Abstract

We review a few rigorous and partly unpublished results on the regularization of the stress–energy in quantum field theory on curved spacetimes: (1) the symmetry of the Hadamard/Seeley–DeWitt coefficients in smooth Riemannian and Lorentzian spacetimes, (2) the equivalence of the local $\zeta$-function and the Hadamard-point-splitting procedure in smooth static spacetimes and (3) the equivalence of the DeWitt–Schwinger- and the Hadamard-point-splitting procedure in smooth Riemannian and Lorentzian spacetimes.

This article is part of a special issue of Journal of Physics A: Mathematical and Theoretical in honour of Stuart Dowker’s 75th birthday devoted to ‘Applications of zeta functions and other spectral functions in mathematics and physics’.

1. Introduction

The ‘semiclassical’ Einstein equation

$$G_{\mu\nu} = 8\pi G \langle T_{\mu\nu} \rangle_\Omega$$

(1)

is obtained from the ‘classical’ Einstein equation by replacing the classical stress–energy tensor $T_{\mu\nu}$ with the expectation value of the quantum stress–energy tensor $\langle T_{\mu\nu} \rangle_\Omega$ in a quantum state $\Omega$. There are several angles from which one can approach the question whether this equation is sensible and well defined. On the one hand, one can argue that it can be obtained from a theory of (perturbative) quantum gravity in a suitable limit where gravity becomes classical, but matter is still quantized, and hence the name; see e.g., [FlWa96] for a review of this issue. On the other hand, if we combine our understanding of, e.g., radiation being described by quantum field theory on the fundamental level and the fact that radiation does have an influence
on spacetime curvature for all we know from cosmological observations, we can safely claim that the latter observations indicate that (something like) the semiclassical Einstein equation must hold at least in a suitable regime, although it is certainly not a fundamental equation, as it equates a deterministic classical quantity with a probabilistic quantum expression.

Even if one accepts one or both of the aforementioned physical motivations to consider the semiclassical Einstein equation, questions about the well posedness of this equation remain. We usually assume that spacetime is regular outside of black hole or big bang singularities, so $\langle T_{\mu\nu} \rangle_{\Omega}$ should better be regular as well. However, as the classical expression for $T_{\mu\nu}$ is (at least) quadratic in the field, one can expect that the naïve quantum stress–energy tensor is divergent and has to be regularized in some way. Indeed, various schemes to regularize the quantum stress–energy tensor have been proposed, including some more familiar from flat spacetime such as dimensional regularization [Bro76], $\zeta$-function regularization [DoCr76, Haw77] or Pauli–Villars regularization [BiDa82] and also the ones that are less familiar in that context such as point-splitting regularization [Chr76, Chr78, Wal77, Wal78a]. Naturally, the question arose which regularization scheme was the ‘correct’ one, and a satisfactory answer was first given in [Wal77] (and later generalized in [HoWa05]). In [Wal77], Wald proposed a minimal set of well-motivated conditions, which any sensible regularization scheme should satisfy. We state these conditions, i.e. the ‘Wald axioms’, here in their modern form [Wal95, BFV03, HoWa05].

1. The commutator of the regularized stress–energy tensor $T_{\mu\nu}(x)$ with any product of fields $\phi(x_1) \cdots \phi(x_n)$ equals their commutator with the non-regularized stress–energy tensor $T_{\mu\nu}(x)^3$.  
2. $T_{\mu\nu}(x)$ transforms covariantly under diffeomorphisms and does not depend on the metric and its derivatives at $y \neq x$.  
3. (The expectation value of) $T_{\mu\nu}(x)$ has vanishing covariant divergence.  
4. In Minkowski spacetime and in the Minkowski vacuum state, the expectation value of $T_{\mu\nu}(x)$ vanishes.  
5. (The expectation value of) $T_{\mu\nu}(x)$ does not contain derivatives of the metric of order higher than 2.

While the first condition makes sure that the regularization scheme is ‘minimal’ and ‘state independent’, as the divergence in the non-regularized stress–energy tensor is proportional to the identity, the second ensures that is local and purely geometric, and the third follows from the fact that $G_{\mu\nu}$ has vanishing covariant divergence as well. The fourth condition, introduced to guarantee that the regularization prescription coincides with ‘normal ordering’ in flat spacetime, has to be omitted if one wants to have a non-vanishing cosmological constant (on the right-hand side of the Einstein equations) [Ful91]. Finally, the last condition was meant to avoid the appearance of unstable, ‘runaway’ solutions to the semiclassical Einstein equation. Although it turned out that this condition cannot be fulfilled and that such unstable solutions cannot be avoided, one can still analyze the subclass of stable solutions in a controlled manner in special cases; see, e.g., [Sta80, Vil85, DFP08, Kok09, Pin10, DHMP10].

Wald has conjectured already in [Wa79] that $\zeta$-function regularization, dimensional regularization and the various point-splitting regularization schemes satisfy the essential axioms 1, 2 and 3, and thus, all have a raison d’être although they give slightly different results. In fact, one can infer directly from the axioms 1, 2 and 3 that their solution cannot be unique, but is subject to a finite regularization freedom that can be (under suitable assumptions) parametrized by four divergence-free tensors constructed out of the metric and the Riemann...
tensor [Wal77, HoWa05]; in the absence of a fundamental theory of quantum gravity and matter, this freedom can only be fixed by comparison with experiments [DFP08, DHMP10]. So Wald could not only motivate why most regularization prescriptions on the market should be legitimate but also explain why they naturally give different results. Nevertheless, the understanding of the renormalization ambiguity still seems to be a topic of active research; see, e.g., [ABPS06].

In this work, we shall be concerned with proving parts of Wald’s conjecture, namely the rigorous relation between three different regularization schemes, obtained partially in already published [Mor98, Mor99, Mor00] and partially in yet unpublished [Hac10] previous works of the authors. On the one hand, we shall review the equivalence between the local \( \zeta \)-function regularization and the Hadamard point-splitting regularization in Riemannian (Euclidean) manifolds and the compatibility of the local \( \zeta \)-function scheme with Wick rotation whenever applicable. This scheme is only meaningful in Riemannian manifolds because it is based on spectral properties of the field equations, which strongly depend on the metric signature. Hence, a rigorous comparison with the Hadamard scheme is only possible in the Riemannian context \textit{a priori} and can be taken over to the Lorentzian setting by means of a Wick rotation only in static Lorentzian spacetimes. The situation is comparable in the second case that we shall discuss, i.e. the well posedness of the DeWitt–Schwinger prescription. To wit, like the local \( \zeta \)-function scheme and for the same reasons, the DeWitt–Schwinger prescription is only well defined in Riemannian manifolds. Nevertheless, the computations of the regularized stress tensor for free quantum fields of arbitrary spin in Lorentzian spacetimes in [Chr78, ChDu79], obtained with the DeWitt–Schwinger prescription, are now part of the standard literature [BiDa82], although it was clear that their derivation had not been rigorous in Lorentzian spacetimes and that their legitimation via a Wick rotation was not possible in general Lorentzian spacetimes (see for instance the comments at the beginning of section 6.6 in [BiDa82]). Moreover, as we shall explain in the main body of this work, the DeWitt–Schwinger prescription to regularize the expectation value of the stress–energy tensor fails to take into account the state dependence of this object and thus only gives the ‘geometric piece’ of \( \langle \mathcal{E}_{\mu\nu} \rangle \); this, however, is sufficient to determine the so-called conformal anomaly [Duf77, Wal77]. Hence, although the results of [Chr78, ChDu79] on the conformal anomaly have been confirmed with rigorous calculations for Klein–Gordon [Wal77, Mor03] and Dirac [DHP09] fields by now, it is still important to know whether the DeWitt–Schwinger scheme is generally legitimate on arbitrary Lorentzian spacetimes and if one can formulate it in a way that does take into account the full state dependence of \( \langle \mathcal{E}_{\mu\nu} \rangle \); we shall prove both of these aspects in what follows. Although our proof is based on the direct relation between the so-called Seeley–DeWitt coefficients and the Hadamard coefficients, the DeWitt–Schwinger prescription still differs from the Hadamard scheme in that it does not consist of just applying a suitable differential operator to the regularized two-point function. Our results imply that the local \( \zeta \)-function and the DeWitt–Schwinger prescription both satisfy Wald’s axioms just like the Hadamard regularization scheme, though, in the \( \zeta \)-function case, only on Lorentzian manifolds where a Wick rotation is possible.

As the Seeley–DeWitt/Hadamard coefficients are of such utmost importance in the point-splitting regularization prescriptions (and in non-commutative geometry [CoCha97]), we complement our analysis of the different regularization schemes by reviewing a proof of their symmetry. Although this symmetry had been heavily used and expected to hold because these coefficients also appear in the symmetric Green’s functions of the field equations [Fri75, Gar64], a rigorous proof was missing since the coefficients appear only in infinite series whose convergence is unclear except in analytic spacetimes. The proof of [Mor99, Mor00] proceeds in three steps. First, the symmetry is proven in analytic Riemannian manifolds by employing the
symmetry of the field equations. Then, the proof is extended to analytic Lorentzian spacetimes by means of a local Wick rotation, i.e. one ‘rotates’ the metric rather than the coordinates. Finally, the symmetry is established in general non-analytic Lorentzian spacetimes by locally approximating in a controlled way smooth metrics with analytic ones.

Our paper is organized as follows. After introducing a few preliminary notions in section 2, we continue in section 3 by discussing the expansion of the heat kernel in terms of the Seeley–DeWitt coefficients and the expansion of the two-point function of quantum field in terms of the Hadamard coefficients, followed by a proof of their symmetry in section 4. In sections 5 and 6, we review the proof of the equivalence of the local ζ-function and the Hadamard regularization scheme in Riemannian manifolds and static Lorentzian manifolds and the well posedness of the DeWitt–Schwinger regularization prescription in Lorentzian spacetimes, respectively. This paper ends with our conclusions in section 7.

For simplicity and to increase the accessibility of this work, we consider only the real Klein–Gordon field in four dimensions. However, some of the results that we review have been proven in arbitrary dimensions [Mor98, Mor99, Mor00], and we have no reason to doubt that they can be extended to fields of higher spin as well.

In the following, a manifold (including bundles) is supposed to be smooth (i.e. C∞), unless specified otherwise. Hausdorff and second countable (to ensure paracompactness). Vector fields, tensor fields, metrics and sections are supposed to be smooth as well unless specified otherwise. We choose the signature (−, +, +, +) for Lorentzian metrics and follow [Wal84] regarding the definitions of the Riemann and Ricci tensors.

A spacetime is a time-oriented four-dimensional manifold equipped with a smooth Lorentzian metric. In the text, Riemannian and Euclidean are synonyms.

2. Gaussian states, static spacetimes and Wick rotation

Throughout we suppose to consider globally hyperbolic spacetimes \((M, g)\) only and we moreover stick to the case of a real scalar field \(\phi\) propagating in \((M, g)\), satisfying

\[
P\phi = 0, \quad P := -\nabla_\mu \nabla^\mu + V = -\Box + V,
\]

with the covariant derivative \(\nabla\) being always associated with the metric \(g\), and \(V\) being a smooth scalar function of the form

\[
V(x) := \xi R + m^2 + V'(x).
\]

Here, \(\xi\) is a real constant, \(R\) is the scalar curvature and \(m \geq 0\) is the mass of the particles associated with the field. The domain of \(P\) is the space of real-valued \(C^\infty\) functions with compactly supported Cauchy data. A quasifree state—also known as a Gaussian state—\(\Omega\) is unambiguously defined by choosing a Wightman two-point function \(\langle \phi(x)\phi(y) \rangle_\Omega\). The GNS theorem or the standard Wick expansion allows us to construct a corresponding Fock space realization of the theory.

A globally hyperbolic spacetime \((M, g)\) is said to be static if it admits a time-like Killing vector field \(X := \partial_t\) normal to a smooth space-like Cauchy surface \(\Sigma\). Consequently, there are (local) coordinate frames \((x^0, x^1, x^2, x^3) \equiv (t, \vec{x})\), where \(g_{0i} = 0 (i = 1, 2, 3)\) and \(\partial_t g_{\mu\nu} = 0\) and \(\vec{x}\) are the local coordinates on \(\Sigma\). When discussing the static case, we also assume that \(V\) satisfies \(\partial_t V' = 0\) so that the space of solutions of (2) is invariant under \(t\)-displacements.

In a globally hyperbolic static spacetime, it is possible to construct a \(t\)-invariant Gaussian state \(\Omega\) by performing the Wick rotation, i.e. obtaining the Euclidean formulation of the same QFT. This means that one can pass from the Lorentzian manifold \((M, g)\) to an associated Riemannian manifold \((M_E, g^E)\) by the analytic continuation \(t \rightarrow it\), where \(t \in \mathbb{R}\). In
the temperature of a state \( \Omega_1 \) fulfill this way, \( \tilde{a}_i \) gives rise to another Killing vector \( \tilde{a}_i \) in \( M_E \). \( M_E \) can alternatively be defined by assuming that the orbits of the Euclidean time \( \tau \) are closed with the period \( \beta \), including the case \( \tau \in \mathbb{R} \) as \( \beta = +\infty \). Within this approach [FuRu87], the two-point function of \( \Omega \) is completely determined by a proper Green’s function (in the spectral theory sense) \( S(\tau - \tau', \vec{x}, \vec{x}') \) of a corresponding self-adjoint extension \( P_E \) of the operator

\[
P_E := -\nabla_{\mu}^{(E)} \nabla^{,(E)}_{\mu} + V(\vec{x}) = -\Delta^{(E)} + V(\vec{x}) : C_0^\infty(M_E) \to L^2(M_E, d\mu_{\vec{x}}, x).
\]

(4)

\( S(\tau - \tau', \vec{x}, \vec{x}') \) is periodic with the period \( \beta \in (0, +\infty) \cup \{ +\infty \} \) in the \( \tau - \tau' \) entry and it is called the Schwinger function of \( \Omega \). \( S \) is the integral kernel of \( P_E^{-1} \) when \( M_E \) is compact and \( P_E > 0 \) [Wa79], and in that case, \( P_E = P_E^* \), i.e. \( P_E \) is essentially self-adjoint. In general, a \( t \)-invariant state \( \Omega \) is determined by the choice of a self-adjoint extension of the Wick rotated Klein–Gordon operator \( P_E \). When \( 0 < \beta < +\infty \), the value \( T = 1/\beta \) has to be interpreted as the temperature of a state \( \Omega \) because the Wightman two-point function \( \langle \phi(x)\phi(y) \rangle_\Omega \) satisfies the KMS condition at the inverse temperature \( \beta \).

3. Hadamard/heat-kernel Seeley–DeWitt coefficients

In order to introduce the Hadamard and Seeley–DeWitt coefficients, we need a few definitions and results from bitensor calculus.

If \( VM \) and \( WM \) are vector bundles over a manifold \( M \) with typical fibers constituted by the vector spaces \( V \) and \( W \), respectively, then we denote by \( VM \boxtimes WM \) the exterior tensor product of \( VM \) and \( WM \). \( VM \boxtimes WM \) is defined as the vector bundle over \( M \times M \) with a typical fibre \( V \otimes W \). The more familiar notion of the tensor product bundle \( VM \otimes WM \) is obtained by considering the pullback bundle of \( VM \boxtimes WM \) with respect to the map \( M \ni x \mapsto (x, x) \in M^2 \).

Typical exterior product bundles are for instance the tangent bundles of the Cartesian products of \( M \), e.g., \( T^*M \boxtimes T^*M = T^*M^2 \). A section of \( VM \boxtimes WM \) is called a bitensor. We introduce the Synge bracket notation for the coinciding point limits of a bitensor. Namely, let \( B \) be a smooth section of \( VM \boxtimes WM \). We define

\[
[B](x) := B(x, x).
\]

With this definition, \([B]\) is a section of \( VM \otimes WM \). In the following, we shall denote by unprimed indices the tensorial quantities at \( x \), while primed indices denote the tensorial quantities at \( y \). Moreover, covariant derivatives shall be denoted by the usual abbreviated notation

\[
B_{,\mu} := \nabla_{\mu} B.
\]

As an example, let us state the well-known Synge rule, proved for instance in [Chr76].

**Lemma 1.** Let \( B \) be an arbitrary smooth bitensor. Its covariant derivatives at \( x \) and \( y \) are related by Synge’s rule. Namely,

\[
[B_{,\mu}] = [B]_{,\mu} - [B_{,\mu}].
\]

Particularly, let \( VM \) be a vector bundle, \( f_a \) be a local frame of \( VM \) defined on \( O \subset M \) and \( x, y \in O \). If \( B \) is symmetric, i.e. the coefficients \( B_{ab} \) of \( B(x, y) := B^{ab}(x, y) f_a(x) \otimes f_b(y) \)

fulfill

\[
B^{ab}(x, y) = B^{ba}(y, x),
\]

then

\[
[B_{,\mu}] = [B_{,\mu}] = \frac{1}{2}[B]_{,\mu}.
\]

Other relevant properties of \([\cdot]\) can be found in, e.g., [Ful91].
3.1. Hadamard coefficients, Hadamard states and point-splitting regularization

An important tool of the Hadamard point-splitting renormalization prescription in curved spacetime is the so-called Hadamard coefficients. They appear in the explicit expression of the Hadamard parametrix. That notion, in turn, has its physical reason in the definition of a relevant class of quantum states called (locally) Hadamard states [KaWa91, Rad96a, Rad96b, Wal95]. To discuss them, we consider a Gaussian state $\Omega$ for a real scalar field $\phi$ on a globally hyperbolic spacetime $(M, g)$ as before.

**Definition 2.** We say that $\langle \phi(x)\phi(y) \rangle_{\Omega}$ is of ‘local Hadamard form’, and $\Omega$ is ‘locally Hadamard’, if

$$\langle \phi(x)\phi(y) \rangle_{\Omega} = \lim_{\varepsilon \downarrow 0} \frac{1}{8\pi^2} \left( \frac{u(x, y)}{\sigma_{\varepsilon}(x, y)} + \sum_{n=0}^{\infty} v_n\sigma_{\varepsilon} \log \left( \frac{\sigma_{\varepsilon}(x, y)}{\lambda^2} \right) + w(x, y) \right)$$

where $x$ and $y$ are taken in any geodesically convex neighborhood. Here,

$$\sigma_{\varepsilon}(x, y) := \sigma(x, y) + 2i\varepsilon(T(x) - T(y)) + \varepsilon^2,$n

where $T$ is any local time coordinate increasing toward the future, and $\sigma(x, y)$ denotes one half of the signed squared geodesic distance of $x$ and $y$ (well defined in a geodesically convex neighborhood) and $\lambda > 0$ denotes a renormalization length scale. Finally, $w$ is a smooth biscalar determined by the state up to re-definition of $\lambda$.

The bidistribution $h_\varepsilon$ is the ‘Hadamard parametrix’ and the coefficients (bi-scalars) $v_n$ are called ‘Hadamard coefficients’.

The convergence of the series in the expression of $h_\varepsilon$ is just asymptotic. However, a proper point-wise convergence can be obtained by introducing a set of suitable cutoff functions (see [Fri75, HoWa01] for details). The parametrix $h_\varepsilon$ solves the Klein–Gordon equation in each argument separately up to smooth terms. From that one obtains the following recursive differential equations (actually they do not depend on the signature of the metric) already studied by Riesz in his seminal paper [Rie53] (see also [Gar64]), determining $u = u(x, y)$ and all the Hadamard coefficients $v_n = v_n(x, y)$ in a fixed geodesically convex neighborhood when assuming $[u] = 1$:

$$2\sigma_{\varepsilon} \partial_{\varepsilon} \sigma_{\varepsilon} - (\square_{\varepsilon} \sigma - 4) u = 0,$n

$$- P_\varepsilon u + 2v_{n+1} \sigma_{\varepsilon} + (\square_{\varepsilon} \sigma - 2) v_0 = 0,$n

$$- P_\varepsilon v_n + 2(n+1) v_{n+1} \sigma_{\varepsilon} + ((n+1) \square_{\varepsilon} \sigma + 2n(n+1)) (v_{n+1}) = 0 \quad \forall n \geq 0.$$n

In particular, it turns out that $u$ coincides with the square root of the so-called VanVleck–Morette determinant [Ful91, Mor99]. As a consequence, the following relations can be proven (see, e.g., [Mor03]).

**Lemma 3.** The following identities hold for the Hadamard parametrix $h_\varepsilon(x, y)$

$$(P_x h_\varepsilon) = [P_x h_\varepsilon] = -6[v_1], \quad (P_y h_\varepsilon)_{\mu;\nu} = [(P_y h_\varepsilon)_{\mu;\nu}] = -4[v_1]_{\mu;\nu},$$n

$$(P_x h_\varepsilon)_{\mu;\nu} = [(P_x h_\varepsilon)_{\mu;\nu}] = -2[v_1]_{\mu;\nu}.$$
These identities have a great deal of effect concerning the point-splitting renormalization of the stress–energy tensor evaluated on a Hadamard state $\Omega$. It is essentially defined by subtracting the universal Hadamard singularity from the two-point function of $\Omega$, before computing the relevant derivatives:

\[ \left( : T_{\mu\nu} : (x) \right)_{\Omega} = \left( D_{\mu\nu}(x, y) \left( \langle \phi(x)\phi(y) \rangle_{\Omega} - h_t(x, y) \right) \right)_{\Omega} = \lim_{y \to x}. \] (9)

$D_{\mu\nu}(x, y)$ is the following second-order partial differential operator\(^4\) (cf [Mor03, equation (10)], and [Hac10] and [ElGo11], where some minor misprints have been corrected):

\[
D_{\mu\nu}(x, y) := D_{\mu\nu}^{\text{can}}(x, y) + \frac{1}{4} g_{\mu\nu} P_s,
\]

\[
D_{\mu\nu}^{\text{can}}(x, y) := (1 - 2\xi) g^\alpha_{\mu} \nabla_{\nu} \nabla_{\alpha'} - 2\xi \nabla_{\mu} \nabla_{\nu} + \xi g_{\mu\nu} + \frac{1}{4} g_{\mu\nu} \left( 2\xi + (2\xi - \frac{1}{2}) g^\rho_{\mu} \nabla^\rho \nabla_{\nu} - \frac{1}{2} m^2 \right).
\]

Here, covariant derivatives with primed indices indicate covariant derivatives w.r.t. $y$; $g^\alpha_{\mu}$ denotes the parallel transport of vectors along the unique geodesic connecting $x$ and $y$; the metric $g_{\mu\nu}$ and the Einstein tensor $G_{\mu\nu}$ are considered to be evaluated at $x$; and we have assumed $V = 0$ for simplicity.

The form of the ‘canonical’ piece $D_{\mu\nu}^{\text{can}}$ follows from the definition of the classical stress–energy tensor, while the last term $\frac{1}{4} g_{\mu\nu} P_s$ has been introduced in [Mor03] and it gives no contribution classically, just in view of the very Klein–Gordon equation satisfied by the fields. However, in the quantum realm, its presence has important consequences due to lemma 3 because the Hadamard parametrix satisfies the Klein–Gordon equation only up to smooth terms, and thus, the above definition without this additional term would not yield a conserved stress-tensor expectation value. As a matter of fact, the following theorem is valid ([Mor03] theorem 2.1).

**Theorem 4.** The stress–energy tensor expectation value defined by (9) fulfills the Wald axioms 1, 2 and 3 for every value of $\lambda > 0$ and, with a suitable choice for the scale $\lambda > 0$, it satisfies 4. For all $\lambda$, it displays the trace anomaly when the conformal coupling $\xi = 1/6$ and $m = 0$ are chosen:

\[
g^{\mu\nu} \left( : T_{\mu\nu} : (x) \right)_{\Omega} = -\frac{v_1(x, x)}{4\pi^2}.
\]

To conclude we remark an important theoretical result: if a globally hyperbolic spacetime is static and $\Omega$ is defined as in section 2 through the Wick-rotation procedure, $\Omega$ turns out to be Hadamard [Wal95, Mor03] for $0 < \beta \leq +\infty$. In particular, the Minkowski vacuum, which can be constructed in that way, is Hadamard.

### 3.2. Seeley–DeWitt coefficients

We now introduce another class of biscalars called the Seeley–DeWitt coefficients. They appear if one tries to regularize both the Euclidean and the Lorentzian one-loop effective action by means of the asymptotic expansion of the heat kernel. Actually, the notion of heat kernel is properly defined only in the Euclidean case, though the terminology has been adopted for the Lorentzian case as well. For the moment, we focus on the mathematical issues only, and just from a very formal point of view, while we leave aside the physical motivations leading to the Euclidean approach (especially the definition of the considered quantum state) as well as precise mathematical definitions that will be discussed in a subsequent section. We just say

\(^4\) Often, the symmetrized version of $D_{\mu\nu}$ is considered. However, since $(\langle \phi(x)\phi(y) \rangle_{\Omega} - h_t(x, y)$ is already symmetric, it is not necessary to symmetrize the differential operator.
that a formal motivation for passing from the Lorentzian to the Euclidean side and vice versa relies upon the natural extension of the Wick rotation procedure discussed in section 2 when dealing with static spacetimes. On a Euclidean manifold \((M, g)\), the \textit{Euclidean effective action} \(S_{\text{eff}}\) is defined via an Euclidean path integral as

\[
e^{-S_{\text{eff}}} = \int [d\phi] e^{-\frac{i}{\hbar} \mathcal{L}(\phi, \partial \phi)},
\]

\(P := -\Delta + V : C_{0}^{\infty}(M) \rightarrow L^{2}(M, d\gamma),\)

with \(\Delta\) being the Laplace–Beltrami operator associated with \(g\), and \(V : M \rightarrow \mathbb{R}\), being some given smooth function, such that \(P \geq 0\), is the Euclidean Klein–Gordon operator defined on \((M, g)\). \([d\phi]\) is supposed to denote some (formal) measure on the space of field configurations. The argument of the exponential in the integrand is the classical (Euclidean) Klein–Gordon action taking boundary terms into account. On Lorentzian manifolds, formally speaking, one would put an imaginary unit in front of both actions in the above formula. In that case, however, the rigorous heat-kernel theory cannot be applied since it strongly relies upon the fact that \(\Delta\) is (strongly) elliptic and several regularity results (including convergences of expansions) generally cease to hold true. See [Wa79, Ful91, Mor99] for comments on these issues.

The relevance of the effective action in our case is the fact that one can formally define the expectation value of the regularized stress–energy tensor in analogy to the classical case

\[
\langle \mathcal{T}_{\mu\nu}(x) \rangle := \frac{2}{\sqrt{\det g}} \frac{\delta S_{\text{eff}}}{\delta g^{\mu\nu}}.
\]

The natural question that arises is where the state \((\Omega)\) dependence of the right-hand side is hidden. Indeed, one can interpret the situation in such a way that the measure \([d\phi]\) is state dependent [Mor03]. We shall consider these issues in forthcoming sections. To compute \(\langle T_{\mu\nu}(\cdot) \rangle_{\Omega}\) in this picture, one therefore needs to compute the mentioned functional derivative with respect to the metric. As we are going to see, already \(S_{\text{eff}}\) is affected by divergences, and thus, a regularization process is necessary. If the regularization is such that the effective action is diffeomorphism invariant, then the resulting functional derivative will automatically lead to a conserved \(\langle T_{\mu\nu}(\cdot) \rangle_{\Omega}\).

Let us proceed to understand why the effective action is divergent and how to regularize it. Evaluating the above integral as if we were in a finite-dimensional vector space, and thus computing a Gaussian integral, one finds (up to a constant)

\[
e^{-S_{\text{eff}}} = (\det P)^{-\frac{1}{2}} = e^{-\frac{1}{4} Tr \log P},
\]

and hence,

\[
S_{\text{eff}} = \frac{1}{4} \int_{M} d\gamma \log \left[ \frac{\log P}{\log P} \right](x) = \int_{M} d\gamma \mathcal{L}_{\text{eff}}(x),
\]

where the identity (valid in finite-dimensional cases) \(\det P = Tr \log P\) has been used, the trace is evaluated by integrating the kernel of the operator \(\log P\) at coinciding points and \(\mathcal{L}_{\text{eff}}\) is interpreted as the \textit{effective Lagrangian}. The above integral is certainly diverging, as one can already infer from the identity (that holds true for \(M\) compact when replacing \(P\) in (10) by its unique self-adjoint extension \(\tilde{P}\) and referring to the weak operator topology)

\[
\log P = \lim_{\varepsilon \downarrow 0} \left\{ -\int_{0}^{\infty} ds \frac{e^{-sP}}{s} \right\},
\]

where \(\gamma\) denotes the Euler–Mascheroni constant and \(I\) is the identity operator. We discard the divergent term proportional to \(I\), i.e. trace class only in finite-dimensional spaces, and define (where again, to be rigorous, one should replace \(P\) by \(\tilde{P}\))

\[
\mathcal{L}_{\text{eff}}(x) := -\int_{0}^{\infty} ds \frac{e^{-sP}}{s} \left( x, x \right).
\]
The integral kernel \( e^{-iP} \) of the appearing exponential of \( P \) is called the heat kernel because it satisfies the heat equation

\[
(\partial_s + P_x) e^{-iP}(s, x, y) = 0.
\]

It is possible to prove that, at least when \( M \) is compact and \( P \geq 0 \) or, more weakly, it is bounded below (but there are several other generalizations, see [Wa79, Mor99] also for references), the heat kernel exists and is an integrable function, and in geodesically convex neighborhoods, the following expansion is valid:

\[
e^{-iP}(s, x, y) = \frac{1}{(4\pi s)^{\frac{d}{2}}} e^{-\frac{\sigma(x, y)}{2s}} \sum_{n=0}^{\infty} a_n(x, y) s^n + \text{‘smooth biscalar’}
\]

The convergence of the series is ‘asymptotic’ in a certain sense discussed in section 1.2 of [Mor99] (and it is not asymptotic in the Lorentzian case). The functions \( a_n(x, y) \) are smooth biscalars completely determined by the recursive differential equations [Ful91, Mor99]

\[
a_0 = u, \quad P_x a_n + \sigma_{\mu\nu} a_{n+1, \mu} + \left(\frac{1}{2} \Delta \sigma + n - 1\right) a_{n+1} = 0,
\]

with \( u \), again, denoting the square root of the VanVleck–Morette determinant and \( a_n \) being related to \( a_n \) via

\[
a_n = \sum_{j=0}^{n} \frac{\left(-m^2\right)^j}{j!} a_{n-j}.
\]

In the Lorentzian framework, formally speaking, one obtains the same expansion and the same coefficients, though defined with the Lorentzian metric, and in particular, \( \Delta \) is replaced by \( \Box \) in the recursive equations above.

The reason why we have displayed expansion (14) in two versions is the following: the version in terms of \( a_n \) is more convenient in the regularization procedure, because the appearing \( m^2 \) avoids potential infrared singularities in the integral with respect to \( s \) present in \( L_{eff} \). In contrast, the version given in terms of \( a_n \) is important to show the relation between the Hadamard coefficients \( v_n \) and the \( a_n \). Namely, a short computation and comparison with the scalar Hadamard recursion relations discussed in subsection 3.1 reveals the well-known identity

\[
a_{n+1} = (-1)^{n+1} 2^{n+1} n! v_n.
\]

4. The symmetry of the Seeley–DeWitt/Hadamard coefficients

An intriguing issue concerns the symmetry of the above-introduced functions \( a_n(x, y) \) (or, equivalently, \( v_n(x, y) \)) under an interchange of their arguments \( x \) and \( y \) when \((M, g)\) is smooth and is either Riemannian or Lorentzian. The symmetry is by no means evident in view of the fact that their definition, relying on (8), (7) and (6), is highly non-symmetric when swapping \( x \) and \( y \) because derivatives act on \( x \) only. In [Wal78a], such a symmetry was (indirectly) argued to hold for the analytic case. In [FSW78], the symmetry was argued to hold for the \( C^\infty \) case and used to simplify some technical computations. Nevertheless, these papers did not report the corresponding proof. In the literature concerning the point-splitting procedure successive to [Wal78a], e.g. [BO86], this symmetry is assumed to hold implicitly. The issue was analyzed in [Mor99, Mor00] and a proof was presented both for the Euclidean and the Lorentzian case.
In the following, we review the main ideas of the proof, and refer to [Mor99, Mor00] for technical details.

**Theorem 5.** The Seeley–DeWitt/Hadamard coefficients \( a_n(x, y) \) defined in a geodesically convex neighborhood of a \( C^\infty \) manifold \((M, g)\), either Riemannian or Lorentzian, associated with the Klein–Gordon (resp. Riemannian or Lorentzian) operator \( P \) (with \( V \) smooth but arbitrary) are symmetric if we swap the arguments \( x \) and \( y \).

**Sketch of proof.** First of all, given a Riemannian manifold \( M \) and a geodesically convex neighborhood \( \mathcal{O} \subset M \), where the \( a_n \) are defined, one modifies \( M \) and \( V \) outside \( \mathcal{O} \), in order to produce a compact manifold \( M' \supset \mathcal{O} \) equipped with an essentially self-adjoint operator \( P' \) bounded below and coinciding with \( P \) in \( \mathcal{O} \). This does not affect the definition of the \( a_n \) since they depend on the local geometry in \( \mathcal{O} \) only. As \( e^{-tP'} \) is self-adjoint, it follows that \( [e^{-tP'}](x, y) = [e^{-tP'}](y, x) \) for \( x, y \in \mathcal{O} \). The convergence properties of expansion (14) [Mor99] ensure in this case that \( \partial^\alpha_x \partial^\beta_y (a_n(x, y) - a_n(y, x)) \bigg|_{xy} = 0 \) for any multi-indices \( \alpha \) and \( \beta \), referring to any fixed coordinate frame on \( \mathcal{O} \). If the metric \( g \) is a real analytic function of the said coordinates, the coefficients \( a_n(x, y) \) turn out to be the analytic functions of the coordinates on \( \mathcal{O} \times \mathcal{O} \) and, just due to the Taylor expansion, one has \( a_n(x, y) = a_n(y, x) \) in a neighborhood of the diagonal of the open set \( \mathcal{O} \times \mathcal{O} \) and thus everywhere thereon since it is connected. Whenever the smooth metric \( g \) is not real analytic, it is however possible to construct a class of analytic metrics \( g_t \), depending on the parameter \( t \in (0, 1) \), uniformly converging to \( g \) as \( t \to 0 \). In view of the structure of equations (6)–(8) exploiting a suitable version of the theorem on the analytic dependence of parameters for the solutions of a class of differential equations, one can show [Mor99] that the associated coefficients \( a_n^{(1)}(x, y) \) satisfy as expected \( a_n^{(1)}(x, y) \to a_n(x, y) \) as \( t \to 0 \), ensuring the symmetry of \( a_n(x, y) \) since \( a_n^{(1)}(x, y) = a_n^{(1)}(y, x) \) if \( t > 0 \).

Let us pass to the case where \((M, g)\) is Lorentzian. It is now enough to establish the symmetry property for the analytic case because the extension to the smooth case is identical to that in the Euclidean case. So we assume that in a geodesically convex neighborhood \( \mathcal{O} \subset M \) the metric \( g \) and, thus, the coefficients \( a_n(x, y) \) are real analytic functions in a suitable coordinate frame thereon. As proved in [Mor00], it is possible to think of \( \mathcal{O} \) as a real section of a complex manifold \( \mathcal{U} \) equipped with a complex analytic metric \( h \) whose restriction to \( \mathcal{O} \) is nothing but \( g \). The pivotal fact is that this complex manifold admits another real section \( \mathcal{O}_E \) whose metric \( g_E \) obtained by restriction of \( h \) is Euclidean and \( \mathcal{O}_E \) is geodesically convex as well. In this sense, the real analytic Lorentzian metric \( g \) is the complex analytic continuation of the real analytic Euclidean metric \( g_E \). This procedure realizes a local Wick rotation, depending, however, on the chosen coordinate frame. Once again, exploiting a suitable version of the theorem on the analytic dependence of parameters for the solutions of a class of differential equations (on complex manifolds now), one verifies that the function \( a_n(x, y) - a_n(y, x) \) in \( \mathcal{O} \) is the analytic continuation of a corresponding function \( a_n^{(1)}(x_E, y_E) - a_n^{(1)}(y_E, x_E) \) in \( \mathcal{O} \).

Since the latter is the zero function, as previously established, we have \( a_n(x, y) = a_n(y, x) \) in \( \mathcal{O} \) for the Lorentzian (analytic) case, too.

5. **The equivalence of the local \( \zeta \)-function and the Hadamard regularization scheme in static spacetimes**

We intend to give a rigorous and well-known meaning to the formal definition (11) in the Euclidean case relying upon an analytic continuation procedure; another procedure will be discussed later. We start by providing a definite meaning [Haw77] to the determinant \( \det P \) in
the former identity (12). If $P$ is an $n \times n$ positive-definite Hermitian matrix with eigenvalues $0 < \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n$, the following elementary result is valid

$$\det P = e^{-\frac{\sum \lambda_j}{2}} \text{if} \quad \zeta(s|P) := \sum_{j=1}^{n} \lambda_j^{-s}, \quad z \in \mathbb{C}. \quad (18)$$

This trivial result can be generalized to non-negative self-adjoint operators whose spectrum is discrete and each eigenspace has a finite dimension as happens for the unique self-adjoint extension $\mathcal{P}$ of Laplace–Beltrami operators in compact Riemannian manifolds or perturbations of the form $P = -\Delta + V$ in (10). Consider the series with $s \in \mathbb{C}$ (the prime on the sum henceforth means that any possible null eigenvalue is omitted and, as is customary, we write $P$ in place of $\mathcal{P}$)

$$\zeta(s|P) := \sum_{j} \lambda_j^{-s}. \quad (19)$$

As is known, the series converges absolutely to an analytic function if $\text{Re} \ s$ is large enough. As in (18), the idea [Haw77] is to define, once again, if the right-hand side exists:

$$\det P := e^{-\frac{\sum \lambda_j}{2}} \quad \text{and} \quad S_{\text{eff}} := -\frac{1}{2} \frac{d\zeta(s|P)}{ds} \bigg|_{s=0}. \quad (20)$$

However, the function $\zeta$ on the right-hand side has to be understood as the analytic continuation of the function defined by the series (19) in its convergence domain, since the series may diverge at $s = 0$—and this is the standard situation in the infinite-dimensional case! For $P$ as in (10) the procedure works and (20) makes sense (e.g. see [Mor99a]).

The idea can be further implemented giving rise to a $\zeta$-function procedure to compute the stress–energy tensor, suitably interpreting (11). As a matter of fact [Mor98], one takes the $g_{\mu \nu}$ functional derivatives of the right-hand side of (19):

$$Z_{\mu \nu}(s, x|P) := \sum_{j} \frac{2}{\sqrt{\det g}} \frac{\delta \lambda_j^{-s}}{\delta g^{\mu \nu}} \quad (21)$$

and, after an analytic continuation of $Z_{\mu \nu}(s, x|P)$ in a neighborhood of $s = 0$, define

$$\langle : T_{\mu \nu} : (x) \rangle_{\Omega} := -\frac{1}{2} \frac{dZ_{\mu \nu}(s, x|P/\mu^2)}{ds} \bigg|_{s=0}. \quad (22)$$

The arbitrary mass scale $\mu$ has to be introduced for dimensional reasons. The outlined procedure works (the functional derivative can be computed giving a precise meaning to the right-hand side of (21) and the series converges to an analytic function for $\text{Re} \ s$ sufficiently large) at least for compact Euclidean manifolds with $P$ as in (10) as proved in [Mor98]. In particular, it can be verified that $\langle : T_{\mu \nu} : (x) \rangle_{\Omega}$ defined as in (22) is conserved and produces the conformal anomaly. However, the overall issue remains: how to relate $\langle : T_{\mu \nu} : (x) \rangle_{\Omega}$ with the renormalized stress–energy tensor in Lorentzian spacetime and for a state $\Omega$? An answer was presented in [Mor98] and [Mor03] (see especially theorem 2.2 in the latter)

**Theorem 6.** Let $(M, g)$ be a globally hyperbolic spacetime endowed with a global Killing time-like vector field normal to a compact space-like Cauchy surface and a Klein–Gordon operator $P$ in (2), where $V$ does not depend on the Killing time. Consider a compact Euclidean section of the spacetime $(M_{\text{E}}, g_{\text{E}})$ obtained by

(a) a Wick analytic continuation with respect to Killing time and

(b) an identification of the Euclidean time into Killing orbits of period $\beta > 0$.

Let $S$ be the unique Green function of the Euclidean Klein–Gordon operator $P_{\text{E}}$ associated with $P$ by means of the Wick rotation when $P_{\text{E}}$ is assumed to be strictly positive, and $\Omega$ is the Hadamard state associated with $S$. 

T-P Hack and V Moretti
\[ \langle T_{\mu\nu} : (x) \rangle_{\Omega} \text{ computed through the } \zeta\text{-function procedure (22) coincides with the analytic continuation of Killing time in static coordinates (Wick rotation) of } \langle T_{\mu\nu} : (x) \rangle_{\Omega} \text{ computed through the point-splitting prescription as in (9) when the scales } \lambda \text{ and } \mu \text{ are chosen suitably.} \]

6. The well posedness of the DeWitt–Schwinger regularization prescription in Lorentzian spacetimes

As described in subsection 3.2, one can formally obtain the expectation value of the regularized stress–energy tensor by first regularizing the effective action and then taking the functional derivative with respect to the metric. If such regularization of the effective action leads to a diffeomorphism-invariant action, the associated stress-tensor expectation value is automatically conserved [Wal84, appendix E]. The original motivation behind the DeWitt–Schwinger point-splitting regularization was indeed to proceed in this way, whereby the effective action is regularized by means of the formal asymptotic expansion of the heat kernel. However, the actual computations in the seminal works [Chr76, Chr78] have been performed directly on the level of the stress tensor, without the detour via the effective action. Nevertheless, we shall now repeat the formal steps of this detour before we proceed to give a reformulation of the regularization prescription used in [Chr76, Chr78], which is both rigorous on general smooth Lorentzian spacetimes and takes into account the state dependence of \[ \langle T_{\mu\nu} : \rangle_{\Omega} \].

To wit, inserting the heat-kernel expansion (14) in the definition of \( L_{\text{eff}} \) (13), one finds that the contributions due to \( n = 0, n = 1 \) and \( n = 2 \) lead to divergent integrals with respect to \( s \) if \( x = y \) (or if \( x \) and \( y \) are light-like related in the Lorentzian case). Particularly, we observe UV-divergences at the lower integration limit, while infrared divergences at the upper limit are not present on account of \( e^{-m^2 s} \). One therefore defines the renormalized effective Lagrangean in the Riemannian case as

\[
L_{\text{eff, ren}}(x) := -\int_0^\infty ds \frac{1}{s} \frac{1}{(4\pi s)^2} \sum_{n=3}^\infty \alpha_n(x, x) s^n,
\]

(23)

and \( \langle T_{\mu\nu} : \rangle_{\Omega} \) by the functional derivative of the associated renormalized effective action

\[
S_{\text{eff, ren}} := \int_M d^4x L_{\text{eff, ren}}(x).
\]

In the Lorentzian case, one would define these quantities by replacing \( s \) with \( is \). We point out two important things. First, we know that the Hadamard coefficients \( v_n \) and, hence, \( \alpha_n \) are covariant biscalars. Therefore, the renormalized effective Lagrangian is a scalar, and consequently, \( \langle T_{\mu\nu} : \rangle_{\Omega} \) is automatically conserved. Second, it is clear that \( L_{\text{eff, ren}}(x) \) has no state dependence whatsoever. This holds because we know that the coefficients \( \alpha_n \) are completely specified by local curvature terms and \( m \) and \( \xi \). In fact, we have ‘lost’ the state dependence by disregarding the smooth remainder term in the expansion of the heat kernel. Defining \( \langle T_{\mu\nu} : \rangle_{\Omega} \) via \( L_{\text{eff, ren}}(x) \) therefore completely disregards the state dependence of \( \langle T_{\mu\nu} : \rangle_{\Omega} \). Apart from the appearance of the Hadamard coefficients, there does not seem to be a close relation to our definition of \( \langle T_{\mu\nu} : \rangle_{\Omega} \) in terms of applying a suitable bidifferential operator \( D_{\mu\nu} \) to the regularized two-point function and then taking the coinciding point limit. However, one can reformulate the above renormalization of the effective action in the following way [Chr76, Wa79]. One formally pulls the functional derivative with respect to the metric in the
definition of \(\langle T_{\mu\nu} \rangle_\Omega\) under the integral with respect to \(s\) and then finds via additional formal steps
\[
\langle T_{\mu\nu} \rangle_\Omega := \frac{2}{\sqrt{|\det g|}} \frac{\delta S_{\text{eff}}}{\delta g^{\mu\nu}} = \left[ \frac{2}{\sqrt{|\det g|}} \frac{\delta \sqrt{|\det g|} P(x, y)}{\delta g^{\mu\nu}} \int_0^\infty ds \, e^{-sp} \right]
\]
\[
= \left[ \frac{\delta S}{\delta \phi(x) \delta \phi(y)} \int_0^\infty ds \, e^{-sp} \right]
\]
\[
= \left[ \frac{\delta T_{\mu\nu}}{\delta \phi(x) \delta \phi(y)} \right]_0^\infty ds \, e^{-sp}
\]
\[
= [D_{\text{can}}^{\mu\nu}(x, y) [P^{-1}](x, y)],
\]
where the outer square brackets denote the coinciding point limit. In the above formal derivation, it has been used that the integral kernel \(P(x, y) = \delta(x-y)P_s\) of \(P\) is obtained as the second functional derivative of the classical action \(S\) with respect to the field \(\phi\) and that the canonical differential operator \(D_{\text{can}}^{\mu\nu}\) that we have considered in section 3.1 is nothing but the second functional derivative of the classical stress–energy tensor with respect to the field \(\phi\). In the context of renormalization of the effective action in Lorentzian spacetimes, one usually considers \(P^{-1}\) to be the \textit{Feynman propagator} \(\Delta_F\) (note that \(P^{-1}\) is not unique). Hence, the divergences of \(\langle T_{\mu\nu} \rangle_\Omega\) computed as above are interpreted to stem from the divergences of the Feynman propagator at coinciding points. To renormalize \(\langle T_{\mu\nu} \rangle_\Omega\) in the Lorentzian case, one therefore inserts the DeWitt–Schwinger expansion \(14\) of the heat kernel in the integral expression for \(P^{-1}\) in terms of \(e^{-sp}\) to obtain
\[
\Delta_F(x, y) := \lim_{\epsilon \to 0} \epsilon \int_0^\infty ds \frac{1}{(4\pi s)^2} e^{-\frac{(\sigma + i\epsilon) s}{m^2}} \sum_{n=0}^\infty \alpha_n(x, y) s^n
\]
\[
= \lim_{\epsilon \to 0} \frac{1}{8\pi^2} \sum_{n=0}^\infty \left( \sigma + i\epsilon \right)^{\frac{n-1}{2}} K_{n-1} \left( \sqrt{2m^2(\sigma + i\epsilon)} \right) \alpha_n(x, y),
\]
where the \(\epsilon\)-prescription suitable for the Feynman propagator has been inserted and an integral identity for the \textit{modified Hankel function} \(K_n\) has been used. Expanding this in powers of \(\sigma\), inserting \(\alpha_0 = u\) and removing the \(\epsilon\)-prescription from the regular terms, we find
\[
\Delta_F(x, y) = \frac{1}{8\pi^2} \left\{ \frac{u}{\sigma + i\epsilon} + \log \left( \frac{(\sigma + i\epsilon) m^2 \epsilon^2 \gamma}{2} \right) \left( \frac{m^2 u}{2} - \frac{\alpha_1}{2} + \frac{m^4 u^2 \sigma^2}{8} - \frac{m^2 \alpha_1 \sigma}{4} \right) \right\}
\]
\[
- \frac{m^2 u}{2} - \frac{5m^4 u \sigma}{16} + \frac{\alpha_1 \sigma}{2} - \frac{\alpha_2 \sigma}{4} + \frac{\alpha_2}{2m^2} + O(\sigma^2 \log(\sigma + i\epsilon)),
\]
and, inserting the relation between \(\alpha_n\) and \(\nu_n\) as given in \(17\) and \(16\), we see explicitly that, barring the different \(\epsilon\)-prescription, \(\Delta_F(x, y)\) displays the Hadamard singularity structure. Again we point out that the ‘correct’ Feynman propagator is always \textit{state dependent}, while the above expression is manifestly \textit{state independent}, being essentially only a local curvature expression. Once more, this stems from the fact that one has disregarded the smooth (non-local) remainder in the expansion of the heat kernel. Note, however, that while this smooth remainder term is essentially well understood in the Riemannian case, this does not hold in the Lorentzian case, as there the whole DeWitt–Schwinger expansion is not rigorous. Hence, in respect of the Hadamard expansion of the two-point function of a Hadamard state, there does not seem to be a possibility of introducing the state dependence in a rigorous way in the DeWitt–Schwinger renormalization as we have presented it up to now. Moreover, it is already
visible from the few terms, which we have provided, that in terms of the Hadamard series the smooth term \( w \) of the above distribution contains inverse powers of the mass and, hence, diverges in the massless limit. Of course, this is particularly also the case for the logarithmic terms, which displays the infrared singularity of the integrals with respect to \( s \).

By the well-known distributional identities (see, e.g., [ReSi75, Ful91])

\[
\lim_{\epsilon \to 0} \frac{1}{x + i \epsilon} = \mathcal{P} \frac{1}{x} + i \pi \delta(x), \quad \lim_{\epsilon \to 0} \log(x + i \epsilon) = \log |x| + i \pi \Theta(-x),
\]

where \( \mathcal{P} \) denotes the principal value, one finds that \([D_{\mu\nu}^{\Re}(x, y)[\mathcal{P}^{-1}](x, y)]\) is a complex number, and one therefore has to consider its real part as the ‘correct’ definition of \( \langle T_{\mu\nu} \rangle_\Omega \).

In terms of the Hadamard series that we have discussed in subsection 3.1, this corresponds to the consideration of the symmetric part

\[
h^{\sigma}(x, y) := \frac{1}{2} \left( h(x, y) + h(y, x) \right)
\]

in the definition of the point-splitting prescription, where here and in the following we omit \( \epsilon \) in \( h_\sigma \). Note that this encodes the same information as the full \( h \) in the coinciding point limit.

With the setup we have just described, the regularization of \( \langle T_{\mu\nu} \rangle_\Omega \) goes as follows [Chr76]. Applying \( D_{\mu\nu}^{\Re} \) to the real part of \( \Delta_F \) given in terms of the DeWitt–Schwinger expansion, one finds that, as in the regularization of the effective action, divergences come from the terms of orders \( n = 0, n = 1 \) and \( n = 2 \). Hence, one identifies the divergent part of the stress–energy tensor as \( D_{\mu\nu}^{\Re} \) applied to the first three terms in the expansion. However, these terms of course also contain smooth contributions, and in fact, one has to take care to not subtract ‘too much’; otherwise, one could spoil the covariant conservation of \( \langle T_{\mu\nu} \rangle_\Omega \), which was automatic in the renormalization of the effective action. Namely, although in the latter renormalization one has subtracted the first three terms of the DeWitt–Schwinger expansion as well, some of the subtractions have been zero on account of the vanishing of \( \sigma \) in the coinciding point limit. As we now derive the series, we could accidentally introduce these vanishing terms since second derivatives of \( \sigma \) do not vanish in the coinciding point limit present in \( L_{\log}(x) \).

However, as observed in [Chr76], this can be avoided if one defines the divergent part of \( \langle T_{\mu\nu} \rangle_\Omega \) by applying \( D_{\mu\nu}^{\Re} \) to the real part of \( \Delta_F(x, y) \) and then discarding all terms that are proportional to inverse powers of the mass. Proceeding like this, Christensen has computed in [Chr76, Chr78] the divergent part of the quantum stress–energy tensor and has obtained the trace anomaly by computing the negative trace of the divergent part. This follows because the full expression of the stress–energy tensor must have a vanishing trace in the conformally invariant case as, despite its divergence, it is completely given in terms of the real part of \( \Delta_F \), which in turn is a bisolution of the Klein–Gordon equation by its very construction in terms of the DeWitt–Schwinger series. Note that Christensen has introduced the massless limit by replacing \( m^2 \) in the logarithmic divergence by an arbitrary scale \( \lambda \). This may seem rather ad hoc, but from our point of view this is a reasonable procedure if we remember that we have defined the Hadamard series with an arbitrary length scale in the logarithm right from the start; moreover, as shown in [Wa79], the scale can be consistently introduced as an ‘IR-regulator’.

Finally, since the smooth terms proportional to inverse powers of the mass had been discarded to ensure conservation, the massless limit could be performed in a meaningful way.

Having reviewed the DeWitt–Schwinger point-splitting renormalization of the stress–energy tensor, let us recapitulate its seeming disadvantages.

(a) It has been defined via an expansion of the heat kernel, which is not well defined in general curved Lorentzian spacetimes.
(b) It does not take into account the state dependence of \( \langle T_{\mu\nu} \rangle_\Omega \).
(c) It employs a Hadamard series whose smooth part \( w \) diverges in the massless limit.
We shall now give a regularization prescription that closely mimics the one of Christensen, but disposes of the above three problems.

**Theorem 7.** Let \( \Omega_2(x, y) := \langle \phi(x)\phi(y) \rangle_\Omega \) be the two-point function of a Hadamard state \( \Omega \), let
\[
\Omega_2'(x, y) := \frac{1}{2}(\Omega_2(x, y) + \Omega_2(y, x)),
\]
and let us define for \( x \) and \( y \) in a geodesically convex neighborhood
\[
h_{DS}(x, y) := \frac{1}{8\pi} \left\{ \frac{\rho \alpha}{\sigma} + \log \left[ \frac{m^2 e^{2\gamma}}{2} \right] \left( \frac{m^2 u}{2} - \frac{\alpha_1}{4} + \frac{m^4 u\sigma}{8} + \frac{\alpha_2 \sigma}{4} - \frac{m^2 \alpha_1 \sigma}{4} \right) 
- \frac{m^2 u}{2} - \frac{5m^4 u\sigma}{16} + \frac{\alpha_1 \sigma}{2} - \frac{\alpha_2 \sigma}{4} + \frac{\alpha_2}{2m^2} \right\},
\]
\[
h_m(x, y) := \frac{1}{8\pi \rho^2} \frac{\alpha_2}{2m^2}, \quad h_0(x, y) := h_{DS}(x, y) - h_m(x, y),
\]
Moreover, let us split the canonical bidifferential operator
\[
D^{\text{KG, can}}_{\mu\nu} := (1 - 2\bar{\xi}) g^{\rho\sigma} \nabla_\rho \nabla_\sigma - 2\bar{\xi} \nabla_\rho \psi \nabla_\sigma + \bar{\xi} G_{\mu\nu} + g_{\mu\nu} \left\{ 2\bar{\xi} \square - (2\bar{\xi} - \frac{1}{2}) g^{\rho\sigma} \nabla_\rho \nabla_\sigma - \frac{1}{2} m^2 g^{\rho\sigma} \nabla_\rho \nabla_\sigma \right\}
\]
as
\[
D^{\text{KG, can}}_{\mu\nu} := D^{0}_{\mu\nu} + D^{m}_{\mu\nu}, \quad D^{m}_{\mu\nu} := -\frac{1}{2} m^2 g_{\mu\nu}, \quad D^{0}_{\mu\nu} := D^{\text{KG, can}}_{\mu\nu} - D^{m}_{\mu\nu}.
\]
The stress–energy tensor regularization prescription defined as
\[
\langle : T^{\text{DS}}_{\mu\nu} : \rangle_\Omega := \left[ D^{\text{KG, can}}_{\mu\nu}(\Omega_2' - h_{DS}) + D^{0}_{\mu\nu} h_m \right]
\]
fulfills the Wald axioms of state independence, local covariance and covariant conservation. Particularly, it displays the trace anomaly
\[
g^{\mu\nu} \langle : T^{\text{DS}}_{\mu\nu} : \rangle_\Omega \mid_{m^2 = 0} = -\frac{[v_1]}{4\pi^2}.
\]

**Proof.** First of all, let us remark that the regularization prescription is well defined, as the relation between \( a_n \) and \( v_n \), given in (17) and (16) implies that \( \Omega_2' - h_{DS} \) is of class \( C^2 \) (the worst terms in \( \Omega_2' - h_{DS} \) are of the form \( \sigma^2 \log \sigma \)). Additionally, the prescription fulfills the requirement of local covariance, since it only involves the subtraction of objects given in terms of the DeWitt–Schwinger/Hadamard coefficients. Moreover, state independence follows manifestly from the definition, as the modification of the canonical prescription is given in terms of \( D^{0}_{\mu\nu} h_m \), which is a state-independent term.

To prove covariant conservation, we recall that, in the proof of theorem 4, it has been implicitly computed that for any smooth biscalar \( B(x, y) \) the following relation holds:
\[
\nabla_\mu \left[ D^{\text{KG, can}}_{\mu\nu} B \right] = -\left[ \nabla_\nu P_x B \right].
\]
Applying this to our current case, we find
\[
\nabla_\mu \langle : T^{\text{DS}}_{\mu\nu} : \rangle_\Omega = \nabla_\mu \left[ D^{\text{KG, can}}_{\mu\nu}(\Omega_2 - h_{DS}) + D^{0}_{\mu\nu} h_m \right] = -\left[ \nabla_\nu P_x(\Omega_2' - h_{DS}) + \nabla_\nu P_x h_m \right] = -\left[ \nabla_\nu(P_x \Omega_2' - P_x h_{DS} + P_x h_m) \right],
\]
where we have defined
\[
P^0 := -\square + \bar{\xi} R.
\]
A straightforward computation employing the Hadamard/DeWitt–Schwinger recursion relations yields
\[ Ph_{\text{DS}} = P^0 h_m. \]
From this and the fact that \( \Omega_s^2 \) naturally solves the Klein–Gordon equation, conservation follows.

By Wald’s results [Wal78a], the above findings already imply that \( \langle \mathcal{T}_{\mu\nu}^{\text{DS}} \rangle_{\Omega_s^2} \) displays the ‘correct’ trace anomaly. However, it is instructive to compute it explicitly. To this end, we obtain with steps similar to the ones already taken and using the implicit computational results obtained in the proof of theorem 4
\[
g^{\mu\nu}\langle \mathcal{T}_{\mu\nu}^{\text{DS}} \rangle_{\Omega_s^2} = g^{\mu\nu}[D_{\mu\nu}^{KG,\text{can}}(\Omega_2 - h_{\text{DS}}) + D_0^{\mu\nu}h_m]
= m^2[\Omega_s^2 - h_{\text{DS}}]
= m^2[\Omega_s^2 - h_0] - \frac{1}{16\pi^2}[\alpha_2]
= m^2[\Omega_s^2 - h_0] - \frac{1}{8\pi^2}[2v_1 - m^2v_0 + \frac{m^4u}{4}].
\]
□

A few comments on the result are in order. First, on practical grounds, the above result is really equivalent to the computation of Christensen in [Chr76, Chr78] because the terms of the DeWitt–Schwinger expansion that we have omitted are all proportional to \( \sigma^2 \) and, hence, vanish upon the application of the occurring differential operators in the coinciding point limit. In this sense, we have been able to put his results on firm grounds. Second, the modification term \( D_0^{\mu\nu}h_m \) does not ‘simply cure the conservation anomaly’. In this sense, the regularization prescription just analyzed differs from the one introduced in [Wal78a] and improved in [Mor03] in that it ensures conservation in a different way. Namely, conservation does not follow by adding a term by hand or by modifying the classical stress–energy tensor. In contrast, it follows by the explicit structure of the smooth term \( w \) in the DeWitt–Schwinger two-point function in combination with discarding specific terms proportional to inverse powers of the mass. Recall that the latter procedure has been motivated by analyzing carefully the subtractions in the (non-rigorous) regularization of the effective action. Finally, let us remark that the above prescription yields a smooth \( \langle \mathcal{T}_{\mu\nu}^{\text{DS}} \rangle_{\Omega_s^2} \), although \( \Omega_s^2 - h_{\text{DS}} \) is only known to be twice differentiable, because the non-smooth terms proportional to \( \log \sigma \) all vanish in the coinciding point limit.

7. Conclusions

In this work, we have proven parts of Wald’s conjecture in [Wa79], namely, that the local \( \zeta \)-function and the DeWitt–Schwinger regularization prescriptions of the stress–energy tensor for quantum fields in curved spacetimes both satisfy the essential Wald axioms of state independence, local covariance and covariant conservation, albeit only in static Lorentzian manifolds in the \( \zeta \)-function case. Moreover, we have shown how to reformulate the DeWitt–Schwinger prescription in such a way that it is able to take into account the full state dependence of the stress–energy tensor expectation value. Consequently, both prescriptions are physically meaningful for all we know, and the results obtained by using them can be trusted although they do not seem to be rigorous at first glance.
As a side note, it turns out that both the DeWitt–Schwinger and the Hadamard prescriptions require equal amounts of computation work in contrast to the seemingly widespread attitude that the latter is rigorous, whereas the former is better suited for computations (see, e.g., [DeFo06, DeFo08]). Notwithstanding, the power of the Hadamard prescription is that it can be directly generalized to obtain a regularization of all field polynomials [BFK96, BrFr00, HoWa01, Mor03, HoWa05]; this is done by means of the mathematical tools of ‘microlocal analysis’ [Hör71, DuHo72, Hör90], which have been introduced to the framework of quantum field theory in curved spacetimes in [Rad96a, Rad96b]. It is not clear how this can be done with the DeWitt–Schwinger prescription.

Finally, we would like to mention a consistency problem of the semiclassical Einstein equation that is not solved in full generality by any regularization prescription—this equation is only well defined in general if one can associate with each spacetime $M$ a ‘unique’ state $\Omega_M$, because the spacetime is unknown prior to solving the semiclassical Einstein equation, but solving the equation is not possible before saying which $\Omega$ is chosen for the evaluation of $\langle \mathcal{T}_{\mu\nu} \rangle_{\Omega}$. However, it is known that such an assignment of a state to a spacetime is impossible [HoWa01, BFW03, FeVe11]. Notwithstanding, this problem can be overcome if it is possible to restrict oneself to a limited class of spacetimes on which a unique state can be defined; this has been done in [Pin10].
