Primary pituitary lymphoma (PPL) represents an extremely rare entity. Here, we have reported two recently identified cases of immunocompetent PPL having diffuse large B-cell lymphoma by surgical biopsy. Both patients had hypopituitarism, with one patient developing right ptosis. In both patients, MRI and FDG-PET/CT depicted sellar mass that extended into the cavernous sinus with the right sphenoid also present in one of the patients. No systemic disease was found in these two patients. Surprisingly, we found that both patients had infiltrative lesions in sphenoid sinus mucosa pathologically, but the sphenoid bones that composed the sellar base were visually intact during the biopsy procedure. Chemotherapy was administered to both patients, where one patient achieved remission at the recent follow-up, whereas the other one did not respond to the treatment. The diagnosis of PPL is usually difficult if solely dependent on history, clinical presentation, biochemical indexes, and radiographic findings. We have also updated and reviewed the epidemiologic features, clinical presentations, pathological characteristics, potential mechanisms, therapeutic orientation, and prognostic advances of PPL. A total of 40 cases (including ours and four pediatric patients), histologically diagnosed, were analyzed in terms of clinical presentation, endocrine abnormality, radiological features, pathology, treatment, and follow-up. Hypopituitarism and headache were the most common presentation of PPL, while diabetes insipidus was reported in 13 patients (43.3%). B cell lymphoma was the most common type of pathology, followed by T-cell and NK/T cell. PPL was more invasive in nature at the suprasellar region (72.5%), cavernous sinus (52.5%), and sphenoidal sinus (27.5%) in 29, 21, and 11 patients, respectively. Pediatric patients with PPL seem to be different compared to their adult counterparts in terms of pathogenesis, clinical presentation, and radiological features. The management of PPL usually follows the treatment protocols.
Primary pituitary lymphoma (PPL) is an extremely rare clinical entity with only 40 immunocompetent cases identified and reported to date. It is commonly considered to be a diffuse lymphoma that is limited to the sellar or parasellar regions without any evidence of systemic involvement. The disease shows a slight but not significant female prevalence with an onset at around the age of 60 years (1–3). Regarding the histology, a large majority are of B cell origin compared to T cell or NK/T cell origin, as in the case for primary CNS lymphoma (3, 4). The clinical presentations are always atypical, including headache, hypopituitarism, diplopia, hemianopia, and fever (5). The PPL prognosis is usually poor, which emphasizes the importance of earlier detection and management to improve the outcomes (6). Here, we have reported two recently diagnosed cases of PPL with a comprehensive review of our current understanding of PPL. We also concluded that PPL tends to spread to the sphenoidal area through vascular and bony approaches, which might be a distinct entity from primary CNS lymphoma.

INTRODUCTION

Primary pituitary lymphoma (PPL) is an extremely rare clinical entity with only 40 immunocompetent cases identified and reported to date. It is commonly considered to be a diffuse lymphoma that is limited to the sellar or parasellar regions without any evidence of systemic involvement. The disease shows a slight but not significant female prevalence with an onset at around the age of 60 years (1–3). Regarding the histology, a large majority are of B cell origin compared to T cell or NK/T cell origin, as in the case for primary CNS lymphoma (3, 4). The clinical presentations are always atypical, including headache, hypopituitarism, diplopia, hemianopia, and fever (5). The PPL prognosis is usually poor, which emphasizes the importance of earlier detection and management to improve the outcomes (6). Here, we have reported two recently diagnosed cases of PPL with a comprehensive review of our current understanding of PPL. We also concluded that PPL tends to spread to the sphenoidal area through vascular and bony approaches, which might be a distinct entity from primary CNS lymphoma.

METHODS

We conducted a literature review using the PubMed database. Keywords of “pituitary lymphoma”, “pituitary tumor”, and “lymphoma” were used to select adequate papers till May 2020 where the diagnosis of PPL was confirmed histologically. PPL caused by systemic lymphoma or the ones that occurred in immunosuppressed patients were excluded. Only studies in English were considered. Also, we have reviewed references of relevant studies. Some detailed information that was not provided by the original papers was again referred through the latest update (2), acquired through the e-mail contact with the corresponding authors of each article. A total of 36 adult cases (Table 1) with four pediatric cases (Table 2) were reviewed in terms of clinical presentation, endocrine abnormality, radiological features, pathology, treatment, and follow-up (Figure 1). Firstly, we present our two cases.

Case Presentation

Case 1

A 61-year-old male was presented to our clinic reporting episodes of headache and hypophyseal mass for nine months and right eyelid ptosis for four months. In January 2019, he started with an intermittent headache, blurred vision, weakness, and anorexia. He was then admitted to a local hospital for further examination. His serum sodium level was 127 mmol/L with normal blood pressure. The biochemical indexes indicated that he suffered from hypopituitarism. The symptoms of diabetes insipidus were not observed. Pituitary MRI showed a suspicious low signal in the right-wing of the pituitary. Further, he had a history of partial thyroidectomy ten years ago due to a thyroid nodule, with unknown postoperative pathological results. Based on the above evidence, an initial diagnosis of autoimmune hypophysitis was made. The patient then started the replacement therapy using 30 mg hydrocortisone per day and Euthyrox at 50 µg qd, which alleviated headache and improved the right eye acuity.

Five months later, the patient developed sudden right eyelid ptosis. A new MRI disclosed that the pituitary mass had invaded the right cavernous sinus. Glucocorticoid impact therapy with an initial dose of 500 mg qd was initiated, which improved his right eyelid ptosis on the second day of therapy. Nevertheless, a relapse of ptosis occurred three months later and another MRI revealed a 1.3 × 0.9 cm sellar mass with extension to the right cavernous sinus and internal carotid artery. Immunology tests, including ANA, ANCA, serum IgG4, and ACL were reported negative. Lumbar puncture and thoracoabdominal CT scan did not show any remarkable findings. The diagnosis of autoimmune hypophysitis could not be excluded and the cortisol treatment was continued (prednisone 50 mg qd) in addition to 75 mg azathioprine per day.

In October 2019, he was referred to our clinic with several tests, including an electrolyte, serum and urine osmolality, sex hormone (FSH, LH, E, P, T, PRL), IGF-1, thyroid (TSH, FT3, FT4), immunology (IgG4, ANCA, sACE, ESR) and tumor markers tests (CEA, AFP, ßhCG), which were all within the normal range. The MRI indicated a possible sellar macroadenoma (12.7 × 6.7 × 11.1 mm) with Knosp IV; the progression of the sellar lesion is shown in Figure 2. Physical examination revealed truncal obesity and diabetes mellitus due to glucocorticoid treatment. His right eye showed ptosis with loss of pupil’s direct/indirect light reflex and ocular motility. FDG-PET/CT revealed a hypermetabolic lesion in the right sellar with infiltration to the right sphenoid sinus, suggesting invasive pituitary adenoma. The systemic disease was, therefore, excluded.

The patient underwent a sellar biopsy using an endonasal transsphenoidal approach and the mass on the right side of the sellar displayed a grayish-white hard tissue that looked similar to fish-meat with insufficient blood supply on tissue modality. Pathological analysis established the diagnosis of diffuse large B-cell lymphoma. Cell immunohistochemistry was positive for p53, Bcl-2, Bcl-6, C-MYC, CD20, and CD5, whereas the index for pituitary hormones and epithelial cells tested negative. Cell proliferation index Ki-67 was found to be 70%. Fluorescent in situ hybridization (FISH) of EBER ISH was negative, and no

| Carrasco et al., 2010 | (25) | F 49 | Weakness, headache, asthenia, weight loss, increase in thirst, polyuria, cold intolerance, abdominal pain, nausea, and dizziness, later diplopia | Panhypopituitarism, hyperprolactinemia | Sellar and suprasellar enhancing mass with thickening of the pituitary stalk and chiasmal compression, later infiltration of the left cavernous sinus | Lymphoplasmacytic B cell lymphoma (low grade) | Tumoral resection but only a biopsy of the pituitary mass, CHT (iv and intrathecal MTX, dexamethasone, cytarabine), fractionated conformational RT of 30 Gy | Remission at four years after surgery |
| Li et al., 2010 | (5) | F 41 | Polydipsia and polyuria, galactorrhea amonorrhea syndrome, headache, blurry vision, bitemporal hemianopsia | Partial anterior hypopituitarism, hyperprolactinemia | Intraser and suprasellar mass with thickening of the pituitary stalk, obstructive hydrocephalus | High-grade, large B cell lymphoma | Surgery, RT (25 fractions of 200 cGy for a total dose of 5000 cGy), and CHT with intrathecal MTX | No recurrence for seven months after surgery |
| Bayraktar et al., 2010 | (26) | F 47 | Headache, blurry vision, bitemporal hemianopsia | Sellar mass with partial encasement of the right internal carotid artery within the cavernous sinus | Diffuse large B cell lymphoma | Surgery, DeAngelis CHT protocol (methotrexate, vincristine, Procarbazine, cytarabine), R-CHOP, R-ICE, prophylactic intrathecal MTX, autologous stem cell transplantation | Multiple relapses during CHT, clinical remission eight months after stem cell transplantation. |
| Hayasaka et al., 2010 | (27) | M 71 | Appetite loss and sudden visual loss | Hyperprolactinemia | Intrasurellar and suprasellar mass that was moderately and homogeneously enhanced, focal moderate FDG uptake only in the pituitary gland, well-circumscribed mass extending into the suprasellar cistern and compressing the optic chiasm with penetration into the right cavernous sinus | Non-Hodgkin lymphoma (CD20+, CD5-, CD10-, Bcl6+, Bcl1) | Surgery, a 5040 cGy course of intensity-modulated RT | Remission at one year |
| Martinez et al., 2011 | (28) | F 71 | Facial palsy, bilateral temporal hemianopsia, syncopal spells, acromegaly | Increased level of IGF-1 and GH | Large B-cell lymphoma, adenoma, and lymphocytic hypophysitis | Non-Hodgkin lymphoma (CD20+, CD5-, CD10-, Bcl6+, Bcl1) | Surgery | Remission at one year |
| Papanastasiou et al., 2012 | (29) | F 60 | Muscle weakness, headache, and eyelid ptosis | Partial anterior hypopituitarism | Pituitary sellar mass extending into the suprasellar region, compressing the optic chiasm and invading the left cavernous sinus | Diffuse large B-cell non-Hodgkin’s lymphoma | Surgery, systemic CHT with intraspinal MTX infusion, and the R-MPV regimen | Died of a hospital-acquired infection at two months |
| Rainsbury et al., 2012 | (30) | F 67 | Headache, left visual field defect | None | Pituitary tumor extending inferiorly to occupy the sphenoid sinus | Diffuse, large, high-grade B-cell pituitary lymphoma | Surgery, 4 cycles of CHT and stereotactic RT | No recurrence at 15-month follow up |
| Wiens et al., 2012 | (31) | F 58 | Headache, right-sided ptosis, fatigue, vision loss, increased thirst and urine output, altered mental status, weight loss, slurred speech | Partial anterior hypopituitarism | Large, heterogeneously enhancing intrasellar lesion and a much larger suprasellar component extending to the right cavernous sinus | T-cell lymphoblastic lymphoma with corticotrophic cell hyperplasia | Surgery, intrathecal CHT, RT (craniospinal radiation was administered (18 fractions of 200 cGy for a total dose of 3600 cGy), boosted with an additional 1080 cGy to the pituitary fossa and 5040 cGy to the lower spine) | Leptomeningeal carcinomatosis one week after surgery |
| Wilke et al., 2012 | (32) | F 59 | Headache, diplopia | Partial anterior hypopituitarism, hyperprolactinemia | Enhancing sellar mass extending to the suprasellar cistern and along the pituitary stalk and cavernous sinuses | High-grade B-cell non-Hodgkin’s lymphoma | None | Died before the therapy initiated |
| Tarabay et al., 2016 | (2) | M 73 | Headache, diplopia, retro-orbital pain | Hypopituitarism, hyperprolactinemia | Sellar mass extending to the suprasellar cistern, cavernous sinus, and orbital apex in contact with optic chiasm and optic nerve | Diffuse large B-cell lymphoma | Surgery, CHT (R-CHOP, high dose MTX) | Clinical remission and radiological improvement at 15 months |

| Silfen et al., 2001 | (37) | M 15 | Polydipsia, polyuria, and weight loss | Panhypopituitarism | Enhancing lesion in the region of the pituitary stalk | High-grade malignant B-cell lymphoma | CHT (high-dose MTX and cytarabine, prednisone, vincristine, cyclophosphamide, doxorubicin, and hydrocortisone) | Remission for 17 months |
| Baleydier et al., 2001 | (38) | M 9 | Diplopia, signs of meningeal irritation, weight loss, limb muscle weakness | DI | Enhancing infundibular stalk thickening and a nodular hypothalamic mass | Large B-cell lymphoma (identified by CSF cells) | CHT (protocol LMB 96 of the SFOP) | Complete remission for a year after diagnosis |
| Capra et al., 2004 | (39) | F 14 | Short stature | GH deficiency | Enhancing and thickened pituitary stalk with the absence of the normal bright signal in the posterior pituitary | B-cell large cell lymphoma | Intravenous and intrathecal chemotherapy alone as per the FAB-LMB 96 (group C) protocol | Complete clinical remission ten months from diagnosis |
| Huang et al., 2013 | (40) | F 7 | DI, later panhypopituitarism | Panhypopituitarism | Diffuse thickening of the pituitary stalk with extension to the hypothalamic region, a small, nodular, heterogeneous enhancement of the pineal gland | Diffuse large B-cell lymphoma | CHT | The disappearance of tumor after 16 months of biopsy with persistent panhypopituitarism |

CHOP: cyclophosphamide–doxorubicin–vincristine–prednisolone; CHT, chemotherapy; DI, diabetes insipidus; F, female; G-CSF, granulocyte-colony stimulating factor; M, male; MTX, methotrexate; NM, not mentioned; R-CHOP, rituximab–cyclophosphamide–vincristine–adriamycin–prednisone; R-MPV, rituximab–methotrexate–vincristine–procarbazine; RICE, rituximab–ifosfamide–carboplatin–etoposide; RT, radiotherapy.

FIGURE 1 | Flowchart of study selection using the PRISMA guidelines.
abnormality was found in CSF and bone marrow. The diagnosis of primary pituitary lymphoma was eventually established, and the patient received chemotherapy (rituximab 800 mg iv d1, MTX 7 g iv 4 h d2, lenalidomide 25 mg po d1–14) with 5 mg intrathecal dexamethasone and 50 mg cytarabine. After two courses of chemotherapy (R²-MTX), the patient achieved remission from prolonged headache and ptosis. MRI confirmed a significant reduction in the size of the sellar mass (Figure 3).

Case 2
A 65-year-old woman was presented to our clinic with complaints of headache, nausea, and vomiting. Two months earlier, she had developed symptoms of intermittent headache and nausea with no obvious precipitating factors. Then she gradually had thirst, polydipsia, polyuria, anorexia, and weakness. The biochemical indexes measurement showed values indicative for anterior hypopituitarism, with FT₄ of 8 pmol/L, TSH of 0.11 µIU/ml (normal range is 0.380–4.340 µIU/ml), LH< 0.01 mIU/ml (normal range is 1.24–8.62 mIU/ml), FSH of 1.16 mIU/ml (normal range is 1.27–19.26 mIU/ml), ACTH (8 AM) of 1.91 pmol/L (normal range is 2.2–17.6 pmol/L), serum cortisol (8 AM) of 0.536 µg/dl (normal range is 4.0–22.3 µg/dl), and IGF-1 of 150 ng/ml (normal range is 94–252 ng/ml). She had hypernatremia (serum sodium of 150 mmol/L), increased plasma osmolality (304 Osm/kgH₂O), and hyposthenuria (98 Osm/kgH₂O). The examination of the visual field and visual acuity were found normal, although the MRI revealed a 1.5 × 1.3 × 2.2 cm soft tissue mass in the sellar region, which had no defects in the optic chiasm. The PET/CT identified a pituitary mass with a high intake of FDG in the sellar region and had no other remarkable findings. Replacement therapy with desmopressin, prednisone acetate, and Euthyrox was then administered, which provided the remission from thirst, but headache continued with intermittent nausea and vomiting. In December 2019, the patient underwent a sellar biopsy using an endoscopic transphenoidal approach. Pathological analysis revealed diffuse large B-cell lymphoma. Immunohistology studies showed CD3, CD5, CD20, Bcl-2, Bcl-6, C-MYC, PAX-5, Mum-1, and p53 to be positive. Cell proliferation index Ki-67 was 90%. Fluorescent in situ hybridization (FISH) for EBER ISH was negative. Therefore, the patient was diagnosed with primary pituitary diffuse large B-cell lymphoma. The patient then received chemotherapy in her local hospital. However, in February 2020, a recent MRI revealed an obvious enlargement of the sellar mass compared to the former one, which may
indicate the patient’s insensitivity to chemotherapy. Our latest follow-up revealed that the patient died in July 2020, which is eight months after the diagnosis.

RESULTS

Age and Sex
Out of the 36 adult cases reviewed here, 19 patients (52.8%) were female and 17 patients (47.2%) were male (F: M was 1.12:1) and the mean age was found to be 58 years (mean age for males was 56 years and 61 years for females). Out of the four pediatric patients, two were of each sex (Figure 4).

Tumor Location and Pathology Type
B cell lymphoma was the most common pathology type in PPL patients (in 32 patients, 80%), followed by T cell (in five patients, 12.5%) and NK/T cell (in two patients, 5%). Out of the five cases of T cell type, four had concomitant pituitary adenomas or B cell lymphoma, showing the tendency of T cell type PPL. Tumor location was identified through radiological findings of MRI or FDG-PET/CT, or both of them, in which 37 patients had a tumor in the intrasellar region (92.5%), 29 patients in the suprasellar region (72.5%), 21 patients in cavernous sinus (52.5%), and 11 patients in the sphenoidal sinus (27.5%) (Figure 5).

Clinical Presentation
Hypopituitarism (in 30 patients, 75%) and headache (in 23 patients, 57.5%) were the most common presentations of PPL, followed by hemianopia (in 12 patients, 30%) and diplopia (in 12 patients, 30%). Other symptoms included fatigue, weight loss, fever, retro-orbital pain, nausea, and vomiting (Figure 6).
Among the patients with hypopituitarism (30 patients, 75%), panhypopituitarism was present in 11 patients (36.7%). Notably, diabetes insipidus was reported in 13 patients (43.3%). Apart from the patients concomitant with panhypopituitarism, only five patients showed complete anterior hypopituitarism (16.7%), while 12 patients showed partial anterior hypopituitarism (40%) (Figure 7).

**Treatment Strategies and Outcome**

The therapeutic regimen for PPL is usually a combination of surgery, chemotherapy, and/or radiotherapy. Since the case reports included in our study had an unbalanced follow-up duration, it might have resulted in inevitable statistical bias and the possibility that the tumor recurrence and metastasis were neglected. Thus, we attempted to evaluate the response to treatment as “responding” or “non-responding”, where “responding” indicated that the patient had achieved remission or had stable remnant tumor without progression after the therapies were initiated whereas, the “non-responding” implied that the patient had tumor progression, death, metastasis, or relapses after the treatment was adopted.

In this review, treatment strategies were reported in 35 patients, out of which 10 patients (28.6%) received a single treatment modality while 25 patients (71.4%) received combined ones. Only one patient underwent just a resection but died soon after the surgery. Two patients received radiotherapy, but only one of them was sensitive to it, and the other showed no response to the treatment. Notably, seven patients received chemotherapy, and six of them (85.7%) turned out to be effective. In the combined treatment group, four out of five patients (80%) responded to chemotherapy and radiotherapy, six out of nine patients (66.7%) responded to resection and chemotherapy, whereas two out of four patients (50%) responded to resection and radiotherapy while five out of seven patients (71.4%) responded to resection, chemotherapy, and radiotherapy.

**Mortality**

Among 40 patients of PPL, 12 of them (30%) died, where deaths were caused by the tumor (3), myocardial infarction (1), pulmonary failure (1), pneumonia (1), infection (2), and metastasis (2) while one patient died soon after the treatment, whereas the other one died before the treatment. The median mortality time was 8.7 months (P25:2 months, P75:8 months).

**Differential Diagnosis**

The diagnosis of PPL was not suspected in 27 patients, and before biopsy could confirm PPL, other diagnoses were made. Pituitary adenoma was the most common in the differential diagnosis (18 cases, 66.7%), followed by lymphocytic hypophysitis (four cases, 14.8%), Langerhans cell histiocytosis (three cases, 11.1%), metastases (three cases, 11.1%), and lymphoma (three cases, 11.1%). Meningioma and germinoma were found in two cases (7.4%), while other diagnoses included sphenoid sinusitis, granulomatous disease, schwannoma, intrasellar solitary plasmacytoma, sellar/suprasellar hemangiopericytoma, and rhabdomyosarcoma of the sphenoid sinus.

**DISCUSSION**

Primary CNS lymphoma (PCNSL) in immunocompetent patients is rare and represents about 2–4% of all intracranial neoplasms and 4–6% of all extranodal lymphomas (41–43).
However, in recent years, a rising incidence has been recognized, particularly in patients older than 60 years (43). Although PPL can develop in immunosuppressed individuals, it seems to be irrelevant to the immune status of PCNSL patients. Therefore, further studies are required to investigate the underlying mechanism of this pathological damage. Previous studies tend to categorize PPL as a sub-population of PCNSL, but we recommend it to be considered as a distinct entity from PCNSL. The origins of anatomic regions involved in the PPL are embryologically different from that of the cerebral parenchyma, as these anatomic structures are outside the blood–brain barrier (2).

Surprisingly, we found that both patients had infiltrative lesions in sphenoid sinus mucosa pathologically, but the sphenoid bones that composed the sellar base were visually intact during the biopsy procedure. In this review, we identified 13 patients (32.5%) with sphenoidal involvement, where seven patients (58.3%) showed no evidence of bony erosion. Notably, two patients, including the one in our case had no radiographic evidence of sphenoidal involvement but were confirmed histologically (14). Because most cases reviewed here did not undergo pathological analysis of sphenoidal mucosa, it is highly likely that there were more patients with sphenoidal involvement of PPL. Therefore, we speculated that PPL tends to spread to the sphenoidal area through vascular and bony approaches. The vascular approach was considered because a large proportion of PPL cases demonstrated sphenoidal involvement without bony erosion. Bony erosion happens in 8% of Hodgkin’s Lymphoma (44) cases and 15% in diffuse large B-cell lymphoma, which is less common at the early stage of the lymphoma system (45) but is still a viable way by which the tumor spreads to the sphenoidal area with or without visual changes in the sphenoidal bones. To the best of our knowledge, it is the first time that the characteristic of sphenoidal involvement is concluded for PPL, which might be different from other lymphomatous pathologies. Hence, we hypothesized that the biopsy of the mucosal sphenoid sinus could be an alternative to sellar biopsy, therefore, reducing the surgical risk while conducting diagnosis.

PPL is more invasive in nature when compared to other pituitary pathologies like adenomas or lymphocytic hypophysitis. It is often aggressive and may extend to the sphenoid sinus, cavernous sinus, or the floor of the third ventricle (26). PPL is usually located in the sellar or parasellar region. But we have also found the involvement of clivus and pituitary stalk (2). The correlation between tumor location and pathology type was not identified, which means that a radiological finding cannot indicate the specific pathology of lymphoma (Figure 5). We noticed that four patients developed metastasis after the diagnosis of PPL. The pathology of these patients did not follow the prevalence of B cell lymphoma, where three of them showed symptoms of fever. Reports of leptomeningeal dissemination, metastasis lesions in the bone marrow, liver, lung, adrenal gland, retroperitoneal lymph nodes raised the possibility that PPL might be the initial lesion location for the systemic disease (3, 18, 20, 31). Further studies are required to test and confirm this hypothesis.

PPL usually has atypical characteristics that make it difficult to distinguish from other pituitary tumors. Endocrine abnormalities and neurological deficits are found to assist tumor localization and explain some specific clinical presentations. Hypopituitarism (30 patients, 75%) and headache (23 patients, 57.5%) were the most common presentations of PPL, followed by hemianopia in 12 patients (30%) and diplopia in 12 patients (30%). Other symptoms included fatigue, weight loss, fever, retro-orbital pain, nausea, and vomiting. About 80% of the patients represented a cranial nerve deficit (II and III CN were most frequently involved), which means that it extended to the cavernous sinus (2). Hypopituitarism in PPL usually presents with various symptoms, including fatigue, muscle weakness, loss of libido, amenorrhea, thirst, and polyuria (3). Anterior hypopituitarism was present in about 70% of the cases, and more than one-third had diabetes insipidus associated with poor prognosis, which was also seen in our review (1, 2). Moreover, the brain tissues taken at the post-mortem of the PCNSL patients identified pituitary gland involvement in about 25% of cases, particularly in the posterior lobe and not the anterior one (46). Such a frequent involvement of the posterior pituitary should be paid more attention. Distinct radiological features were not identified in the sellar and suprasellar lymphomas (29). Therefore, the pathological analysis was required to confirm the diagnosis and adjust the treatment.

As for diagnosis, it seems that pituitary biopsy is currently a gold standard for confirmation. Medical history, physical exam and radiological criteria is highly unlikely to reach the correct diagnosis. Surprisingly, some biomarkers were developed for early detection of PCNSL. Royer-Perron et al. reviewed several biomarkers of PCNSL for diagnostic purpose, such as different microRNAs (miR-21, miR-19, miR-92a, etc.), which could be tested in CSF and vitreous fluid, and IL-10 in the CSF (47). Other biomarkers tested in CSF include Circulating U2 small nuclear RNA fragments, Tumor cell-free DNA, Neopterin, Osteopontin, STAC1, SBCMA, APRIL,BAFF, VSIG4, GPNMB4, and APOC2 (47–50). Based on the studies of the markers above, we believe the specific markers for PPL would be developed soon. However, these markers could not replace the value of biopsy so far and need to be evaluated within a larger patient cohort.

The specific pathogenesis of PPL is still controversial. PPL may either derive from neoplastic transformation of normal lymphocytes that enter the CNS due to inflammatory processes or from the transformation of normal resident lymphoid tissue in the CNS (2, 28). Also, some multipotent cells, i.e., chromophobes, marginal zone cells, follicular cells, folliculo-stellate cells, and colony-forming units, might activate and proliferate to develop pituitary lymphoma (29). Risk factors, including AIDS and other immunodeficiency states, along with lymphocytic hypophysitis and pituitary adenomas increase the susceptibility to PPL (1). PPL may share similar pathogenesis with primary thyroid lymphomas, noted more commonly in patients with coexisting Hashimoto thyroiditis (HT) (26). The patient of case 1 had undergone partial thyroidectomy due to a thyroid nodule, but we could not confirm whether it was
associated with HT and if it was possibly a potential pathogenic factor. EBV infection is another precipitating factor that induces oncogenic protein expression with subsequent loss of apoptosis and increased proliferation of lymphocytes, but both our patients were found to be EBER-ISH negative (51).

Pediatric patients with PPL seem to be different from their adult counterparts in terms of pathogenesis, clinical presentation, and radiological features. A data suggested that PPL in pediatric patients may be a different disease from that found in adults (40). They tend to have a smaller tumor size, mainly located in the pituitary stalk, which is easily misdiagnosed as germ cell tumors or Langerhans cell histiocytosis that occurs more often in children (39, 40). More importantly, these children were not likely to develop a symptom of headache. No distinct difference was observed in gender and age, and a good prognosis was achieved under chemotherapy. However, more studies are required for further investigation.

The management of PPL usually follows the protocols of treatment for PCNSL because of the lack of studies conducted on this extremely rare disease (2). The therapeutic regimen for PPL is usually a combination of surgery, chemotherapy, and/or radiotherapy (including gamma knife surgery and common radiotherapy) (5). The surgical treatment using the transphenoidal approach may be a viable option considering the specific location and bulk mass of the PPL lesion. However, the surgical intervention suggests no obvious benefits to the outcome of PCNSL, and the main purpose of it remains to establish a diagnosis via biopsy (42, 52).

Chemotherapy was proven effective in the treatment of PCNSL. The therapeutic regimen consisted of high-dose chemotherapy based on methotrexate (HD-MTX) combined with rituximab and other cytostatic drugs that can penetrate the blood–brain barrier and are highly recommended if the patient’s general condition permits (53). Both our patients received chemotherapy as the first-line of treatment but with varied clinical outcomes. Case 1 patient was sensitive to chemotherapy, which was confirmed by MRI that revealed a significant reduction in the size of the sellar mass, while the Case 2 patient showed a larger sellar mass compared to the previous radiological findings. Pathologically, both our patients showed a Bcl-2, Bcl-6, and C-MYC positive pattern indicating a poor prognosis. The index of p53 was positive in both patients and was more strongly expressed in the Case 2 patient, which might have contributed to the distinction of response against chemotherapy. Notably, the Case 2 patient exhibited aberrantly high positivity of Bcl-6 (95%+) and C-MYC (80%+), also the Ki-67 index had increased up to 90%, which indicated a much poorer prognosis. Given the dominant use of methotrexate in the treatment of PPL, we speculate that the insensitivity of chemotherapy in the Case 2 patient might have resulted from drug resistance or ineffectiveness. Several alternative drugs such as pemetrexed and ibritinib and salvage chemoinmunotherapy with rituximab, ifosfamide, and etoposide (R-IE regimen) were found to be clinically effective to some degree in relapsed or refractory PCNSL (54–56). Proper antitumor agents based on mRNA expression of drug-resistance genes in tumor tissues, including MDR-1, MRP-1, MRP-2, MXR-1, MGMT, GST-pei, and topoisomerase II alpha can also be selected accordingly (57).

Moreover, high-dose chemotherapy with autologous stem cell transplantation (HD-AST), which was first shown as an efficient therapeutic approach to recurrence, was proposed as a valuable alternative to the whole brain radiotherapy (WBRT) to consolidate the first-line of treatment (58). Two of the PPL patients reviewed in our study had received HD-AST after the occurrence of multiple relapses, but only one patient showed a good evolution (23, 26). Molecular studies are targeting PCNSL, which may be a novel therapeutic option in the future. Immune-mediated therapies and targeted therapies are under investigation and will achieve a more precise treatment with less damaging clinical outcomes (59).

PPL has a much poorer prognosis when compared to the pituitary involvement of systemic lymphoma (6). The overall mean survival rate of immunocompetent PPL patients was 14.4 months. There was no significant difference in terms of survival rates according to the adjuvant treatment strategies, although a combination of radiotherapy and chemotherapy provided a little longer mean survival rate than radiotherapy or chemotherapy alone (2). A newly developed prognostic score for PCNSL (Taipei Score) may offer disease risk stratification and facilitate clinical decision-making. Here, an age ≥80, deep brain lesions, and ECOG ≥2 were considered independent risk factors for PFS where each factor was assigned one point and there were four distinct risk groups (0–3 points) (60). Currently, the prediction of prognosis and treatment modalities of PPL follow the protocols of PCNSL due to its extreme rarity and also the scarcity of adequate research materials. Although PPL might have a different nature from PCNSL, we should also notice the similarity between these two pathologies. We believe that an exclusive prognostic score for PPL will be developed one day with more studies and cases being reported. Fortunately, with the advancing therapeutic strategies nowadays, the treatment outcomes are improving, and also PCNSL is now considered curable in some cases (59).

CONCLUSION

PPL is an emerging rare clinical entity with a poor prognosis, where advanced therapeutic strategies with a more precise and less damaging effect are under investigation. We are less likely to reach a confirmative diagnosis without the pathological analysis since distinguishing PPL from other sellar tumors is difficult just through the clinical presentations or radiographic findings. Molecular studies are required in the future to investigate the pathological mechanism and establish the biomarkers for early detection and therapeutic orientation. The prognostic score for PCNSL might be a useful tool to predict the clinical outcome of PPL. Since only 40 cases are reported to date, further investigations about PPL are expected in the future, and more details about the distinction between PPL and PCNSL are yet to be studied.
