate vaccines (PCV) was followed to interpret chest radiographs (Cherian et al., 2005). In brief, readers first judged the

---

Box 1. WHO definitions of pneumonia and severe pneumonia used as inclusion criteria (World Health Organization, 2014).

**Pneumonia:**
- History of cough or reported breathing difficulty, AND
- Increased respiratory rate (RR) or chest indrawing.

**Severe pneumonia:**
- History of cough or reported breathing difficulty AND at least one of the following:
  - Oxygen saturation <90% or central cyanosis,
  - Severe respiratory distress (e.g. grunting, very severe chest indrawing),
  - Signs of pneumonia with a general danger sign: inability to breastfeed or drink, lethargy or reduced level of consciousness, convulsions.

**Increased RR** is defined according to age as follows:
- RR ≥ 50 breaths per minute in children aged two months or more and less than 12 months.
- RR ≥ 40 breaths per minute in children aged 12 months or more and less than 60 months.
quality of the film (uninterpretable or interpretable, the latter stratified as suboptimal or adequate) and then classified findings for all interpretable radiographs. Significant pathology was defined as the presence of consolidation, other infiltrates, and/or pleural effusion. Endpoint radiologically confirmed pneumonia was defined as consolidation, pleural effusion, or both on any hemithorax. Initially, two paediatricians independently interpreted the radiographs. Discordant results were read by a third reader, trained in WHO criteria for interpretation of chest radiographs. An additional external quality control measure was included in the study protocol, whereby a paediatric radiologist would read a random sample of 10% of the chest radiographs. However, as substantial discordance was observed between the two primary readers, all chest radiographs were again independently interpreted by the paediatric radiologist using the WHO criteria. This last reading was accepted as final interpretation for analysis.

Biological sample testing and laboratory methods

Blood was collected under aseptic conditions following the hospital’s validated standardized procedures. Blood for haematology, biochemistry, and culture was processed following standard procedures. Blood was cultured using an automated blood culture system (Bact/ALERT®). Bacterial isolates were identified by colony morphology, growth requirements, and basic biochemical tests. Antibiotic susceptibility was determined using disk diffusion in accordance with the guidelines of the Clinical Laboratory Standard Institute (CLSI, 2015).

Additionally, real-time polymerase chain reaction (RT-PCR) for LytA gene of Streptococcus pneumoniae in dried-spot collected blood, and host-response biomarkers in additional blood (2 mL, EDTA tube) were investigated (findings reported elsewhere) (Brotons et al., 2017). The blood samples were centrifuged at 3000 × g for three minutes, and the serum was separated and stored at −80 °C.

NPW samples were homogenized and aliquots frozen at −80 °C and subsequently shipped to Barcelona, Spain, where they were subjected to molecular screening (multiplex RT-PCR QIAStat respiratory panel, Qiagen, for 17 viral targets and four bacterial targets). NPW were also subjected to detection of pneumococcus and capsular and by PCR for other targets (findings reported elsewhere).

Rapid influenza diagnostic tests (Alere BinaxNOW®) were performed as per discretion of the treating clinicians and nurses, independently of the current study. Investigations for active tuberculosis included Mantoux test and gastric aspirates for microscopy and GeneXpert®.

Data management and statistical analysis

The lead investigator entered data into a computerized password-protected database (ODK®) with study identification number. Errors in data entry were limited by pre-defined ranges for every value. Stata 15.1 was used for data analyses (StataCorp, 2017). Mean with standard deviation (SD) and median with interquartile range (IQR) were used to summarize normally and non-normally distributed variables respectively.

Results

Study profile and demographic characteristics

Between 1st July 2017 and 30th June 2018, 1591 children were admitted to the paediatric department of JDWNRH. Among them, 286 (18.0%) were children aged 2–59 months with respiratory symptoms, of which 189 (66.1%) were recruited (Figure 1).

The baseline characteristics of the 189 children are presented in Table 1. Median age was 10.8 months; over half of the children were infants. Most children were adequately immunized according to age. There was no known case of HIV infection. Children were mainly from the district of Thimphu, although the study included patients from 16 out of the 20 districts in Bhutan. On average, families reported that it had taken around 15 min to reach the closest healthcare facility. Twenty-seven children (14.3%) were referred from another health centre. Summer, fall, and spring each comprised around 30% of the recruited cases, while winter had the lowest number of pneumonia admissions (10.1%). October was the month with the highest number of cases (37; 19.6%) (Figure 2).

![Figure 1. Study profile.](image-url)
Clinical characteristics

Clinical characteristics upon admission are presented in Tables 2 and 3. Wasting (WAZ ≤ −2 SD) was detected in 17 children (9.0%). On admission, 77 children (41.2%) presented with fever, half of the children were breathing fast according to age, and three-quarters were hypoxic. Median basal oxygen saturation was 85% (IQR 80–90) among the 173 children with available measurement in room air without oxygen therapy. On auscultation, typical lung consolidation-related sign (crackles) was most common (57.5%), followed by rhonchi (45.2%) and wheezing (25.0%).

On admission, 35.8% of the children were anaemic, 36.9% had leucocytosis, and 25.3% had neutrophilia. Two common inflammatory markers were tested at JDWNRH: C-reactive protein (CRP) with a mean of 2.06 mg/dL (SD 2.09), and erythrocyte sedimentation rate (ESR) with a mean of 24.89 mm (SD 28.02). Twenty-five

* One patient was diagnosed with asthma.
children (13.2%) had CRP levels above the threshold (>4 mg/dL) commonly considered suggestive of high risk of bacterial infection, whereas 25 children had high ESR (≥50 mm) (Sanders et al., 2008; Bruel et al., 2011). Only four children presented with both high CRP and ESR.

Chest radiography was performed in 178/189 children (94.2%). Images were available for interpretation by the study investigators in 150 of them (84.3%). In 28 cases, children were discharged before investigators could interpret the radiography findings and the radiograph was missing. One film was judged uninterpretable. Among the final 149 readable chest radiographs, 79 (53.0%) were normal, 39 (26.2%) were classified as primary endpoint pneumonia, and 31 (20.8%) as other infiltrates.

Microbiological findings

While HIV infection was not suspected in any child by the treating physicians, active tuberculosis was suspected in 10 children (5.3%) but was not confirmed by the laboratory tests in any of them.

Blood culture was performed in 148/189 children (78.3%), of which 45 (30.4%) had received antibiotics prior to sample collection (Table 4). Thoracentesis was performed in one child with pleural effusion. Six different pathogens were isolated among the eight non-contaminated positive blood cultures: S. pneumoniae (two cases), Pseudomonas sp. (two cases), Escherichia coli, Acinetobacter sp., Salmonella typhi, and Serratia rubidaea (one case each). Drug sensitivity results are shown in Supplementary Table 2. S. pneumoniae was isolated in the only sample of pleural fluid that was collected, which corresponds to the same child with positive blood culture, subsequently also confirmed by RT-PCR in blood.

NPW was collected in 129/189 children (68.3%). The NPW sample was too scarce or of bad quality to run the test in 14 children (10.9%). Among the remaining 115 children, 52 (45.2%) had received antibiotics prior to sample collection. Bordetella pertussis was detected in three (2.6%) children, and Mycoplasma pneumoniae in one (0.9%) child; Chlamydia pneumoniae and Legionella pneumophila were not detected among respiratory samples.

At least one virus was identified in 103/115 NPW samples (89.6%) (Table 4). Viral co-infection was detected in 35/103 children (34.0%): 22 presented double infection, 10 presented triple infection, and three children were infected with four viruses. The most commonly isolated virus was respiratory syncytial virus (RSV) (52; 45.2%), followed by rhinovirus (42; 36.5%), human parainfluenza virus (19; 16.5%), and influenza virus (16; 13.9%). Coronavirus were detected in two children (1.7%). Routine rapid flu test was performed under the Influenza national surveillance programme in 32/189 children (16.9%), being positive for influenza A in seven cases, for influenza B in one case, and for co-infection of influenza A and B in one case. Analysis by RT-PCR confirmed the detection of influenza virus in 4/9 children with positive rapid flu test, and detected 10 additional cases with influenza virus.

Among children with at least one virus detected, 4/86 (4.6%) had a positive blood culture for bacteria and 24/89 (27.0%) had radiological endpoint pneumonia. Among children with no virus detected, 3/9 (23.3%) had a positive blood culture and 4/11 (36.4%) had radiological endpoint pneumonia (Supplementary Table 3). No children with influenza had a positive blood culture. However, 6/15 (40.0%) children with influenza identified in their nasopharynx had radiological endpoint pneumonia.

Lumbar puncture was not indicated in any of the children.

Evolution during admission

Children were hospitalized for a median of four days (IQR 2–6) (Table 5). Thirty children required PICU admission, with a median stay of 72 h (IQR 24–96). Three-quarters of the children were put on oxygen therapy, of which half for at least three days. Most children (72.0%) received antibiotics during admission. Antibiotics were stopped in the first two days of admission in 10 children (7.4%) and advised to be continued after discharge in 90 (66.2%). Main diagnoses given by the treating physician at discharge are shown in Supplementary Table 4. Half of the children were discharged with a diagnosis of pneumonia or bronchopneumonia. In terms of the seasonal variability of the most common clinical syndromes given by the treating physician at discharge, bronchopneumonia was mainly in fall (50.0%), bronchiolitis in spring (43.6%), and pneumonia did not show a clear seasonal pattern (Supplementary Figure 1).

Six children had a fatal outcome (case fatality rate 3.2%); all had been referred from other centres in critical condition.
NPW was not collected in three children due to the severity of their illness upon arrival. Of the other three children, one child presented a triple co-infection by *B. pertussis*, parainfluenza virus, and influenza virus. Four fatal cases were diagnosed as suffering of pneumonia, and two of bronchiolitis. Two deaths occurred within the first 24 h of admission to our centre. A summary of the main characteristics of these six children is presented in Supplementary Table 5.
### Table 3
Laboratory findings on admission, blood sample

|                     | n/N  | %   |
|---------------------|------|-----|
| **Haematology**     |      |     |

| **Coronavirus (Co229E, CoRHIU1, CoNL63, CoOC43)** | 2/115 | 1.7 |

*Abbreviations: NPW: nasopharyngeal washing; PCR: polymerase chain reaction; RSV: respiratory syncytial virus; RT-PCR: real-time polymerase chain reaction.*

<sup>b</sup> Coagulase-negative staphylococci, and *Bacillus* spp were considered contaminants, as per our protocol.

<sup>c</sup> Bacterial growth was detected in 22 blood cultures, but it was attributed to contamination in 14 cases.

<sup>d</sup> Seven children had positive rapid flu test for influenza A, one child for influenza B, and one child for influenza A and B. Of the seven children with rapid flu test positive for influenza A, detection of influenza A by RT-PCR in NPW was also positive in four cases, but negative in one case, and “failed/inhibited” in the remaining two cases. For the child with rapid flu test positive for influenza B and for the child with rapid flu test positive for both influenza A and B, RT-PCR in NPW was negative for both influenza A and B in both children.

<sup>e</sup> Parainfluenza viruses 1, 2, 3, and 4 were detected in 2 (1.7%), 1 (0.9%), 14 (12.2%), and 3 (2.6%) children respectively.

### Discussion
This is the first published series of comprehensive epidemiological, clinical, and microbiological data describing Bhutanese children under five years of age hospitalized with WHO-defined clinical pneumonia. Mortality related to pneumonia was 3.2%, similar to other studies from LMICs (Jroundi et al., 2014; Lazzerini et al., 2016; Bénet et al., 2017; Chen et al., 2018; O’Brien et al., 2019). Nevertheless, this remains high for Bhutan in spite of the country offering free and easily accessible healthcare services. The six children who died were referred from other health centres and reached the study hospital in critical condition. The high proportion of infants in our study highlights that infants are particularly vulnerable and prone to hospitalization due to severe pneumonia (Fancourt et al., 2017; Chen et al., 2018; Jakhar et al., 2018). There was no child known or suspected to be infected with HIV, which is consistent with the very low number of under-five year old children infected with HIV in Bhutan (UNAIDS, 2018).
Winter, which is the coldest season in Bhutan, surprisingly showed the lowest number of cases (10.1%); this finding differs from what is commonly seen in other settings, whereby hospitalization of childhood pneumonia tends to peak during the coldest season (Murdoch et al., 2014; Ben-shimol et al., 2015). However, this finding is consistent with those reported by the national sentinel surveillance programme for severe acute respiratory infections, and with the proportion of all-cause paediatric admissions, lower during winter (Royal Centre for Disease Control, 2018). This could be partially explained by the fact that winter coincides with the school break in Bhutan, with less contact among children; and families moving from the capital to the villages with lower population density.

Hypoxemia is a well-established predictor of severity in children with pneumonia (Duke et al., 2001; Lozano, 2001). A high proportion of children in this study (74.9%) presented with hypoxemia, which is much higher than reported in other settings (Subhi et al., 2009; O’Brien et al., 2019). We defined hypoxemia as SpO2 < 90%, which is considered appropriate for altitudes under 2500 m, as is the case with Thimphu (2334 m). This characteristic might therefore not be generalizable to Bhutanese children who live at different altitudes than that of Thimphu.

While bacterial aetiology was infrequent, viruses were identified in a considerable proportion of children. These microbiological findings coincide more with the etiological profile of pneumonia in children from high-income countries, highlighting the advanced stage of the epidemiologic transition that Bhutan seems to have reached (Omran, 2005; Prayle et al., 2011). The findings from the PERCH study, conducted in seven LMICs with routine use of PCV, are similar (O’Brien et al., 2019). Even in the absence of a deployed PCV in Bhutan (PCV was introduced only in January 2019), the burden of pneumococcal invasive disease appears to be low in children.

The low proportion of confirmed bacterial cases could be explained by several reasons. First, vaccination coverage was high, which is representative of the rest of the country, although the PCV was not in routine use during the recruitment period (WHO, 2016). Second, almost one-third of the children had received antibiotics prior to collection of blood sample, which reduces the yield of blood culture by around 45% (Berkley et al., 2005; Rhodes et al., 2010; Driscoll et al., 2017; O’Brien et al., 2019). Small blood volume is another factor known to compromise the sensitivity of blood culture (Berkley et al., 2005; Bouza et al., 2007; Driscoll et al., 2017). Blood collection is challenging in children, especially in infants. Blood volumes collected for each child were not recorded in this study but, in practice, around 1 mL was dedicated for blood culture in most cases, despite the 2–3 mL recommended in the protocol. Nevertheless, these findings confirm the low yield of blood culture in hospitalized children with pneumonia and question both the need of blood culture for uncomplicated cases of pneumonia and using blood culture as the preferred screening tool for invasive bacterial disease in children with pneumonia. Molecular methods have been found to be more sensitive than blood culture to detect pneumococcal invasive disease (Muñoz-almagro et al., 2011; Selva et al., 2013; O’Brien et al., 2019). This was not the case in this study.

*B. pertussis* was isolated in respiratory samples of three children. This is similar to the detection rate of around 1% of hospitalized pneumonia cases in similar studies (Jroundi et al., 2014; Barger-kamate et al., 2016). One of these three children, aged five months, had a fatal outcome. This underlines the high fatality ratio of pertussis-infected pneumonia, especially in infants who are unvaccinated, and suggests the need of intervention such as maternal vaccination to reduce morbi-mortality associated with pertussis in vulnerable populations.

Viral detection was common. The use of PCR techniques has increased the ability to detect respiratory viruses (Ruuskanen et al., 2011). However, evidence of the detection of viruses in asymptomatic individuals has raised concern about the clinical significance of these positive findings. Attribution of causality is not straightforward, as viruses can commonly be found both in symptomatic but also asymptomatic individuals (Jartti et al., 2008; Ruuskanen et al., 2011; Rudan et al., 2013; O’Brien et al., 2019). While the causative role of RSV, influenza, adenovirus, human metapneumovirus, and bocavirus in childhood pneumonia is well-established, the pathogenic role of other viruses such as rhinovirus is still questioned (Fry et al., 2007; Caracciolo et al., 2008; Ruuskanen et al., 2011; Shi et al., 2017; Jayaweera et al., 2018; O’Brien et al., 2019). Using molecular methods, rhinovirus has been shown to be the most frequent respiratory pathogen isolated in children, and its detection in asymptomatic children is significantly higher than other respiratory viruses (Kusel et al., 2006; Jartti et al., 2008; Ruuskanen et al., 2011). Nevertheless, clinical relevance of rhinovirus has been proven by the association of this virus with respiratory symptoms in children, mainly wheezing (Kusel et al., 2006; Khetsuriani et al., 2007). In our series, 27.5% of the children with rhinovirus presented with wheezing. Infection with coronavirus (Cor229E, CorHKU1, CorNL63, CorOC43) was low in the present study. Similarly, the new coronavirus (SARS-CoV-2) seems to cause a low infection rate in children (World Health Organization, 2020). The reason why coronavirus infection rate in children is low is unknown.

In addition, the interpretation of positive viral findings is challenging due to the identification of multiple co-existing viral infections (Jartti et al., 2008; Ruuskanen et al., 2011). Co-infections were common in the present study, which is consistent with the existing literature (Ruuskanen et al., 2011; Jroundi et al., 2014; Jiang et al., 2017). Considering radiological pneumonia endpoint as a proxy for bacterial pneumonia, 27.0% of children with positive NPW findings had a viral-bacterial co-infection, and 40.0% of children with influenza detected in NPW had an influenza-bacterial co-infection. The contribution of viral-bacterial co-infections is well-acknowledged in the aetiology of childhood pneumonia, particularly the interaction between influenza virus and *S. pneumoniae* (O’Brien et al., 2000; Kwoﬁe et al., 2012; Brealey et al., 2015). The combined effect of bacteria and viruses was shown to increase the severity of the disease, and bidirectional interactions have been described: respiratory viruses leading to bacterial superinfection, and bacteria pathogens promoting respiratory viral superinfections (Brealey et al., 2015). However, there is still a lack of robustness supporting these findings.

| Table 5 | Evolution during admission |
|-------------------|--------------------------|
|                  | n/N | % |
| **Evolution and outcome** | |
| Hospital stay | | |
| <24 h | 9/189 | 4.8 |
| ≥24 to <72 h | 67/189 | 35.4 |
| ≥72 h to ≤7 days | 82/189 | 43.4 |
| Admission to paediatric intensive care unit | 30/189 | 15.9 |
| Admission to high dependency unit | 41/189 | 21.7 |

| Antibiotics during admission | 136/189 | 72.0 |
| Outcome | | |
| Alive at discharge | 183/189 | 96.8 |
| Death | 6/189 | 3.2 |
| Transferred | 1/189 | 0.5 |
| Absconded | 0/189 | 0 |
| Withdrawn from the study | 0/189 | 0 |

*Twelve children required continuous positive airway pressure (CPAP).* One child was put on bilevel positive airway pressure (BiPAP) and was changed to CPAP after improvement. One child only required high flow nasal cannula oxygen.

---

---
This study has several limitations. Most children in the present study lived in Thimphu, and the microbiological findings may not be generalized to the rest of the country. Bhutan is very diverse: comprised of cities, such as Thimphu, and isolated households in very remote areas, leading to different lifestyles and environmental exposures; and also diverse in terms of altitude, with different climates and precipitations.

Conclusions

The burden of pneumonia requiring hospitalization was highest among infants. Respiratory viruses were detected in a considerable number of children, although a clear pathogenic role cannot be established. Together with the relatively low proportion of children presenting a likely bacterial pneumonia – around a quarter as per positive blood culture and radiological findings – these findings emphasize the advanced stage of the epidemiologic transition that Bhutan seems to have reached. This study is the first step to better understand the aetiology and clinicopathological characteristics of pneumonia in Bhutanese children. Henceforth, the development of targeted pneumonia interventions and hypothesis-driven research is encouraged to reduce the morbidity and mortality associated with this disease. Fostering a robust pneumonia aetiology surveillance in children under five years of age appears important and would allow the assessment of the impact of the recently introduced PCV in reducing the burden of pneumonia.

Funding

SJ received a pre-doctoral fellowship from the Secretariat of Universities and Research, Ministry of Enterprise and Knowledge of the Government of Catalonia and co-funded by European Social Fund. This work was supported by a scholarship from the Spanish Society of Paediatric Infectology (Sociedad Española de Infectología Pediátrica, SEIP). None of the funding sources were involved in the study design, data collection, analysis, interpretation of the data, and writing of the manuscript.

Ethical approval

The study protocol was approved by the Research Ethics Board of Health, Ministry of Health, in Thimphu in March 2017 (protocol number PO/2016/086), and by the research ethics committee from the Hospital Clinic in Barcelona (HCB/2017/0741).

Conflict of interest

No conflict of interest to declare.

Acknowledgments

We thank all the children and their parents or caregivers who participated in this study, as well as the paediatric department of JDWNRH including paediatricians, residents in paediatrics, and interns who contributed to identifying eligible cases for the study. We are very grateful to all nurses who participated in the collection of biological samples and contributed to the success of this study, especially those in the paediatric ward. We thank Dr. Kinley Tshering, paediatrician, who read and interpreted all the chest radiographs; the radiological and microbiological departments of JDWNRH for their support; and Laia Blanco Lopez for contributing to the microbiological analysis of viruses in NPW. We are very grateful to Gaurav Kwatra and Laura Puyol for their assistance in the shipment of the biological samples.

We are grateful to the Spanish Society of Paediatric Infectology (Sociedad Española de Infectología Pediátrica, SEIP) for their financial support, which contributed to the shipment and testing of biological samples. We acknowledge support from the Spanish Ministry of Science and Innovation through the “Centro de Excelencia Severo Ochoa 2019–2023” Program (CEX2018-000806-S), and support from the Generalitat de Catalunya through the CERCA Program. CISM is supported by the Government of Mozambique and the Spanish Agency for International Development (AECID).
