Source apportionment of VOCs and their impacts on surface ozone in an industry city of Baoji, Northwestern China

Yonggang Xue1,2, Steven Sai Hang Ho1,2,3, Yu Huang4,1,2, Bowei Li1,4, Liqin Wang1,2, Wenting Dai1,2, Junji Cao1,2 & Shuncheng Lee5

Level of surface ozone (O₃) has been increasing continuously in China in recent years, while its contributors and formation pathways are less understood. In this study, distributions of volatile organic compounds (VOCs) and the roles on O₃ pollution have been investigated in a typical industrial city of Baoji in Northwestern China by means of monitoring of their concentrations and other trace gases. The air samples have been collected at three sites according to urban function area. Concentration of VOCs in Weibin site, which near to industrial zone, was higher than most of other cities in China, and the ambient VOCs were dominated by aromatics and alkenes. The temporal variations of VOCs and O₃ coincided with the surface wind, implying that the formation of O₃ was impacted by both exports of plumes upwind and local photochemical reactions. Result of source apportionment indicated that industrial emission, vehicular exhaust, and solvent evaporation were three major pollution origins. Alkenes and aromatics contributed to the largest fractions of photochemical reactivity, suggesting the strong influences from industrial and traffic sectors. The study presents the characteristic VOCs and other factors in the contribution of O₃ formation in China.

Ozone (O₃) is important constituent of the atmosphere, the concentration of ozone mostly decreases from stratosphere to surface ground downward. Surface or tropospheric O₃ originated mainly from regular transportation from stratosphere, direct emissions in source-dominated regions, and photochemical reactions between volatile organic compounds (VOCs) and nitrogen oxides (NOₓ). In between, photochemistry plays an important role on both sources and sinks of O₃, subjected to the atmospheric NOₓ levels. Xue et al. reported that the in-situ photochemical production is the main source for the surface O₃ in megacities in China based on calculations with observation-based model. In urban site, the mixing ratio of NOₓ is often high (up to 70 ppbv) due to large quantities of emissions from heavy industries and vehicular engines. The O₃ budget is thus sensitive to photochemical reactivity of VOCs and NOₓ. Under short term regulatory measures, reduction of anthropogenic VOCs emission is efficient in shrinking of O₃ peak. However, the approaches only lead the reaction mechanism between VOCs-NOₓ-O₃ transferred from NOₓ-dependent to VOCs-dependent while VOCs becomes a limiting factor, in the case of no decline of NOₓ emission. Instead, to further reduce surface O₃ level, regulations on both VOCs, biogenic VOCs (BVOCs) and NOₓ are needed in a long term run.

Understanding of the sources of VOCs is a base for O₃ pollution control. Common anthropogenic activities include coal burning from industrial and residential uses, vehicle exhausts, gasoline volatilization, solvent use, petrochemical manufacturing and biomass burning. In addition, biogenic source, in particular of vegetation emission, is a vital factor in VOCs budget. Source apportionments of VOCs in ambient environments are always deployed with receptor models, like positive matrix factorization (PMF), chemical mass balance (CMB),

Table 1. Level (in ppbv) and compositions (in %) of VOCsPAMS mixing ratio in Baoji.

| Site         | Region      | Level (ppbv) | Alkene % | Alkane % | Aromatic % | Isoprene % | TVOCsPAMS (ppbv) |
|--------------|-------------|--------------|----------|----------|------------|------------|-----------------|
| Beibin       | Urban       | 15.50 ± 2.00 | 46.2     | 14.00    | 37.6       | 12.1       | 23.6            |
| Chencang     | Rural       | 10.72 ± 1.43 | 56.0     | 7.1      | 12.3       | 0.5        | 30.5            |
| Miaogou      | Rural       | 9.67 ± 5.40  | 56.0     | 7.1      | 12.3       | 0.5        | 30.5            |

Results and Discussion

Characterization of VOCs. Table 1 summarizes the mixing ratios of different classes of VOCsPAMS quantified at the three sites (the mixing ratios of individual compound were listed in Table S1). Isoprene is classified separately from alkenes to evaluate its strong indication from biogenic sources. The average mixing ratios of total quantified VOCsPAMS (TVOCsPAMS) were 48.03 ± 18.15, 17.00 ± 11.36, 17.27 ± 10.18 ppbv measured in the Weibin, Chencang and Miaogou sites, respectively. Comparing to the ambient levels in the Chinese megacities, our VOCsPAMS in Weibin site were higher than those in Beijing in summer of 2005 (36.4 ± 12.1 ppbv), but close to Southern regions such as Guangzhou (40.58 ± 0.89 ppbv) and Hong Kong (45.83 ppbv) where influenced by industrial and traffic emissions in major urban centers.

In general, the abundances of most VOCsPAMS descended notably in the order of Weibin > Chencang > Miaogou. The composition of VOCsPAMS significantly varied among the sites as well. The highest levels of aromatics and alkenes were observed in the Weibin site, with the mixing ratios of 16.6 ± 8.0 and 7.7 ± 4.5 ppbv, respectively. The high abundances can be ascribed to the existence of fossil fuel combustion sources installed in the industries nearby the site. Particularly, aromatics had a molar contribution of 51.0% of TVOCsPAMS in the Weibin site. Isoprene was the next abundant compound, followed by undecane, 2-methylhexane, toluene, and iso-pentane. This distribution was consistent with the emission profiles of metal smelt, coke production and power plants, which were located at the upwind position of the Weibin site. The result also implies that the strong impacts from combustion sources such as industrial coal burning and vehicular emission. In comparison with the Weibin site, lower mixing ratio of benzene was measured in the Chencang site. C2-C5 alkenes, C9-C12 alkanes and xylenes were higher than other VOCsPAMS, where the VOCsPAMS profile represents the more dominance of traffic-related sources. This finding was relatable to the facts that the Chencang
site was next to two highways (Lian-huo highway and Bao-han highway) and less factories nearby. At the Miaogou site, the mixing ratios of most VOCsPAMS were the lowest among the three sites, with exceptions of toluene, styrene, undecane, isoprene, and p-diethylbenzene. Toluene and styrene are universal components in solvents used in manufacture, while C13-C16 alkanes and isoprene are tracers for diesel exhaust and biogenic sources, respectively. This VOCsPAMS distribution indicates that the air quality at Miaogou site was impacted by a mix of natural and anthropogenic pollution sources. Scattered small-scale paint factories presented around the site in the on-site survey, and the plants in the forests can contribute greatly on the biogenic emissions.

One-week temporal variation of VOCsPAMS levels at the Weibin site is illustrated in Fig. 1. The mixing ratios of TVOCsPAMS in Weibin site varied with surface wind directions. Higher mixing ratios of VOCsPAMS were shown on the sampling days of June 16, June 17 and June 19, when the dominant wind was easterly (Figure S1). Dense power plants, metal smelt, coke production and coal chemical industries were located in the eastern and northeastern regions of Baoji. The high-frequency easterly surface winds could thus bring up those discharged pollutants to the downwind locations. The consequent effects can be also reflected on the significant elevation of corresponding marker species such as benzene and propene. In addition, from the time series, the highest TVOCsPAMS was often seen in the afternoon when the easterly surface wind was dominated within a day. While the wind direction swiped from easterly to westerly gradually, the TVOCsPAMS had an obvious decline. This could also demonstrate the strong impact from the industrial emissions.

Correlation between VOCs species. Correlation analysis between individual VOCsPAMS compound was used to interpret the potential and dominant pollution sources. Propane and n-butane are important VOCs from vehicular emissions, and their correlation acts a useful indicator for traffic contribution. In the current study, propane was well-correlated with n-butane at both sites (0.82 < \( R^2 < 0.87 \)), with slopes of 0.51, 0.37, and 0.49 for the Weibin site, Chencang and Miaogou, respectively (Fig. 2a). The ratios of n-butane/propane were close to that reported in a tunnel study (1–0.5), demonstrating the inalienable input from vehicular emission in Baoji. The regression of aromatics and long-chain alkanes (e.g. \( C_{24-C_{29}} \)) did not show significance among the sampling sites, pointing to a wide variety of source contributions (Fig. 3c, Table S2). In the Weibin site, toluene was highly correlated (\( R^2 = 0.50–0.95 \)) with other aromatics (e.g., ethylbenzene, xylenes, and styrene) and n-decane (\( R^2 = 0.65 \)) but fairly to poorly with undecane and dodecane (\( R^2 = 0.29 \) and 0.47, respectively). Reversibly, good correlations (\( R^2 > 0.65 \)) between benzene and the long-chain alkanes (except n-decane with an \( R^2 = 0.22 \)) were found. Benzene was also correlated poorly with ethylbenzene, xylenes, and styrene (\( R^2 = 0.24–0.29 \)) (Table S2). Benzene is a typical VOCsPAMS emitted from diesel-fueled engine, coal combustion, biomass burning, and natural gas combustion. While gasoline-fueled engine emission, paint production, printing, and other solvent involved activities release more toluene, ethylbenzene, xylene and styrene in composition. Those correlations not only prove the high contribution of combustion sources in the Weibin site, and also suggest that the ambient levels of toluene, ethylbenzene, xylene, styrene, 1,3,5-trimethylbenzene and n-decane might be additionally elevated by solvent-related industries. Figure 2b presents the correlations between toluene and benzene varied from Weibin site to Miaogou site. In the Weibin site, the mixing ratio of benzene was far higher than toluene (slope of toluene versus benzene = 0.05), ascribed to the strong benzene emissions from the local factories and transportation from the industrial zone with the easterly wind. In contrast to the Weibin site, the mixing ratios of toluene, styrene and dodecane were unexpectedly high in the Miaogou site. This also indicates that the solvent involved manufacture processes in the scattered paint and printing factories had a large contribution to the emissions of toluene and other aromatics.

The molar ratio of xylenes (m-/p-isomers) and ethylbenzene is often used to access the air mass aging, considering that the differences in degradation rates [i.e., hydroxyl (OH) reaction coefficients \( (k_{OH}) \)] in which xylene have higher \( K_{OH} \) of 1.36–2.30 × 10^{-11} in comparison of lower \( K_{OH} \) of 7.0 × 10^{-12} for ethylbenzene. In this study, the ratios of xylenes to ethylbenzene were both high at the Weibin site and Chencang sites (1.84 and 2.03, respectively, Fig. 3d), attribute to the fresh emissions from the pollution sources. However, a much low average ratio was found in the Miaogou site (0.42), additionally with a poor correlation between the two chemicals (\( R^2 = 0.10 \)). It is reasonable that relatively more aged air mass in Miaogou region due to its geographical position, even though its average VOCsPAMS levels were close to that at Chencang site.

Source apportionment of VOCsPAMS. Source apportionment was conducted with PMF receptor model. The mixing ratios and uncertainties for the VOCsPAMS from those valid samples collected in the three sites were used. Calibration was run for 3–7 factors and with random seeds. The seven factors solution produced mathematical ([\( Q \) values both robust and true] close to the theoretical \( Q \) value) with reasonable explanation. The results are illustrated in Fig. 3. In Factor 1, it has high loadings of benzene, propylene, 1-butene and 1-pentene in a descending order in mixing ratios, that was close to the profile of coal combustion emissions. Factor 2 is filled with propane, n-butane, n-pentane, iso-pentane and toluene. Most of these VOCsPAMS were relevant to the fuel evaporation, in particular of gasoline and CNG. Factor 3 is characterized by n-decane, undecane, xylene, ethylbenzene, 1,2,3-trimethylbenzene, 1,2,4-trimethylbenzene, p-diethylbenzene, 3-methylpentane, ethylene, 1-pentene. The composite was corresponding to and dominated by the diesel-fuel combustion. However, it must be noted that 3-methylpentane, a common marker for gasoline exhaust, was unexpectedly high in this factor. Even though the major contribution of Factor 3 could be characterized by the diesel combustion, the gasoline emission might still contribute a few. Factor 4 is consistent with a typical gasoline exhaust profile. Factor 5 is singly filled with high abundance of iso-butane but no representative source could be identified, thus is marked as others. Factor 6 is dominated by those VOCsPAMS from solvent evaporation (i.e., toluene, styrene and long-chain alkanes). Isoprene is the major component in vegetation emission, even it is always detected in the vehicle exhaust. Considering...
that high contribution of vegetation, isoprene is identified as a biogenic source marker. Factor 7 can be identified as biogenic source since isoprene had the highest contribution.

Taking all of the samples in accounting, vehicle exhaust (44.5%), industrial discharges (20.1%), and solvent usage (19.7%) are the top three major pollution sources contributed to ambient VOCs PAMS in Baoji (Fig. 4). As mentioned above, Baoji is a typical industrial city, and the main industries include power plants, coal chemical industry, metal smelting, and coke productions. Most of the related industries use coal as fuel or feed, this could cause high level of benzene in ambient air. In addition, heavy industries induce dense heavy truck usage for transport in the city Baoji. These together makes high contribution of industrial and diesel vehicle exhaust.

Figure 1. Temporal variations of TVOCs (sum of VOCs PAMS) with surface wind direction in Weibin site and Miaogou.
With normalized to the mass of TVOCs PAMS, the contributions of the potential sources on each sample were obtained, and their strengths were compared by taking the mean values at the different sites (Table S3). The loading of TVOCs PAMS in the Weibin site was ~2.8 times on average of those in the Chencang and Miaogou. The industry emission and gasoline-related sources were the two largest contributors (37.9% and 29.0%, respectively) in the Weibin site. In the Chencang, diesel exhaust was the most important source, contributing to 59.4% of TVOCs PAMS. Solvent-related emission contributed 36.7% of TVOCs PAMS in the Miaogou due to trace commercial painting activities. Covering with a high density of forest area, the mixing ratio of isoprene at the Miaogou was high. Therefore, a stronger strength of biogenic emission of 13.3% was found, in comparison with only 5.1 and 7.1% at the Weibin site and Chencang, respectively.

Chemical reactivity of VOCs. The chemical reactivity of VOCs PAMS was studied to investigate their potential oxidation ability with OH•, which can consequently lead the formation of surface O₃. The sum of OH• loss rate (L_OH) was calculated on basis of reaction rate constant between an individual VOCs PAMS and OH• and its mixing ratio. Table 2 lists the L_OH accounted at the three sites. As much higher TVOCs PAMS mixing ratios at the Weibin site, higher L_OH (27.20 ± 12.55 s⁻¹) was obtained in comparison of those at other two sampling sites. The L_OH in Weibin site was mainly dominated by the groups of alkenes and aromatics due to the strong influences of industrial and traffic emissions. In addition to their high chemical reactivity, the two pollution sources are thus considered to play key roles on hydroxyl radical-driven oxidations in Weibin site Baoji. The air quality at the Chencang was less impacted by the direct industrial activities, and the L_OH was thus less than half of that in the Weibin site. The group of alkanes, which has a lower chemical reactivity, was the major contributor (35.6%) to L_OH. At the remote site, even though the mixing ratios of most VOCs PAMS were relatively low, the high abundance of extremely-reactive isoprene dominated 32.5% to L_OH, resulting of an equivalent level of oxidation potential as that accounted in the Chencang.

Considering that alkenes play important roles on the chemical reactivity, the contributions of the most significant individuals at different concentration levels were displaced in Fig. 5. At a low mixing ratio region (0–35 ppbv), mostly in samples collected in the Chencang and Miaogou, the biogenic-emitted compounds (i.e., isoprene) showed their dominance and strong strengths to drive the L_OH while the impacts from anthropogenic sources shrined as a long distance far from the two sites. At a higher mixing ratio of TVOCs PAMS (>35 ppbv, for the samples collected in the Weibin site), propene and 1-butene were the two most important contributors to L_OH, representing that the industrial and traffic emissions not only can elevate the mixing ratios of VOCs PAMS and amounts of OH• oxidation, and also lead further surface O₃ formation.

Characterization of surface O₃. Temporal variation of surface O₃. The variations of surface O₃ at the three sites were depicted in Fig. 6. The highest O₃ concentrations exceeded the national standard in China of 160 μg m⁻³ in the five sampling dates. The diurnal patterns of surface O₃ levels were similar at the Weibin site and

![Figure 2. Regression plots between of VOCs species at Weibin, Chencang and Miaogou sites of Baoji.](image-url)
Miaogou sites, showing maxima between noon and early evening (Figure S2). In typical, double concentration peaks could be identified during this time interval. The first peak appeared around 13:00, and the next one was recorded between 16:00–17:00. The surface O₃ concentrations decreased gradually after 18:00 and the lowest values at the Weibin site and Miaogou sites were often observed at 07:00 and 08:00, respectively. It should be noted that the surface O₃ levels were significantly lower at the Weibin site than Miaogou site during the nighttime. The cases have been detailly explained in following sections.
Influences from meteorological conditions. The correlations between surface O3 and important meteorological parameters were fully studied. High O3 concentrations were often detected under high ambient temperatures and low RHs, which offer favor conditions for either formation or reservation of O3. In the current study, the O3 values were positively correlated to the temperature in both of the Weibin site (R² = 0.59) and Miaogou (R² = 0.61) during daytime, when associated with higher light intensity and radiations. Besides, water vapor could scavenge O3 and its precursors in atmosphere by wet deposition. As expected, the surface O3 levels was found to be negatively correlated with RHs at Weibin site (R² = 0.46) and Miaogou (R² = 0.51) sites. The O3 levels were also coincided with the surface zonal winds within our observation period (Fig. 6). In the Weibin site, higher surface O3 concentrations were often seen in accordance of strong easterly wind, consistent with higher mixing ratios of TVOCsPAMS measured simultaneously (Fig. 2). More obvious impacts from the direction of surface winds could be seen at the Miaogou site. Five episodes were defined between Jun 16 and Jun 20, when the O3 levels increased with easterly winds and under higher ambient temperatures. Particularly, the double O3 peaks occurred in the afternoon on Jun 16, Jun17 and Jun 19, while strong northeasterly and northerly winds were dominated. This suggested that the polluted air masses were transported from the Weibin site and industrial zone in the northeastern region of Baoji. Xue et al. investigated a variety of pollution origins on the
formation of O₃, and concluded that the surface O₃ level in the Miaogou area was dominantly impacted by the exports from the well-processed industrial plumes. The results of our study were consistent with the findings. The first O₃ peak in the afternoon was reasonably initiated by the formations from the local pollutants (i.e., photochemically reactive of isoprene emitted from biogenic sources), while the second peak could be resulted by the transportation of the industrial plume with high VOCs emission from the upwind locations.

Ozone formation potential. While L₁Ο₉Η was used to assess the VOCs activities, ozone formation potential (OFP) could be more direct method to measure the contributions of VOCsPAMS in the O₃ formation8, 54. Ozone formation potential (OFP) were calculated based on the average mixing ratios and the maximum incremental reactivity coefficients (MIR) of VOCsPAMS quantified in the present study54:

$$\text{OFP} = \text{MIR}_i \times C_i$$

where $C_i$ represents the mixing ratio (ppbv) for species $i$. The MIRs were obtained from Carter54. The estimated OFP for the top 20 contributors were given in Table 3. The highest overall OFP (185.36 ppbv on average) was accounted in the Weibin site, in comparison of 42.89 and 56.74 ppbv at the Miaogou and Chencang sites, respectively. The contributions of each VOCsPAMS to overall OFP varied from the sites, that might be driven by their degrees of degradation and dilution in transportation processes48. In the Weibin site, alkenes and aromatics were dominated and totally contributed >90% of the overall OFP loading. The marker species of propene and $m$-diethylbenzene were the two most important VOCsPAMS which contributed to more than half of overall OFPs, indicating that vehicle and industrial emissions greatly affected the surface O₃ formation. At the Miaogou site, isoprene and solvent-characterized VOCs such as toluene, styrene, xylene, and long-chain alkanes contributed most of OFPs loading. In another aspect, air mass aging can also contribute the variation of OFPs28. Even though the overall estimated OFPs was low at the Miaogou site, the actual O₃ levels were not the lowest as expected (Fig. 6). This can be ascribed to the transport of O₃ from other upwind districts3. The results from the current study concluded that the fresh plume from industrial and traffic sources at the upwind location could highly impact on the air quality in Baoji, and lead the occurrence of O₃ episodes in residential areas in summer.

Conclusions

Ozone pollution control is a challenging task in China, partly due to a huge number of VOCs emissions. In this study, the high levels and compositions of alkenes and aromatics in the the ambient of Baoji suggest the large contributions from the combustion sources in surrounding industries. The temporal variations of VOCsPAMS were driven by the directions of surface winds, in which the pollutants were transported from upwind regions. Aging of air mass was much obviously at the Miaogou site owing to its location distanced from the dense pollution origins. The O₃ formation in Baoji was influenced by both export of well-processed industry plume and photochemical reactions. More long-term VOCs monitoring and environmental assessment are thus needed to interpret the characteristic roles of VOCs in the production of surface O₃ in different regions in China. Development of mathematical models is vital to conclude the data in assistance to solve the related environmental issue.

Table 3. The top 20 most abundant O₃ formation potential species measured at the Weibin site, Chencang and Miaogou sites of Baoji (ppbv). m-Xylene and p-xylene are co-eluted in the chromatographic separation.

Material and Methods

Description of sampling sites. Three observation fields managed by the Baoji Municipal Environmental Protection Bureau were selected and categorized as (i) Weibin, (ii) Chencang and (iii) Miaogou, respectively, in this study (Figure S3). The Weibin site (E 107°8’35”, N 34°21’17”) was located in the western part of Baoji city where it is at a downwind location of an industrial zone (about 13 km). The Chencang site (E 107°14’19”, N 34°21’44”) was located at an elementary school in the east of Baoji. No any anthropogenic pollution sources rather than vehicular emission were observed around this site. The Miaogou site (E 107°11’06”, N 34°18’23”) was set up in the southern Baoji administrative region. The location is surrounded by Qin Mountain where the forests dominated the most land covers. Very scattered factories were found nearby this region. All sampling equipment was set up on the rooftop of the site buildings, which were 10–20 m above the ground.

Field Sampling. Samplings were conducted at 08:00–09:00, 15:00–16:00, 16:00–17:00 and 21:00–22:00, respectively, from June 15 to June 21, 2016. The VOCs in the air was drawn into a ¼” o.d. stainless steel multi-bed adsorbent tube filled with Tenax-TA, Carbograph 1 TD and Carboxen 1003 (C3-DXXX-5266, ca. 380 mg in adsorbent weight per tube, Markes International Ltd., Llantrisant, U.K.) using a low-flow module pump (ACTI-VOC, Markes International Ltd.) at a flow rate of 50 mL min⁻¹ for 60 min in laboratory demonstration under insignificant breakthrough (<5%) was observed either in field or laboratory demonstration under this sampling flow and volume. Two sorbent tube samples were thus collected in each time interval. The sampling inlet was set-up at 1.5 m above the ground level. Prior to the sampling, all sorbent tubes were cleaned in a thermal conditioner (TC20, Markes International Ltd.) at 330°C for 20 min before use. All pre-conditioned and sampled tubes were sealed with Difflok caps (Markes International Ltd.) and stored in desiccators at 0°C for a maximum of two weeks. The desiccators were filled with silica gel and activated carbon to avoid passive absorption of any water vapor and VOCs, respectively. The pump was calibrated with a mass flow calibrator (Defender 510, Bios, Torrance, CA, USA) before each sampling event. A Teflon filter assembly (47mm, Whatman, Clifton, NJ, USA) and a home-made ozone scrubber, manufactured by a 1 m long and ½” o.d. saturated potassium iodide (KI) coated copper tube, were installed in the air upstream to remove any influences from particulate matter (PM) and O₃, respectively. The O₃ removal efficiency was >99% at a concentration level of 100 ppbv for 60 min in laboratory test. One field blank was collected on each sampling day. The sorbent samples were properly transported to the laboratory for chemical analysis.

Real-time concentrations of the trace gases were monitored continuously during the sampling event. NO₂/NOx was measured with a chemiluminescence detector (Model 42i, Thermo Electron, Waltham, MA, USA), and surface O₃ was monitored with an ultra-violet (UV) photometric O₃ analyzer (Model 49i, Thermo Electron). The time resolution for these instruments was 5 min and the minimum detection limit (MDL) for both NO₂/NOx and O₃, respectively.

...
O₃ were 0.5 ppbv. The meteorological data (i.e., temperature, wind speed/direction and Relative Humidity) were recorded with an multi-parameter automatic weather stations (WXT520, Vaisala).

**Chemical Analysis.** A total of 72 valid sorbent tube samples were collected. They were all analyzed using a thermal desorption (TD) unit (Series 2 UNITY-xr system, Markes International Ltd.) coupled with a gas chromatograph/mass spectrometric detector (GC/MSD, Models 7890 A/5977B, Agilent, Santa Clara, CA, USA) within one week. The chemical analysis procedure can be found in our previous work. A tube was connected into the TD unit at room temperature (~25°C) and purged with ultra-high purity (UHP) helium (HE) gas at a flow rate of 40 mL min⁻¹ for 60 s to eliminate air and oxygen intrusion. For the primary desorption stage, the analytes were desorbed at 330°C for 5 min and refocused onto a cryogenic-trap (U-T1703P-2S, Markes International Ltd.) to capture high volatility target compounds at ~15°C. For the secondary desorption stage, the trap was dry-purged for 6 s and rapidly heated from ~15°C to 320°C and maintained for 5 min. The analyses were passed via a heated transfer line at 160°C, and re-refocused onto a cold GC capillary column head (Rtx®-1, 105 m × 0.25 mm × 1 μm film thickness, Restek Corporation, Bellefonte, PA, USA) at ~45°C with an aid of liquid nitrogen (N₂) in GC oven. Once the second desorption is completed, the oven temperature program started at an initial temperature of ~45°C for 4 min, ramped to 230°C at a rate of 6°C min⁻¹, and maintained at 230°C for 5 min. The constant flow rate of He carrier gas was 1.0 mL min⁻¹ throughout the GC analysis. The MSD was operated in selective ion monitoring (SIM) mode at 230°C and 70 eV for electron ionization. Identification was achieved by comparing the mass spectra and retention times of the chromatographic peaks with those authentic standards. Certified PAMS standard mixtures (Restek Corporation) were used in calibrations. A multi-point calibration curve was established to quantify each of the target compounds with linearity >0.999. The minimum detection limits (MDLs) were in the range of 0.003–0.808 ppbv with a sampling volume of 3 L. The measurement precision for the analysis of eight replicates of standard samples at 2 ppbv were ≤5%.

**Method for Source apportionment.** A standard receptor model of PMF (Version 3.0) recommended by U.S.EPA was used for source apportionment in this study. In principle, the PMF model is based on the following equations:

\[
x_{ij} = \sum_{k=1}^{p} g_{ik} f_{kj} + e_{ij}
\]

(2)

\[
Q = \sum_{i=1}^{n} \sum_{j=1}^{m} \left( x_{ij} - \sum_{k=1}^{p} g_{ik} f_{kj} \right) \mu_{ij}
\]

(3)

\[
U = (EF \times \text{conc})^2 + (\text{MDL})^2 \quad (\text{conc} > \text{MDL})
\]

(4)

where \(x_{ij}\) is the concentration of the jth congener in the ith sample of the original data sets; \(g_{ik}\) is the contribution of the kth factor to the ith sample; \(f_{kj}\) is the fraction of the kth factor arising from congener j; \(e_{ij}\) is the residual between the measured \(x_{ij}\) and the predicted \(x_{ij}\) using p principal components. \(\mu_{ij}\) is the uncertainty of the jth congener in the ith sample of the original data sets containing m congener and n samples. Q is the weighted sum of squares of differences between the PMF output and the original data sets. One of the objectives of PMF analysis is to minimize the Q value.
