Algebraic Complexity Classes

Meena Mahajan

Abstract. This survey describes, at an introductory level, the algebraic complexity framework originally proposed by Leslie Valiant in 1979, and some of the insights that have been obtained more recently.

Mathematics Subject Classification (2010). Primary 68Q15; Secondary 68Q05.

Keywords. algebraic complexity, circuits, formulas, branching programs, determinant, permanent.

1. Introduction

In this survey, I am going to try and describe the algebraic complexity framework originally proposed by Leslie Valiant [Val79, Val82], and the insights that have been obtained more recently. This entire article has an “as it appeals to me” flavour, but I hope this flavour will also be interesting to many readers. The article is not particularly in-depth, but it is an invitation to read [BCS97, Bür00a] and many recent papers on the topic, and to start attacking the open problems in the area.

Valiant started out with the mission of understanding the core essence of reductions and completeness, as witnessed in both recursive function theory and in computational complexity theory. He provided an algebraic framework in which to interpret the clustering of natural problems into completeness classes, even for problems of an algebraic rather than combinatorial nature. He had a remarkable hypothesis:

The idea for writing this survey came while the author was working on the Indo-French CEFIPRA-supported project 4702-1.
Linear algebra offers essentially the only fast technique for computing multivariate polynomials of moderate degree. Clearly, then, we are going to talk about polynomials, not languages or functions.

2. Valiant’s original framework

Let $\mathbb{F}$ be any field, and let $\mathbb{F}[x_1, \ldots, x_n]$ be the ring of polynomials over indeterminates $x_1, \ldots, x_n$ with coefficients from $\mathbb{F}$. Consider a family $(f)$ of polynomials $(f_n)_{n \geq 1}$, where each $f_n$ is in $\mathbb{F}[x_1, \ldots, x_{s(n)}]$ for some function $s : \mathbb{N} \rightarrow \mathbb{N}$. When should we say that $(f)$ is tractable? Clearly, if there are too many variables to keep track of, there cannot be tractability. So we will henceforth demand that $s$ is a polynomially bounded function ($\exists c, \forall n, s(n) \leq c + n^c$); then the $n$th polynomial $f_n$ has $O(n^c)$ variables. But that is of course not enough.

There are many ways in which we can set the bar for tractability. Here’s a first attempt. Can $(f)$ be computed by a formula of reasonable size? To elaborate further, a formula is an expression defined recursively:

1. for each $c \in \mathbb{F}$, “$c$” is a formula of size 0 computing the polynomial $c$,
2. for each indeterminate $x_i$, “$x_i$” is a formula of size 0 computing the polynomial $x_i$, and
3. if $F_1, F_2$ are formulas computing polynomials $f_1$ and $f_2$, then “$(F_1 + F_2)$” and “$(F_1 \times F_2)$” are formulas of size $\text{size}(F_1) + \text{size}(F_2) + 1$ each, computing the polynomials $f_1 + f_2$ and $f_1 \times f_2$ respectively.

Notice that $\text{size}(F)$ is just the number of ring/field operations used to construct $F$.

Instead of such a recursive definition, we could have a more intuitive picture: a formula is a rooted binary tree where internal nodes are labeled $+$ or $\times$ and leaf nodes are labeled from the set $\mathbb{F} \cup X$, where $X$ is the set of indeterminates. The size is just the number of non-leaf nodes.

Now, for tractability, we could require that there is a polynomially bounded function $t : \mathbb{N} \rightarrow \mathbb{N}$ and a family of formulas $(F_n)_{n \geq 1}$ such that each $F_n$ computes $f_n$ and has size at most $t(n)$. Let us use the notation $\mathcal{VF}$ to denote families of polynomials tractable in this sense. (VF: Valiant’s Formulas — of course, Valiant didn’t use this name! This class is also referred to as $\text{VP}_e$: Valiant’s Polynomial-sized Expressions. Personally, I prefer VF. Also note, in formal logic,
the formulas/expressions referred to above are called terms, hence VF means families with polynomial “termic complexity”.)

Here’s a second attempt: Can \((f)\) be computed by a straight-line program of reasonable size? As before, we will declare polynomial size to be reasonable. Straight-line programs are programs where instructions involve adding or multiplying previously computed polynomials, no divisions and no conditionals (no if-then-else). In the more intuitive picture, they correspond to directed acyclic graphs where each node is a source node (indegree 0) labeled from the set \(F\cup X\), or has indegree 2 and is labeled \(+\) or \(\times\). A designated sink node (outdegree 0) is the output node. Each node computes a polynomial in the obvious way, and the graph computes the polynomial at the output node. (The acyclicity constraint ensures that there is a linear ordering of the nodes such that each node, or instruction, only uses previously computed polynomials. This gives the straight-line program.) The size is the number of non-source nodes; again, this corresponds to the number of ring/field operations required. Such graphs are in fact exactly algebraic circuits, and we now look for polynomial size circuit families.

Clearly, this model generalises formulas. The catch is that it generalises it too much! To see why, consider the following circuit family: \(C_n\) has \(n+1\) nodes \(v_0, v_1, \ldots, v_n\), and the labeling is \(v_0 = x_1, v_{i+1} = v_i \times v_i\) for \(i \in [n]\). The family of polynomials \((f_n)\) computed by \((C_n)\) is \(f_n = x_1^n\). Even for small integer values of \(x_1\), writing down the value of \(f_n(x_1)\) is going to require exponentially many bits. How can we say that such a family \((f_n)\) is tractable?

So we need to impose some additional restrictions. The obvious parameter to restrict is the degree of the polynomial. Say that the family \((f_n)\) has moderate degree if for some polynomially bounded function \(d : \mathbb{N} \rightarrow \mathbb{N}\), the degree of each polynomial \(f_n\) is at most \(d(n)\). If degree\((f_n) = D\) is polynomially bounded, then on integer arguments with \(b\)-bit representations, the value of \(f_n\) requires no more than \(\text{poly}(n, b)\) bits. (In general, it needs no more than \(\text{poly}(n, D, b)\) bits.) Henceforth, to qualify for the label tractable, a family \((f_n)\) must have polynomially bounded degree.

(Why didn’t we face this problem when considering VF? Simply because a formula of size \(t\) cannot compute a polynomial of degree more than \(t + 1\). Don’t just believe me; check this by induction on formula size.)

Now we have our second possible definition of tractability: \((f_n)\) is tractable if the sequence degree\((f_n)\) is polynomially bounded, and there is a polynomially bounded function \(t : \mathbb{N} \rightarrow \mathbb{N}\) and a family of
straight-line programs, or algebraic circuits, \((C_n)_{n \geq 1}\), such that each \(C_n\) computes \(f_n\) and has size at most \(t(n)\). Let us use the notation \(\text{VP}\) to denote families of polynomials tractable in this sense. (\(\text{VP}\): Valiant’s analogue of the Boolean complexity class \(P\). Valiant called these families \(p\)-computable \[Val82\].)

The well-studied polynomial family from linear algebra, the determinant of a matrix of indeterminates, is known to be tractable in this second sense. (To define the family \((\text{Det}_n)\), imagine an \(n \times n\) matrix \(A_n\) with a new indeterminate \(x_{ij}\) at each position \((i,j)\), and let \(\text{Det}_n\) be the polynomial that represents the determinant of \(A_n\). Thus \(\text{Det}_1 = x_{11}\), \(\text{Det}_2 = x_{11}x_{22} - x_{12}x_{21}\), and so on. Clearly, this family satisfies the mandatory conditions: \(\text{Det}_n\) has \(n^2\) variables and is of degree \(n\).) This is not surprising; we know that the determinant can be computed efficiently (in polynomial time) over instantiated matrices using, say, Gaussian elimination. But to compute the symbolic determinant via a straight-line program, Gaussian elimination is apparently not directly of use because we can’t search for non-zero pivots and eliminate them (remember, no divisions and no conditionals). However, Strassen \[Str73\] gave a generic method of converting any straight-line program with divisions to a division-free straight-line program; the resulting program’s size is polynomially bounded in the original size, the number of variables, and the degree. Thus we can conclude that there are polynomial-sized straight-line programs for the symbolic determinant. There are more direct algorithms as well; Samuelson, Berkowitz, Csanky, ... . See \[MV97\] for an explicit description of circuits of size \(O(n^4)\) (my favourite one – no surprise!).

Whether the determinant can be computed efficiently by formulas (is \(\text{Det}_n\) in \(\text{VF}\)?) is still famously open. We know that it needs formula size at least \(\Omega(n^3)\), see \[Kal85\]. But we do know that it can be computed by formulas of sub-exponential size \(2^{O(\log^2 n)}\). This can be shown in many different ways, one of which we will look at a bit later, but the earliest demonstration of this follows from Csanky’s algorithm \[Csa76\], which uses binary arithmetic operations and \(O(\log^2 n)\) parallel time. Thus if we use quasi-polynomial (\(2^{\log^c n}\) for some constant \(c\)) formula-size as the defining property for tractability (giving a class that we can call \(\text{VQF}\)), then again the family \((\text{Det}_n)\) has long been known to be tractable. We could also use quasi-polynomial circuit size as the defining property for tractability, giving a class that we can call \(\text{VQP}\). But \(\text{VQP}\) obviously contains \(\text{VP}\) and \(\text{VQF}\), so \((\text{Det}_n)\) is in \(\text{VQP}\); nothing new there. (Note: in defining \(\text{VQF}\) and \(\text{VQP}\), the quasi-polynomial limit on formula or circuit size is over
and above the requirement that the degree and number of variables are polynomially bounded.)

Does VP include essentially all interesting and natural polynomial families? We do not know. In fact, there is a large list of such polynomial families not known to be in VP. The most natural one is the permanent family \((\text{Perm}_n)\) where \(\text{Perm}_n\) is the polynomial representing the permanent of an \(n \times n\) matrix \(A_n\) of indeterminates. It is tantalisingly similar to the determinant; just the sign term is missing.

\[
\text{Det}_n = \sum_{\sigma \in S_n} \text{sign}(\sigma) \prod_{i=1}^{n} x_{i\sigma(i)} \quad \text{Perm}_n = \sum_{\sigma \in S_n} \prod_{i=1}^{n} x_{i\sigma(i)}
\]

Yet, it does not seem to be tractable. How “intractable” is it?

Mirroring the definitions of the Boolean complexity classes \(P\) and \(NP\), Valiant proposed a notion of \(p\)-definability in [Val79]. A polynomial family \((f_n)\) is \(p\)-definable if it can be written as an exponential sum, over partial Boolean instantiations, of another tractable family. Formally, a family \((f_n)\) over \(s(n)\) variables and of degree \(d(n)\) is \(p\)-definable if \(s(n)\) and \(d(n)\) are polynomially-bounded, as always, and further, there exist a polynomially-bounded function \(m\), and a family of polynomials \((g_n)\) in \(VF\), such that \(g_n\) has \(s(n) + m(n)\) variables denoted \(\{x_1, \ldots, x_{s(n)}, y_1, \ldots, y_{m(n)}\}\), and

\[
f_n(\tilde{x}) = \sum_{y_1=0}^{1} \sum_{y_2=0}^{1} \cdots \sum_{y_{m(n)}=0}^{1} g_n(\tilde{x}, \tilde{y}).
\]

This looks like an algebraic analogue \(\sum \cdot VF\) of the boolean class \(\exists \cdot F\), where \(F\) is the class of languages decided by polynomial-size formulas. But it is well-known that \(\exists \cdot F = NP\), so this should be algebraic \(NP\). Later, Valiant redefined \(p\)-definability (no, that is not a circular definition!) as exponential sums of families in \(VP\), rather than \(VF\); that is, \(VNP = \sum \cdot VP\). For clarity, let us agree to temporarily refer to these two definitions as \(VNF\) (or \(VNP_e\)) and \(VNP\). However, Valiant [Val82] showed that these two classes are in fact the same, so just \(VNP\) will do. The proof involves showing that \(VP\) is contained in \(\sum \cdot VF\). And it is of course easier to show upper bounds with the definition of \(VNP\) rather than \(VNF\).

Now Valiant observed that not only \((\text{Det}_n)\), even \((\text{Perm}_n)\) is \(p\)-definable. This should be similar to showing that the 0-1 permanent is in \(\#P\), right? Almost. We are dealing with symbolic polynomials, so we do not have the liberty of looking at an input value and deciding what to do next. Still, the basic idea is the same. For a statement
$S$, let $[S]$ denote the 0-1 valued Boolean predicate that takes value 1 exactly when $S$ is true. Then

$$\text{Perm}_n = \sum_{\sigma \in S_n} \prod_{i=1}^{n} x_{i\sigma(i)} = \sum_{Y \in \{0,1\}^{n \times n}} \begin{bmatrix} \text{Y is a 0-1} \\ \text{permutation} \\ \text{matrix} \end{bmatrix} \cdot \prod_{i=1}^{n} \left( \sum_{j=1}^{n} Y_{ij} x_{ij} \right)$$

$$= \sum_{Y \in \{0,1\}^{n \times n}} \begin{bmatrix} \text{Y has at least one 1 in each row} \\ \text{Y has at most one 1 in each line} \\ \text{(line = row or column)} \end{bmatrix} \times$$

$$\left( \prod_{i=1}^{n} \prod_{j=1}^{n} Y_{ij} \right) \prod_{(i,j) \neq (k,m); i=k \text{ or } j=m} \left( 1 - Y_{ij} Y_{km} \right)$$

Clearly, the polynomial family

$$g_n = \left( \prod_{i=1}^{n} \prod_{j=1}^{n} Y_{ij} \right) \prod_{(i,j) \neq (k,m); i=k \text{ or } j=m} \left( 1 - Y_{ij} Y_{km} \right) \prod_{i=1}^{n} \left( \sum_{j=1}^{n} Y_{ij} x_{ij} \right)$$

has formulas of size $O(n^3)$, and $\text{Perm}_n(\vec{x}) = \sum_{Y \in \{0,1\}^{n \times n}} g_n(\vec{x}, Y)$, so $(\text{Perm}_n)$ is in VNP.

So we have some families in VP (even VF), and some in VNP but maybe not in VP. How do we compare families? For comparing languages, we have many-one reductions and Turing reductions – what is the algebraic analogue? Valiant proposed projections, a most restrictive kind of reduction when dealing with Boolean classes, but completely natural in the algebraic context. We say that $g \in \mathbb{F}[y_1, \ldots, y_m]$ is a projection of $f \in \mathbb{F}[x_1, \ldots, x_n]$ if $g$ can be obtained from $f$ by substituting a value in $\mathbb{F} \cup Y$ for each variable in $X$. (For instance, if $f = x_1 x_2 + x_3 x_4$, then the following are all projections of $f$: $y_1 + y_2$, $y_1 y_2 + 5$, $y_1 y_2 + y_2 y_3$, $2y^2$. But $y_1^2 y_2$, $y_1 + y_2 + y_3$ are not, because a projection cannot increase the degree or number of monomials.) Further, we say that a family $(g_n)$ is a $p$-projection of a family $(f_n)$ if each $g_n$ is a projection of some $f_m$ for an $m$ not too far from $n$. That is, there is a polynomially bounded function $t$, and each $g_n$ is a projection of $f_t(n)$. If we allow $t$ to be quasi-polynomially bounded, we obtain $qp$-projections.
Using these notions of reductions, we have the usual notions of hardness and completeness for algebraic classes. Here’s what Valiant showed:

1. \(\text{Det}_n\) is hard for VF under \(p\)-projections (and is known to be in VP).
2. \(\text{Det}_n\) is complete for the class of quasi-polynomial size formulas VQF under \(qp\)-projections.
3. Over fields with characteristic other than 2, \(\text{Perm}_n\) is complete for VNP under \(p\)-projections. Over fields of characteristic 2, \(\text{Perm}_n\) equals \(\text{Det}_n\) and hence is in VP and VQF.
4. Polynomial families associated with a number of NP-complete languages are complete for VNP under \(p\)-projections.

The first two follow from a proof that a polynomial computed by a size \(s\) formula is a projection of \(\text{Det}_{s+2}\). (It uses the combinatorial definition of determinant, as the signed weighted sum of cycle covers in an associated graph.) The hardness of \(\text{Perm}_n\) for VNP mirrors the hardness of the Boolean permanent for the counting class \#P. As in the case of the upper bound, additional care is needed to take into account non-access to an input instance and fully symbolic computations; in particular, the proof requires a multiplicative inverse of 2 and hence fails over fields of characteristic 2. See [Val79, BCS97, B"ur00a] for various versions of these proofs. See [Bl"a13] for a simplified gadget construction.

3. The current status

We now know much more about the classes VF, VP, VQP, VNP defined above, and about other similarly defined classes. Let’s review these results one by one.

Say that a family of polynomials \((f_n)\) is a \(p\)-family if the number of variables in \(f_n\) and the degree of \(F\) are polynomially bounded functions of \(n\). We only consider \(p\)-families.

Recall that VP consists of \(p\)-families with polynomial-sized circuits. Also note that algorithmically, circuit size roughly corresponds to number of processors needed in a parallel algorithm (associate one processor per gate), while circuit depth – the length of a longest path from the output node to an input node – corresponds to parallel time.

A clever construction due to Hyafil [Hya79] shows that any polynomial of degree \(D\) in \(M\) variables, computable by a circuit of size \(t\), can be computed in parallel time \(O(\log D \times \log(D^2t + M))\). This is a depth-reduction of the circuit, and generalises Csanky’s result which was specifically tailored for the determinant. Further, this
algorithm has parallel multiplicative depth only $O(\log D)$; that is, any root-to-leaf path goes through at most $O(\log D)$ multiplication nodes. This is worth noting since multiplication seems a more costly operation than addition or subtraction. Unfortunately, the resulting circuit, while shallow and depth-reduced, is rather large, roughly $t^{\log D}$. Applying this construction would take us from polynomial-size circuits to shallow quasi-polynomial size circuits. Soon after this, an improved construction was presented by Valiant, Skyum, Berkowitz and Rackoff [VSBR83]: they achieved the same depth-reduction (and also $O(\log D)$ multiplicative depth) with size polynomial in $tD$. In particular, applying this construction to a circuit family $(C_n)$ witnessing that a polynomial family $(f_n)$ is in VP, we see that $(f_n)$ is in $\text{VSAC}^1 \subseteq \text{VNC}^2$.

Wait, what exactly are these new classes? Again, we can think of them as analogues of Boolean classes. The Boolean circuit class $\text{NC}^i$ has circuits of polynomial size and $O(\log^i n)$ depth. The class $\text{SAC}^i$ is similarly defined, polynomial size, $O(\log^i n)$ $\land$-depth, and negations only at inputs. That is, if $\lor$ nodes are allowed to have unbounded in-degree, but $\land$ nodes must have in-degree 2, then these circuits have depth $O(\log^i n)$. (Hence the name SAC, for semi-unbounded alternation.) Clearly, $\text{NC}^i \subseteq \text{SAC}^i \subseteq \text{NC}^{i+1}$. Now define the classes $\text{VNC}^i$ and $\text{VSAC}^i$ as algebraic analogues of these, with $\times$ and $+$ playing the roles of $\land$ and $\lor$ respectively. In the Boolean world, we know that $\text{NC}^1 \subseteq \text{SAC}^1 \subseteq \text{NC}^2 \subseteq \ldots \subseteq \text{NC} \subseteq \text{P}$. In the algebraic world, however, $\text{VNC}^1 \subseteq \text{VSAC}^1 = \text{VNC}^2 = \ldots = \text{VNC} = \text{VP}$.

An important consequence of the depth reduction result of [VSBR83] is that the $(\text{Det}_n) \in \text{VQF}$ result generalises to all of VP; $\text{VP} \subseteq \text{VQF}$. Another important consequence is that at quasi-polynomial size, formulas are as powerful as circuits; $\text{VQF}$ equals $\text{VQP}$. Such an equivalence is not known for $p$-families at polynomial size. (It holds at exponential size, because polynomials in any $p$-family have only exponentially many monomials. An explicit sum-of-monomials expression gives an exponential sized formula.)

Even before the results of [Hya79, VSBR83], Brent [Bre74] had shown that depth-reduction is possible for VF. Any formula $F$ can be rebalanced by identifying in it a suitably chosen node $N$ and rewriting $F$ as a linear form in $N$, say $AN + B$. If $N$ is properly chosen, then the polynomials $A$ and $B$ are computed by small sub-formulas (size at most half of $F$) of $F$, and can be recursively rebalanced. The appropriate $N$ is identified by using the tree separator lemma. This process yields a $O(\log \text{size}(F))$ depth formula. Thus we conclude $\text{VF} = \text{VNC}^1$. 

8
The depth reduction for VP from [VSBR83] proceeds similarly, but works on “proof-trees” or parse trees. Unfolding a circuit into a formula by systematically duplicating reused nodes may yield an exponential sized formula (recall the example $X^{2^n}$.) Let us nonetheless do so. Now, a minimal sub-formula that includes the output node, both children of an included $\times$ node, and exactly one child of an included $+$ node, computes a potential monomial whose degree is the number of leaf nodes in the sub-formula. Call such a sub-formula a proof tree. For a circuit computing a $p$-family of polynomials, we can ignore proof trees of super-polynomial size. For each polynomial-sized proof tree, the balancing technique described above should work. The catch is, there can be too many proof trees (there can be exponentially many monomials), and each proof tree could require cutting at a different node. The clever twist is the following: in the formula depth-reduction, $A$ can be computed recursively because it is the partial derivative of $F$ with respect to $N$. If $F$ is now a circuit rather than a formula, then $F$ may not be linear in $N$, so computing the partial derivative will not help. But if $N$ is chosen to have degree more than half the degree of $F$, then this is indeed the case. So the algorithm of [VSBR83] computes, for each pair of nodes $N, N'$, a new polynomial $F(N, N')$; these polynomial are recursively constructed, and whenever $2\deg(N) > \deg(N')$, $F(N, N')$ equals the partial derivative of $N'$ with respect to $N$. Putting this together carefully gives the depth-required circuit. For details, see [VSBR83] itself. Also see [AJMV98a] and [Vol99] for uniform versions, where the task of describing the depth-reduced circuit given the original circuit is achieved using limited computational resources.

A couple of things slipped by almost unnoticed. We know what is meant by the degree of a polynomial, but what do we mean by $\deg(N)$? This should be the degree of the polynomial computed at the node $N$, and indeed [VSBR83] use degree in this sense. But the uniform versions cannot do so, because computing the degree of a specified node in a given circuit is a completely non-trivial task! See the discussion about DegreeSLP in [ABKPM09, Kay10]. Fortunately, we can equally easily work with an upper bound on the degree of each node. And an upper bound $u(N)$ on the degree at each node $N$ is easy to obtain: $u(N) = 1$ if $N$ is a leaf, $u(N_1 + N_2) = \max\{u(N_1), u(N_2)\}$, $u(N_1 \times N_2) = u(N_1) + u(N_2)$. This upper bound is referred to as the complete formal degree of the circuit (as opposed to the degree of the polynomial it computes). However, just because the output node of $C$ computes a polynomial of degree $d$, this does not imply that each node computes a polynomial of degree at most $d$. Higher
degree monomials may get computed along the way, and get cancelled finally. Is it necessary, in terms of efficiency, to compute them? No! If $C$ is of size $s$ and computes a polynomial $f$ of degree $d$, then we can construct a circuit $C'$ of size $O(sd^2)$ computing the same polynomial and with each node computing a polynomial of degree at most $d$: just compute the homogeneous parts of $f$ separately in the obvious way. Now $C'$ will have complete formal degree $O(d^3 s)$. (See [MP08] for details.) Thus we could have defined VP in terms of circuits of polynomial size and polynomially bounded complete formal degree as well.

There is a much simpler proof of the fact that VP is contained in VNC. This proof yields a weaker upper bound of VSAC$^2$ rather than VSAC$^1$, but is still beautiful, and is still enough to conclude that $VP \subseteq VQF$. I first saw this proof in a survey talk by Pascal Koiran at Dagstuhl [Koi10], and I wish I had come up with it myself! Let $(f_n)$ be in VP, as witnessed by a circuit family $(C_n)$ with complete formal degree bounded by $(dn)$. To depth-reduce $C_n$, partition the nodes into $1 + \lceil \log d_n \rceil$ parts; part $k$ has nodes with formal degree in $[2^{k-1}, 2^k)$. Treating the polynomials from parts $i < k$ as variables, the nodes in part $k$ form a skew circuit, where each $\times$ node has at most one child that is not an input node. (Multiplying two nodes both in part $k$ would create high degree, giving rise to a node in part $k + 1$.) Now, skew circuits can be depth-reduced to VSAC$^1$ rather easily, using a divide-and-conquer argument dating back to Savitch [Sav70]. Doing this separately for each part gives a VSAC$^2$ circuit.

We just introduced a new kind of circuit there: skew circuits. Are they as powerful as general circuits? We do not know! Let’s define $VP_{skew}$; $p$-families of polynomials computed by polynomial-sized skew circuits. It turns out this is a great class to study, because it exactly characterises the complexity of the determinant. Recall what we have already seen; $(\text{Det}_n)$ is hard for $VF = VNC^1$ and is in VP. The upper bound proof from [MV97] actually gives a skew circuit of size $O(n^4)$, but skew circuit constructions were known much earlier: in [Ven92], Venkateswaran first defined Boolean skew circuits to capture nondeterministic circuits, and subsequently many authors independently extended that study to arithmetic rings, [Dam91, Tod92, Cin91, Val92]. And the lower bound proof from [Val79] shows that polynomials computed by skew circuits are $p$-projections of the determinant, though it is not stated this way. Valiant showed that a formula can be converted to a certain kind of graph that we nowadays call an algebraic branching program or ABP (more about this below), and that polynomials computed by
ABPs are \( p \)-projections of \((\text{Det}_n)\). And we now know that ABPs are essentially skew circuits.

Time to define ABPs. These are directed acyclic graphs, with a designated source node \( s \) and a designated target sink node \( t \) (sometimes there may be multiple target nodes), and with edges labeled from \( \mathbb{F} \cup X \) (similar to input nodes in a circuit). For any directed path \( \rho \), the weight of \( \rho \) is the product of the labels of the edges on \( \rho \). The polynomial \( p_v \) computed at a node \( v \) is the sum of the weights of all directed \( sv \) paths. The polynomial computed by the ABP is just \( p_t \). Families computed by polynomial-size ABPs form the class VBP. (In some parts of the literature, edge labels are allowed to be linear forms in \( X \). This does not significantly change the properties of ABPs as we discuss here. We’ll stick to the convention that labels are in \( \mathbb{F} \cup X \).)

So why are ABPs and skew circuits essentially the same? ABPs to skew circuits: clearly, \( p_s = 1 \), and for any other source node (in-degree 0) \( s' \), \( p_{s'} = 0 \). Look at an edge \( u \to v \) of the ABP with label \( \ell \). Then \( p_v \) has a contribution from \( p_u \times \ell \). Summing this over all incoming edges at \( v \) gives a small circuit computing \( p_v \) from previously computed values, and this circuit is skew. For the reverse simulation, reverse this construction: (1) introduce a source node \( s \), (2) for each input node \( u \) labeled \( \ell \), add an edge \( s \to u \) labeled \( \ell \), (3) for each node \( v = u + u' \), create edges \( u \to v \) and \( u \to v \) labeled 1, and (4) for each node \( v = u \times \ell \), create an edge \( u \to v \) labeled \( \ell \).

So now we can add to the list of results at the end of Section 2: \((\text{Det}_n)\) is complete for \( \text{VBP} = \text{VP}^{\text{skew}} \) under \( p \)-projections.

In fact, we can add more. What makes the simulation from skew circuits to ABPs possible is the fact that at each \( \times \) gate, one argument is easy. Toda [Tod92] took this argument further – it is enough if one argument is independent of the rest of the circuit. That is, for each \( \times \) node \( \alpha = \beta \times \gamma \), the entire sub-circuit rooted at either \( \beta \) or \( \gamma \) has no connection to the rest of the circuit except via this edge to \( \alpha \). (Equivalently, one of the edges into \( \alpha \) is a bridge in the circuit.) Call such circuits weakly skew circuits. Toda showed that weakly skew circuits can be converted to skew circuits with linear size blow up. See also [MP08], where Malod and Portier made the size bounds in the conversions even more precise. So now we can say \( \text{VBP} = \text{VP}^{\text{skew}} = \text{VP}_{\text{ws}} \), where the subscript \( \text{ws} \) stands for weakly skew.

(Note: Neither [Tod92] nor [MP08, Mal03] actually claimed linear size blow-up. However, their constructions from weakly skew circuits to ABPs, with the standard conversion from ABPs to skew...
circuits, does give linear blowup. As far as I can see, linear blowup for weakly-skew to skew circuits was explicitly observed in [KK08, Jan08, Gre12a].

Taking this idea further, Malod and Portier provide a brilliant characterization of the class VP. Say that a circuit is disjoint if at every node $\alpha = \beta \circ \gamma$, where $\circ$ could be $+$ or $\times$, the sub-circuits rooted at $\beta$ and $\gamma$ are disjoint. This is just a fancy (convoluted?) way of saying that the circuit is a formula. But now relax this constraint a bit. Say that a circuit is multiplicatively disjoint or MD if at every $\times$ node $\alpha = \beta \times \gamma$, the sub-circuits rooted at $\beta$ and $\gamma$ are disjoint. No restrictions apply to $+$ nodes. Like formulas, MD circuits of size $s$ have complete formal degree bounded by $s$. But the MD restriction seems to allow more computation than formulas; for instance, weakly skew circuits are MD, and so MD circuits can compute $(\text{Det}_n)$ in polynomial size. Malod and Portier showed that in fact polynomial-size MD circuits can compute everything in VP, but nothing more. That is, $\text{VP} = \text{VP}_{\text{MD}}$. While this fact can also be deduced once we have depth-reduction to VSAC$^1$, Malod and Portier give a completely self-contained combinatorial proof which is very neat. Basically, imagine that each node in the VP circuit is labeled with its formal degree. Now make multiple copies of each node, inversely proportional to the formal degree. By carefully deciding which copies of its children to use to construct a copy of a node, multiplicative disjointness can be achieved with only polynomial blow-up in size.

A nice consequence of this characterization of VP is a simpler proof of the fact that VP is contained in $\sum \cdot \text{VF}$. The key observation used is that a circuit is multiplicatively disjoint exactly when every proof tree is already a sub-graph of the circuit (even without any unfolding into a formula). See [MP08] for details.

Before we move on, we note another surprising relation between ABPs and formulas: VF equals the class of $p$-families computed by polynomial-size ABPs of constant width. What is this resource “width”? Recall that an ABP is a DAG with edges going “in the direction from $s$ to $t$”. Suppose we impose a layering constraint. The nodes of the DAG must be laid out at the vertices of a rectangular $w \times \ell$ grid, the node $s$ must be at position $(S, 1)$ for some $S \in [w]$, the node $t$ must be at position $(T, \ell)$ for some $T \in [w]$, and edges can only go across one layer, from $(i, k)$ to $(j, k + 1)$ for some $i, j \in [w]$, $k \in [\ell - 1]$. Of course, any ABP can be converted to one of this form: just sub-divide edges when necessary and label the sub-division path so that its weight is the original edge’s label (use lots of 1s). Now we say that $w$ is the width of the layered ABP and $\ell$ is the length.
A bounded-width branching program family \((B_n)\) is one where for some absolute constant \(c\), each \(B_n\) has width at most \(c\). Seems quite a squeeze – if we view moving from \(s\) towards \(t\) as an incremental computation, then at each stage we can carry forward just \(c\) intermediate polynomials. We shouldn’t be able to do much this way, right? Wrong! Ben-Or and Cleve \([BOC92]\) showed, in a proof cleverly extending Barrington’s famous characterisation \([Bar89]\) of \(\text{NC}^1\) by Boolean bounded-with branching programs, that every formula of depth \(D\) has an equivalent bounded-width branching program (that’s quite a mouthful; let’s agree to call it \(\text{BWBP}\)) of length \(4^D\) and width just \(3\)! Since we already know that formulas can be depth-reduced and \(\text{VF}\) equals \(\text{VNC}^1\), we see that \(\text{VF}\) is contained in a class that we can name \(\text{VBWBP}\): polynomial-sized constant-width ABPs. The converse inclusion is easily seen to hold, again using a Savitch-style divide-and-conquer. Thus we have another characterisation of \(\text{VF}\).

As a matter of curiosity, one may want to know: is the width-3 upper bound tight? Allender and Wang \([AW11]\) recently settled this question affirmatively: they show that a very simple polynomial cannot be computed by any width-2 ABP, no matter what the length. On the other hand, width-3 ABPs are universal, since every polynomial family has some formula family computing it. The question is one of efficiency: which families have polynomial-size width 3 ABPs?

OK, so we’ve had a plethora of class definitions, but just a handful of distinct classes: \(\text{VF} = \text{VP}^e = \text{VNC}^1 = \text{VBWBP}\), \(\text{VBP} = \text{VP}^\text{skew} = \text{VP}^\text{ws}\), \(\text{VP} = \text{VP}^\text{MD}\), \(\text{VQF} = \text{VQP}\), \(\text{VNF} = \text{VNP}\).

As stated in \([B" ur09a]\), Valiant’s hypothesis says that \(\text{VNP} \not\subseteq \text{VP}\), and Valiant’s extended hypothesis says that \(\text{VNP} \not\subseteq \text{VQP}\). Over fields of characteristic not equal to 2, these imply: \(\text{Perm}_n\) is not a \(p\)-projection of \(\text{Det}_n\), and \(\text{Perm}_n\) is not a \(qp\)-projection of \(\text{Det}_n\), respectively.

Some miscellaneous results, in no specific order:

1. Let \(\text{SymDet}_n\) be the polynomial that represents the determinant of a symmetric \(n \times n\) matrix of indeterminates \(B_n\). (For instance, \(\text{SymDet}_2 = x_{11} x_{22} - x_{12}^2\).) Clearly, \((\text{SymDet}_n)\) is a \(p\)-projection of \((\text{Det}_n)\). The converse is also almost true. As shown by Grenet, Kaltofen, Koiran and Portier in \([GKKPT11]\), over any field of characteristic other than 2, \(\text{Det}_n\) is a projection of \(\text{SymDet}_n^3\). Characteristic 2 is a problem: symmetric matrices correspond to undirected graphs, so each undirected cycle gives rise to two directed cycles, and so to get a projection we need division by 2. In characteristic 2, \(\text{Det}_n\) itself is provably not a projection of \(\text{SymDet}_m\) for any \(m\); see \([GMT13]\). The best that
we can currently say in characteristic 2 is that the squared determinant \( (\text{Det}_n)^2 \) is a projection of \( \text{SymDet}_{2n^3+2} \); this is also shown in \[GKKPT]\.

2. VQP is also characterized by quasi-polynomial-size weakly skew circuits of polynomial degree. (From \[VSBR83\] it follows that \( \text{VQP} = \text{VQF} \); hence the above characterization. A direct proof is presented in \[MP08\].) Several natural polynomials are complete for this class under \( qp \)-reductions: the \( (\text{Det}_n) \) family, of course, but also, the trace of iterated matrix product and the trace of a matrix power. These families are all complete for VBP under \( p \)-reductions.

3. While we do not know the exact relationship between VQP and VNP, \( \text{VQP} \) and \( \text{VNP} \) (they both contain VP), we do know that VQP does not equal either VP or VNP. Bürgisser (\[Bü00a\], Section 8.2) has shown that there is an explicit family of polynomials \( (f_n) \) in VQP that is provably not in VNP, let alone in VP. This family is defined as follows: Consider numbers in base \( n \). Let \( \mu \) range over all such numbers with \( m(n) = \lceil \log n \rceil \) digits. More precisely, let \( \mu \) range over length-\( m(n) \) sequences over the alphabet \( \{0, 1, \ldots, n-1\} \), and let \( k_n(\mu) \) denote the value of this sequence, \( k_n(\mu) = \sum_{j=1}^{m(n)} \mu_j n^{j-1} \). Define \( f_n \) as:

\[
f_n(x_1, \ldots, x_{m(n)}) = \sum_{\mu \in \{0, \ldots, n-1\}^{m(n)}} 2^{k_n(\mu)} \prod_{j=1}^{m(n)} x_j^{\mu_j}
\]

Exploiting the fact that the distinct double exponentials appear as coefficients in \( f_n \), Bürgisser shows that \( f_n \) cannot be in VNP.

Furthermore, using \( m(n) = \lceil \log^i n \rceil \) gives a family of polynomials \( f^i \) in VQP with size \( O(n^{\log^i n}) \) but provably not in size \( O(n^{\log^{i-1} n}) \), so within VQP there is a strict hierarchy.

4. From the \( qp \)-completeness of \( (\text{Det}_n) \) for VQP, and the \( p \)-completeness of \( (\text{Perm}_n) \) for VNP, it follows that \( \text{VNP} \subseteq \text{VQP} \) if and only if \( (\text{Perm}_n) \) is a \( qp \)-projection of \( (\text{Det}_n) \). This is a very long-standing open question. Originally the question of whether \( (\text{Det}_n) \) and \( (\text{Perm}_n) \) are \( p \)-equivalent was posed by Pólya \[P13\], who also showed that there is no way of expressing the permanent as the determinant by only changing the signs of selected entries (except for \( n = 2 \); flip the sign of \( a_{12} \) to get matrix \( B \) with \( \text{Det}(B) = \text{Perm}(A) \)). (I haven’t myself seen Pólya’s note, but have seen it referred to in various places.) Marcus and Minc \[MM61\] showed that there is no size-preserving transformation \( (\text{Perm}_n \to \text{Det}_n) \), even if we relax the notion of projections.
to allow linear form substitutions for each variable. For many years, a linear lower bound was the best known (Ω(√2n) due to [vzG87, Cai90, Mes89]), until Mignon and Ressayre [MR04] showed that over the fields of characteristic 0 (e.g., real or complex numbers), even if linear form substitutions are allowed in projections, to express Perm\(_n\) as a projection of Det\(_m\), we need \(m ≥ n^2/2\). The same lower bound was obtained for fields of characteristic other than 2 by Cai, Chen and Li [CCL10].

From Ryser’s work [Rys63] it follows that Perm\(_n\) is a projection of Det\(_m\) for some \(m < n^2\). More recently, Grenet showed [Gre12b] via a very simple and neat construction that Perm\(_n\) is a projection of Det\(_m\) for \(m = 2^n - 1\). This is the best known so far. Thus there is a huge gap between the lower and upper bounds on what is called the determinantal complexity of the permanent.

5. It is natural to believe that the complexity of a \(p\)-family \((f_n)\) in this framework is closely related to the computational complexity of evaluating \(f_n\) for a given instantiation of its variables. In [Bürg00], Bürgisser gave this belief a firm footing. Consider a \(p\)-family \((f_n)\) where \(f_n\) depends on \(n\) variables. Define its Boolean part \(\text{BoolPart}(f)\) as a string function mapping \(x ∈ \{0, 1\}^n\) to the binary encoding of \(f_n(x)\). Note that we have considered only Boolean values. Even so, evaluation may seem difficult, because the circuits for \((f_n)\) can involve arbitrary constants from the field. Bürgisser showed that assuming the generalised Reimann hypothesis GRH, over fields of characteristic zero, \(\text{BoolPart}(\text{VP})\) has non-uniform multi-output NC\(^3\) circuits. Furthermore, assuming GRH, if Valiant’s hypothesis is false over such a field, then the entire polynomial hierarchy has (non-uniform) NC circuits.

6. An extreme depth-reduction result is given by the highly influential paper of Agrawal and Vinay [AV08]. To first see the context, note that any polynomial in \(n\) variables with degree \(d\) has an unbounded fan-in depth-2 circuit of size \(2^{O(d + d\log \frac{d}{\log d})}\). (If \(d ∈ Ω(n)\), then \(2^{O(d)}\) suffices, otherwise the second term in the exponent makes up.) This is because we can just explicitly compute all monomials of degree at most \(d\), and add up the required ones with suitable weights. Now, can we find circuits substantially better than this, say even \(2^{o(d + d\log \frac{d}{\log d})}\), if we allow depth to be increased a bit? Agrawal and Vinay showed that indeed this is possible, even with depth 4, provided there is some circuit (not necessarily depth-reduced) of that size to begin with.
The idea is extremely simple. Perform the depth-reduction from [VSBR83] or [AJMV98b], and ensure with some additional care that degree provably drops at \( \times \) gates. (The price for this is small: a \( \times \) gate may have fanin up to 6, instead of 2.) Now, choose a horizontal cut in the depth-reduced circuit so that for the sub-circuit above it, and for the sub-circuits below it rooted at gates on the cut, the “brute-force” construction described above is small. Obviously there is a trade-off: if the cut is too high up, the lower sub-circuits can have large explicit forms, but if it is too low down, the upper sub-circuit can have large explicit forms. Cut in the right place, and everything works out!

Subsequently the extreme depth-reductions have been pushed further; see [Koi12, Tav13, GKKS13b]. The lower bound results of [GKKS13a, FLMS13] show that the depth-reduction upper bound from [Tav13] is tight and cannot be pushed any further.

This has significant implications for the quest for derandomizing algorithms for the well-studied problem ACIT (arithmetic circuit identity testing) — checking if a given circuit computes the identically-zero polynomial. But that is not directly connected with this survey. One question it raises here is: what kind of extreme depth-reduction can we achieve for VQP? Can we stay within quasi-polynomial size?

4. The syntactic multilinear world

Much of the study concerning VP and VNP involves the families (Det\(_n\)) and (Perm\(_n\)). The polynomials in both families are multilinear. In principle, to compute a multilinear polynomial via a circuit, we need never compute intermediate polynomials that are not multilinear. Let us call such circuits, where the polynomial computed at each node is multilinear, multilinear circuits. However, often it is the case that allowing non-multilinear terms at intermediate stages, and eventually cancelling them out, allows more efficient computation (smaller circuits). This leads to the following quest: what kind of multilinear \( p \)-families have efficient multilinear formulas, or even multilinear circuits, where each intermediate polynomial is required to be multilinear? Even for the (Det\(_n\)) family, which we know is multilinear and in VP, we do not know of polynomial-size multilinear circuits. That being the case, can we prove lower bounds?

This question is trickier than it seems at first glance, because given a circuit, even checking whether it is multilinear is non-trivial.
Fournier, Malod and Mengel [FMM12] recently observed that checking multilinearity of a given circuit is computationally equivalent to the well-studied problem ACIT (arithmetic circuit identity testing) — checking if a given circuit computes the identically-zero polynomial.

So we may want a notion of certifiably multilinear circuits. One such notion is that of syntactic multilinearity, SM. A circuit is said to be syntactically multilinear if at every $\times$ node $\alpha = \beta \times \gamma$, the sub-circuits rooted at nodes $\beta$ and $\gamma$ operate on disjoint sets of variables. Note that this is much more restrictive than multiplicative disjointness. But it certifies multilinearity, since no variable can ever get multiplied by itself. And syntactic multilinearity is easy to check computationally: it is violated if there is some node $\alpha = \beta \times \gamma$, some variable $x$, two input nodes $I, I'$ labeled $x$, and paths from $I$ to $\beta$ and $I'$ to $\gamma$.

If a family has efficient (polynomial-sized) SM circuits, then it has efficient multilinear circuits. The converse may not be true. But it is true if we look at formulas. Given a multilinear formula, identify an SM violation $\alpha, \beta, \gamma, x$ as above. Then we know by multilinearity of the polynomial $p(\alpha)$ that $x$ does not appear in either $p(\beta)$ or $p(\gamma)$. In the appropriate sub-formula, set all instances of $x$ to 0; the polynomials computed at and above $\alpha$ remain unchanged. Doing this systematically gives an SM formula of size no more than the original multilinear formula.

In the first major breakthrough, Ran Raz [Raz09] showed that for computation by SM formulas, and hence by multilinear formulas, both $(\text{Det}_n)$ and $(\text{Perm}_n)$ need size $n^{\Omega(\log n)}$. Clearly, this also means that they are not in SM-$\text{VNC}^1$.

Since $(\text{Det}_n)$ is in VP and even in VBP, SM-VF is strictly weaker than VBP. But this is hardly a fair comparison: we have restricted VF to be SM, but not VBP and VP. Can we say that SM-VF is strictly weaker than SM-VBP or SM-VP? We do not know whether $(\text{Det}_n)$ is in multilinear VP, let alone SM-VP, so a different family is needed as a separating example. Such an example was provided soon thereafter, again by Ran Raz [Raz06]. He constructed an explicit polynomial family that is in SM-VP and even in SM-VSAC$^1$, and showed that it needs SM-formula size $n^{\Omega(\log n)}$ and hence is not in SM-$\text{VNC}^1$. Improved lower bounds for constant-depth circuits and subclasses of formulas were subsequently obtained by Raz, Shpilka and Yehudayoff (see for instance [RY09], [RSY08]).

Let’s step back a bit. Why did we say “in SM-VP, and even in SM-VSAC$^1$”? Aren’t VP and VSAC$^1$ the same? Well, we know
that VP and VF can be depth-reduced. But can we assume that these depth-reduction techniques preserve syntactic multilinearity? Fortunately, they do; Raz and Yehudayoff [RY08] showed that the depth-reduction of [VSBR83] preserves SM, so indeed SM-VP = SM-VSAC\(^1\). Similarly, in [JMR12] it is observed that the formula depth-reduction of [Bre74] also does preserves SM, so SM-VF = SM-VNC\(^1\).

What about other relationships between the algebraic classes? We had considered ABPs – what certifies multilinearity there? It is easy to see that a read-once restriction, where on each path in the ABP each variable appears as a label at most once, does so. Let us therefore use read-once as the definition of syntactic multilinearity in ABPs. Then, as observed in [JMR12], the Savitch-style divide-and-conquer argument preserves SM. So does the conversion from formulas to ABPs, [Val79]. But the conversion from formulas to width-3 ABPs, [BOC92], does not. In fact, Rao [Rao10] showed that even a significant generalisation of Ben-Or and Cleve’s technique, using polynomially many registers instead of just 3, cannot preserve syntactic multilinearity. Of course, there may be other ways of going from SM-VF to SM-VBWBP, but it could equally well be that the classes are distinct.

To get back perspective, in the SM world what we have seen so far is:

\[
\text{SM-VBWBP} \subseteq \text{SM-VF} \subseteq \text{SM-VBP} \subseteq \text{SM-VP}
\]

As mentioned earlier, Raz [Raz06] showed that the inclusion from SM-VF to SM-VP is proper. Very recently, this was improved by Dvir, Malod, Perifel, and Yehudayoff [DMPY12]. They showed that in fact the inclusion SM-VF \(\subseteq\) SM-VBP is strict. Whether the first and the last inclusion are strict is still open.

The proof of [DMPY12] is a clever adaptation of the original technique from [Raz06]. Let us briefly examine this.

The central ingredient in Raz’s proof is randomly partitioning the variables and analysing the rank of the resulting partial derivatives matrix. Consider a polynomial \(f\) on \(2n\) variables \(X = \{x_1, \ldots, x_{2n}\}\), and consider a partition of \(X\) into equi-sized sets \(Y, Z\). Consider a \(2^n \times 2^n\) matrix \(M_f^{Y,Z}\) where rows and columns are indexed by subsets of \(Y\) and \(Z\) (equivalently, multilinear monomials over \(Y\) and \(Z\) respectively). The entry \((m_y, m_z)\) is the coefficient of the monomial \(m_y \cdot m_z\) in \(f\). Intuitively, if \(M_f^{Y,Z}\) has high rank, then \(f\) should be hard. But high rank with respect to what partition? Raz showed that if multilinear \(f\) has small SM-formula size, then for at least one partition \((Y, Z)\) of \(X\), \(M_f^{Y,Z}\) will have low rank. (The existence of the partition witnessing low rank is proved using
the probabilistic method; choose a partition at random, and analyse the probability that the resulting matrix has rank exceeding some threshold.) He also constructed an explicit family $g$ in SM-VSAC\textsuperscript{1} and showed that for every partition $(Y, Z)$ of $X$, $M_{g}^{Y,Z}$ has high rank; hence $g$ is not in SM-VF.

The non-trivial adaptation done in [DMPY12] is to consider not all partitions, but a fairly small set of what they call arc-partitions. They showed that if $f$ is in SM-VF, then for at least one arc-partition $(Y, Z)$ of $X$, $M_{f}^{Y,Z}$ will have low rank. They consider an explicit family $g$ in SM-VBP and show that for every arc-partition $(Y, Z)$ of $X$, $M_{g}^{Y,Z}$ has high rank. Hence $g$ is not in SM-VF. The low-rank proof is again probabilistic, but it has a very appealing combinatorial flavour. So does the very definition of an arc-partition.

5. More on completeness

Assume that completeness is defined with respect to $p$-projections. If a family $(f_{n})$ is complete for a class, then understanding $(f_{n})$ better allows us to understand the class better. If a natural family is complete for a class, then this is evidence that the class itself is natural.

Valiant started off with a proof that Perm is VNP-complete. He also showed that polynomial families associated with a number of NP-complete languages are complete for VNP under $p$-projections. So let us agree that VNP is a natural class.

What about VP? The family that naturally contrasts with Perm is Det, but Det is not yet known to be complete for VP (unless we allow $q_{p}$-projections; that is not quite satisfactory). If this turns out to be the case, it will solve a major open problem, showing that polynomial-degree polynomial-size circuits are no more powerful than polynomial-size branching programs VBP. VBP seems a natural enough class, and Det and many other families are complete for it.

So what problems are complete for VP? One can construct a canonical family complete for VP. By canonical, I mean something similar to saying that

$$\{\langle M, x, 1^t \rangle \mid M \text{ is an NDTM that accepts } x \text{ in } t \text{ or fewer steps}\}$$

is NP-complete. Undoubtedly true, but it doesn’t give any new intuition about what NP is about. In the case of VP, the canonical family is not so trivial to construct (but not very difficult either).
The first description, with a very general completeness result, appears in [Bürg00a] (see section 5.6, Cor 5.32(b)). Bürgisser shows that for every $p$-family $h$, the relativized classes $V^p_h$ and $VNP^h$ have complete families with respect to $p$-projections. Since $V^p_h = VP$ and $VNP^h = VNP$ whenever $h$ itself is in $VP$, this gives families complete for $VP$ and $VNP$ as well. (In fact, it shows the existence of VNP-complete families, independent of Valiant’s original proof.) These complete families compute homogeneous components separately, to keep the degree small, and then add up the required parts. They are constructed by first defining generic polynomials, and then defining the appropriate projection / substitution. The generic polynomials capture the canonical notion referred to above.

Later, a more direct construction tailored for $VP$ (as opposed to $V^p_h$ and $VNP^h$ for all $h$) was described by Ran Raz [Raz10], and also appears in [SY10]. Here the proof of hardness exploits the fact that we can perform depth-reduction on $VP$ circuits. (This was not needed in Bürgisser’s proof.) Roughly, here’s how it goes: For each natural number $N$, consider a circuit $C_N$ with nodes arranged in $2 \log N + 1$ layers numbered $0, 1, \ldots, 2 \log N$. All even layers have exactly $N$ nodes, and compute polynomials $g_{i,j}$ where $i$ is the layer number, $j \in [N]$. Odd layers are used to build these polynomials. At layer 0, the polynomials are just distinct variables, $g_{0,j} = x_j$. At higher layers, we have an inductive definition: $g_{i+1,j} = \sum_{k,\ell \in [N]} g_{i,k} \cdot g_{i,\ell} \cdot y_{i,j,k,\ell}$, where the $y_{i,j,k,\ell}$ are new variables. Thus the nodes at the odd layers are the fanin-3 $\times$ nodes, and nodes at even layers (other than the 0 layer) are $+$ nodes with large fanin. (We can reduce the fanins to 2 later; it won’t change the polynomial computed.) The polynomial computed by this circuit at $g_{2 \log N, 1}$ is $p_N$. The total number of variables is $O(N^3 \log N)$, and the circuit is also of size $O(N^3 \log N)$. The degree of $p_N$ is $2N - 1$. So $(p_N)$ is in $VP$. Why is it $VP$-hard? Take any family $(f_n)$ in $VP$. By the depth-reduction of [VSBR83], it can be computed in VSAC$^1$. The VSAC$^1$ circuit $D_n$ can be normalised to have alternating $+$ and $\times$ nodes, with all $\times$ nodes having fanin 2, and all leaves at the same depth. Choose $N$ at least as large as $\min\{\text{size}(D_n), 2^{\text{depth}(D_n)}\}$, and also at least as large as the number of variables in $C_n$. Now, the computation of $D_n$ can be embedded into $C_N$: Choose the right number of $+$ nodes at each even layer, and by carefully assigning $0,1$ values to the $y$ variables, ensure that they compute the required combinations of polynomials from the previous even layer.

The circuits described above are called universal circuits in [SY10], because every circuit is a projection of the universal circuit
of appropriate size. And if we start with VP circuits, the projections are $p$-projections.

So now we know that VP has complete families under $p$-projections as well. But generic polynomials, universal circuits, and the polynomials they compute, are rather artificial. Are there other families that are defined independent of circuits and are VP-complete? Actually, we know very few. Recently, Stefan Mengel [Men11] made further progress here, considering polynomial families associated with constraint satisfaction problems CSPs. (This builds on earlier work by Briquel, Koiran, Meer [BK09, BKM11], though they did not explicitly look for VP-completeness.) Let’s first review what CSPs are. Think of them as generalising CNF-SAT. In CNF-SAT, each clause forbids one assignment to the variables in it. (eg the clause $x_1 \lor \neg x_3$ forbids $x_1 = 0, x_3 = 1$.) In a CSP, variables can take values from a larger domain, not necessarily 0,1. Each constraint is like a clause; it has a set of variables, and it forbids certain combinations of assignments to these variables. (eg on domain $\{a, b, c\}$ a constraint on $x_1, x_2$ could say that $x_1 \neq x_2$. That is, assignments $aa, bb, cc$ are forbidden, the other 6 assignments satisfy this constraint.) As in SAT, we look for assignments satisfying all constraints. If the domain has size 2, the CSP is Boolean. If each contraint involves 2 (or less) variables, the CSP is binary. As usual, consider not just a CSP but a family of CSPs ($\Phi_n$), where $\Phi_n$ has domain $D_n$. For tractability, we will require that the CSP is $p$-bounded; that is, the CSP has bounded arity (for some fixed constant $c$, each constraint in every $\Phi_n$ looks at no more than $c$ variables), and it has polynomial sized domains (in $\Phi_n$, the variables take values from a set $D_n$, where the size of $D_n$ is $p$-bounded). Now associate with each such CSP ($\Phi_n$) a polynomial family ($Q_n = Q(\Phi_n)$), where $Q_n$ is on the variable set $\{X_d \mid d \in D_n\}$ and is defined as follows:

$$Q(\Phi_n) = \sum_{a: \text{var}(\Phi_n) \rightarrow D_n} [a \text{ satisfies } \Phi_n] \prod_{x \in \text{var}(\Phi_n)} X_{a(x)}$$

$$= \sum_{a: \text{var}(\Phi_n) \rightarrow D_n} [a \text{ satisfies } \Phi_n] \prod_{d \in D_n} X_d^{a^{-1}(d)}$$

(Recall, $[S]$ is Boolean, 1 if and only if statement $S$ is true.) Mengel has this wonderful characterization of the complexity of the family ($Q_n$). The characterization involves associating with the CSP a graph $G$; this graph has a vertex for each variable and an edge between two variables if they occur simultaneously in some constraint. Now the treewidth and pathwidth of the graph (these parameters describe roughly how tree-like or path-like the graph is, if we can consider
blobs of vertices. The smaller the blobs, the better the similarity. See [Bod98] for definitions and an overview.) relate to the complexity. It also involves an assignment bound: a CSP is $c$-assignment-bounded if for each constraint $\varphi$ and each variable $x$ in the constraint, the number of distinct values possible for $x$ in assignments satisfying $\varphi$ is bounded by $c$, even though the domain may be much larger. This seems like a strong condition, but recall that Boolean CSPs are by definition 2-assignment-bounded.

Enough of definitions! Here’s what Mengel shows:

1. For each $p$-bounded CSP $(\Phi_n)$, $(Q(\Phi_n))$ is in VNP. Every family $(f_n)$ in VNP is a $p$-projection of $(Q(\Phi_n))$ for some $p$-bounded $(\Phi_n)$.
2. For each $p$-bounded CSP $(\Phi_n)$ where $G_n$ has bounded treewidth, $(Q(\Phi_n))$ is in VP. Every family $(f_n)$ in VP is a $p$-projection of $(Q(\Phi_n))$ for some $p$-bounded binary $(\Phi_n)$ where $G$ is a tree (treewidth 1).
3. For each $p$-bounded CSP $(\Phi_n)$ where $G_n$ has bounded pathwidth, $(Q(\Phi_n))$ is in VBP. Every family $(f_n)$ in VBP is a $p$-projection of $(Q(\Phi_n))$ for some $p$-bounded binary $(\Phi_n)$ where $G$ is a path (pathwidth 1).
4. For each $p$-bounded $c$-assignment-bounded CSP $(\Phi_n)$ where $G_n$ has bounded treewidth, $(Q(\Phi_n))$ is in VF. Every family $(f_n)$ in VF is a $p$-projection of $(Q(\Phi_n))$ for some $p$-bounded 2-assignment-bounded binary $(\Phi_n)$ where $G$ has pathwidth at most 26.

The hardness proofs involve looking at the structure of parse trees for VP, witnessing paths for VBP.

Note that as stated, this falls slightly short of providing a single complete family for VP. However, applying the hardness reduction from universal circuits will yield a single CSP family that is VP-complete. To the best of my knowledge, this is the first instance of a VP-hardness result for a family defined (almost) independent of circuits.

All the above results require that the CSP has bounded arity. Unbounded arity seems to immediately give rise to intractability. If arity is unconstrained, can other types of restrictions still result in families in VP? For further progress in this direction, see [DM11, CDM13].
6. Computing integers

The questions concerning algebraic complexity classes are closely connected to another very intriguing question. Let $N > 1$ be any natural number. Suppose we want to build up $N$ from 1, using only $+,-$, and $\times$. The most naive way of doing this would be $N = 1 + 1 + \ldots + 1$. But depending on $N$ there can be many other ways. Which is the most efficient way? That is, which way uses the least number of $+$ or $\times$ operations? To do anything non-trivial, we must use $+$ at least once, and the first time we use it we will generate 2. So let us not even count this mandatory $+$. How many more operations are needed?

We can state this as a question about circuits. Each way of building up $N$ is an arithmetic circuit, or a straight-line program (SLP), that uses no constants other than 1 and 2. Let us denote by $\tau(N)$ the size of the smallest such circuit computing $N$. (This is the $\tau$ complexity of $N$). By definition, $\tau(1) = \tau(2) = 0$, and for all $N > 2$, $\tau(N) > 0$. Algorithms for computing $N$ give upper bounds on $\tau(N)$. For instance, to compute $N = 2^k$, here’s an SLP:

$$g_0 = 2, \quad g_{i+1} = 2 \times g_i$$

for $0 \leq i \leq k - 2$. Clearly, $g_i$ computes $2^{i+1}$, so $\tau(2^k) \leq k - 1$. But I’m sure you can already see better ways of doing this. From the circuit viewpoint, an explanation of why this is not the best is that the circuit corresponding to this SLP is skew.

Surely we should be able to use non-skew gates and compute large numbers faster. Here’s another SLP that computes big numbers fast:

$$f_0 = 2, \quad f_{i+1} = f_i \times f_i$$

for $0 \leq i \leq \ell - 1$. Clearly, $f_i$ computes $2^{2^i}$, so $\tau(2^{2^\ell}) \leq \ell$, a much better bound than the earlier $2^{\ell} - 1$ at least for numbers of this form. Note that the way we used non-skewness, we produced a circuit with exponential formal degree (the degree at $f_i$ is $2^i$), but we’re not worried about that for now. Now, using these compact circuits for $2^{2^\ell}$, we can build a better circuit for $2^k$ by just using the binary expansion of $k$: $k = \sum_{i=0}^{t} b_i 2^i$, where $t = \lfloor \log k \rfloor$ and $b_t = 1$. So $2^k = 2\sum_{i=0}^{t} b_i 2^i = \prod_{i=0}^{t} 2^{b_i \cdot 2^i} = \prod_{i:b_i=1} 2^{2^i}$. Compute all the double powers using $t$ operations, and then multiply the required ones using at most $t$ operations. Overall, $\tau(2^k) \leq 2t = 2\lfloor \log k \rfloor$.

We can use the same binary expansion idea to compute any $N$, not just a power of 2. Compute all powers of 2 up to $\log N$, and add the required ones. This shows that for all $N$, $\tau(N) \leq 2\lfloor \log N \rfloor - 1$.

So far we have not used any subtractions. But they can be very useful too. For instance, $\tau(2^{2^\ell} - 1) \leq \ell + 1$; compute $2^{2^\ell}$ and subtract 1.

What about a lower bound? We can actually formalise the intuition that the exponential degree circuits we saw above for $2^{2^\ell}$...
produce the largest possible number in that size. Hence, for any \( N \), 
\( \tau(N) \geq \log \log N \).

In particular, \( \tau(2^{2^\ell}) = \ell \). That sounds impressive – we know the exact value of \( \tau \) for \( 2^{2^\ell} \). But essentially just for that; for all other numbers, we still seem to have a pretty large gap. If \( N = 2^k \), then 
\( \log \log N \leq \tau(N) \leq 2\lceil \log k \rceil = 2\lceil \log \log N \rceil \), so we know \( \tau(N) \) within a factor of 2. But for general \( N \), all we know is 
\( \log \log N \leq \tau(N) \leq 2\lceil \log N \rceil - 1 \). How can we reduce this gap? An obvious search for an efficient way where the last operation is + or − is to express \( N \) as \( M \pm k \), compute \( M \), compute \( k = \pm (N - M) \), and combine, and to choose \( M \) that minimizes \( \tau(M) + \tau(k) + 1 \). (A similar approach can be used for factors of \( N \) and a × as the last operation.) But in computing \( M \) and \( \pm (N - M) \) (or \( N/M \)), the complexity may be subadditive since we can reuse intermediate numbers from the program for \( M \) while computing \( \pm (N - M) \) or \( N/M \). (We are looking for circuits, not formulas.) It is identifying the extent of this reuse that is a challenge.

Similar to Shannon’s bound for functions and circuits (most functions require exponential sized circuits), de Melo and Svaiber [dMS96] showed that most numbers \( N \) have \( \tau(N) \) closer to the upper bound. They showed that for every \( \epsilon > 0 \), most \( N \) satisfy \( \tau(N) \geq \frac{\log N}{(\log \log N)^{1+\epsilon}} \). Moreira [Mor97] improved this by showing that this holds even for \( \epsilon = 0 \). (He also showed that for all \( \epsilon > 0 \), there is an \( N_\epsilon \) such that for all \( N \geq N_\epsilon \), \( \tau(N) \leq \frac{(1+\epsilon)\log N}{(\log \log N)} \).) And yet, showing such lower bounds for specific numbers seems quite hard – the classic “searching for hay in a haystack” paradox.

Let’s move over from individual numbers to sequences of numbers. Let \( (a_n)_{n \geq 1} \) be some sequence of natural numbers. When can we say that the sequence is easy to compute? Each number in the sequence should be “easy” relative to its position in the sequence. That is, the sequence \( (b_n) \), where \( b_n = \tau(a_n) \), should not grow very fast. One possible definition is that \( b_n \) should be polynomially bounded in \( n \). For instance, for \( a_n = 2^{2^n} \), we know that \( b_n = n \). Is that not moderate growth? Not really. Consider a function that maps a position \( n \) to not just the number \( \tau(a_n) = b_n \) but to an SLP of size \( b_n \) computing \( a_n \). For the sequence \( (2^{2^n}) \), this function takes an input \( n \) represented in \( \Theta(\log n) \) bits, and outputs a circuit of size \( n \), that is, exponential in the size of the input. That’s not moderate growth!

OK, so let’s say that a sequence \( (a_n) \) is easy to compute if for some polynomial \( p(\cdot) \), for each \( n \), \( \tau(a_n) \leq p(\log n) \), and otherwise it is hard to compute. We’ve set up this definition so that \( (2^{2^n}) \) is hard to compute, while the sequences \( (n) \), \( (2^n) \) are easy to compute.
Makes sense? Now let’s ask, what other sequences are easy? And what sequences are hard?

A sequence with famously open status is \((n!)\). The completely naive SLP that constructs the first \(n\) numbers with \(n-2\) increments and then multiplies them shows that \(\tau(n!) \leq 2n-4\). But can this be improved significantly? Or is this sequence hard? The best we know is that \(\tau(n!) \in O(\sqrt{n}\log^2 n)\); see [BCS97]. Here is the interesting connection to algebraic circuit complexity. Building on a sequence of constructions by Cheng [Che04] and Koiran [Koi05], Bürgisser [Bür09] showed that if \((n!)\) is hard to compute, then any algebraic circuit for the \((\text{Perm}_n)\) family that uses only the constants \(-1, 0, 1\) must be of superpolynomial size. If we can’t even compute the numbers \(n!\) easily, then we cannot compute the polynomials \(\text{Perm}_n\) efficiently, unless we allow the use of constants that cannot themselves built up efficiently.

Analogous to the \(\tau\) complexity of natural numbers, we can define the \(\tau\) complexity of polynomial families. Let \(\tau(f)\) denote the size of the smallest algebraic circuit using only the constants \(-1, 0, 1\) – call such a circuit constant-free – and computing \(f\). We say that the family \((f_n)\) has polynomially bounded \(\tau\) complexity if for some polynomial \(p(n)\), and for each \(n\), \(\tau(f_n) \leq p(n)\). Bürgisser’s result can now be stated as: if \(\tau(\text{Perm}_n)\) is polynomially bounded, then \((n!)\) is easy to compute.

Let’s examine this a bit closely. Why do we state the hypothesis as “\(\tau(\text{Perm}_n)\) is polynomial”? Is this not equivalent to saying \((\text{Perm}_n)\) is in VP, and hence VNP = VP? Actually, it may not be equivalent. It is possible that \((\text{Perm}_n)\) has polynomial-sized circuits but no polynomial-sized constant-free circuits. Conceivably, using other constants in intermediate computation and then cancelling them out could help. Recall that the proof of VNP-hardness of \((\text{Perm}_n)\) uses constants other than \(-1, 0, 1\); \(1/2\) is needed. (As another example, recall how in showing that \(\text{Det}_n\) is a projection of \(\text{SymDet}_n\), we needed the constant \(1/2\), even though all coefficients in \(\text{Det}_n\) are \(-1, 0, 1\).) So we can define a subclass of VP: families with constant-free circuits of polynomial size.

What can we say about such a subclass? As described above, Bürgisser has shown that if this subclass contains \((\text{Perm}_n)\), then \((n!)\) is easy to compute. Under the same hypothesis, he also shows that the sequences \([2^n e]\), \([(3/2)^n]\) and \([2^n \sqrt{2}]\) are easy to compute.

Malod [Mal03] observed that unlike in the case of VP, for constant-free circuits we may not be able to bound complete formal degree. For VP, if the polynomial computed by a circuit of size
$s$ had degree $d$, we could find an equivalent circuit with formal degree $d$, and another with complete formal degree $O(d^3 s)$, with only polynomial blow up in size. Not so if constants aren’t freely available! Consider the polynomial family $f_n = 2^{2n} (x_1 + \ldots + x_n)$. With arbitrary constants, we have a circuit of size $n$. With only $-1, 0, 1$, we have a circuit of size $2n + 1$: build 2, build $2^{2n}$, build the linear form, multiply. But this circuit has exponential formal degree, and in fact, using only the constants $-1, 0, 1$, any circuit must have exponential formal degree to build up $2^{2n}$. So this polynomial is in VP, it has constant-free circuits of polynomial size, but it does not have constant-free polynomial-size circuits with polynomially-bounded complete formal degree.

This leads to a definition of a further subclass $\text{VP}^0$, first defined in [Mal03]: polynomial families computed by constant-free circuits with polynomially bounded complete formal degree. Define $\text{VNP}^0$ analogous to VNP as $\sum \cdot \text{VP}^0$. Check back; our proof that $(\text{Perm}_n)$ is in VNP also shows that $(\text{Perm}_n)$ is in $\text{VNP}^0$.

The hypothesis $(\text{Perm}_n) \in \text{VP}^0$ is stronger than saying that $\tau(\text{Perm}_n)$ is polynomially bounded. What does it imply? Can it lead to more sequences being easier to compute? Firstly, note that $(\text{Perm}_n) \in \text{VP}^0$ does not immediately imply $\text{VP}^0 = \text{VNP}^0$. All we can say is the following, shown by Koiran [Koi05]: If $(\text{Perm}_n)$ is in $\text{VP}^0$, then for every family $(f_n) \in \text{VNP}^0$, there is some polynomially-bounded function $p(n)$ such that the family $(2^{p(n)} f_n)$ is in $\text{VP}^0$. That is, a “shifted” version of $f_n$ is in $\text{VP}^0$. The precise shift can be described as follows – we know that $f_n$ is a projection of $\text{Perm}_{q(n)}$ for some polynomially bounded $q(n)$, we assumed that $\text{Perm}_{q(n)}$ can be computed by a circuit $C_n$ of size and formal degree bounded by a polynomial function of $n$, we take $p(n)$ to be the formal degree of $C_n$. Now $C_n$ can be massaged to compute $2^{p(n)} f_n$ instead of $\text{Perm}_{q(n)}$.

This motivates another variant of easy-to-compute. Let’s say that a sequence $(a_n)$ of natural numbers is ultimately easy to compute if at least some shifted version of it is easy to compute. That is, there is some other integer sequence $A_n$ such that the sequence $a_n A_n$ is easy to compute. Note that if $(a_n)$ is not ultimately easy, then for infinitely many $n$, all non-zero multiples of $a_n$ have large $\tau$ complexity. Using this property, under the hypothesis that $n!$ is not even ultimately easy to compute, we can obtain a non-trivial derandomization of the Arithmetic-Circuit-Identity-Testing problem; see the last section of [ABKPM09]. Earlier, Koiran showed in [Koi05] that if $n!$ is not even ultimately easy to compute, then we have some separation: either $\text{VP}^0 \neq \text{VNP}^0$, or $P \neq \text{PSPACE}$. This is curious: we have
a consequence involving Boolean classes as well. But it should not be so surprising. \( VP^0 \) and \( VNP^0 \) are computed by (sums of) constant-free poly-formal-degree algebraic circuits, and these are the arithmetic circuits that arise when we consider counting classes like \( \#P \) that count accepting paths of Turing machines. This does not mean that \( VNP^0 = \#P \); the former is a collection of polynomial families whereas the latter is a collection of functions from strings to whole numbers. But the complexity of evaluating polynomial families in the former collection, at Boolean arguments, is closely related to what the latter collection refers to. Koiran’s proof actually shows the contrapositive: he first shows that if \( VP^0 = VNP^0 \) and \( P = PSPACE \), then the sequence \( \tau((2^\ell)! ) \) is polynomially bounded in \( \ell \). So consider instead of each \( n! \) the possibly larger factorial \( (2^{\ell(n)})! \), where \( 2^{\ell(n)} - 1 < n \leq 2^{\ell(n)} \). Then the sequence \( (b_n) = (((2^{\ell(n)})!) \) is easy to compute, and each \( b_n \) is a multiple of \( n! \), so \( (n!) \) is ultimately easy to compute.

Since \( \text{Perm}_n \) is not known to be complete for \( VNP^0 \), what is? It turns out that for several other \( VNP \)-complete families, the hardness proofs use no constants other than \(-1, 0, 1\) and the membership proofs use circuits with small formal degree; hence these families are complete for \( VNP^0 \) as well. As a concrete example, consider the Hamilton cycle polynomial family \( HC_n \) defined as follows: Let distinct variables \( x_{i,j} \) label the edges of the complete directed graph \( D_n \). Let \( C_n \) denote the set of all directed Hamiltonian cycles in \( D_n \); elements of \( C_n \) can be described by cyclic permutations \( \sigma \in S_n \). Then

\[
HC_n(x_{11}, \ldots, x_{nn}) = \sum_{\sigma \in C_n} \prod_{i\sigma(i)} x_{i,i}.
\]

This family is complete for \( VNP^0 \); ([Mal03]).

Returning to the question “What does \( (\text{Perm}_n \in VP^0 \) imply?”, Koiran ([Koi05]) showed that it implies the sequence \( \lfloor 2^n \ln 2 \rfloor \) is easy to compute. He also improved the earlier-mentioned result in two ways, from “\( (VP^0 = VNP^0 ) \land (P = PSPACE) \) \( \Rightarrow \) \( (n!) \) is ultimately easy to compute” to “\( (\text{Perm}_n \in VP^0) \land (P = PSPACE) \) \( \Rightarrow \) \( (n!) \) is easy to compute”.

Under the stronger hypothesis that \( VP^0 = VNP^0 \), we can show more (again due to [Koi05]). If \( VP^0 = VNP^0 \), then the sequences \( (\sum_{i=1}^{2^n} 2^{i^2 - 1}), [2^{2^n} \ln 2], [2^{2^n} \ln 3], [2^{2^n} \pi] \), all have polynomially bounded complexity, something that is not yet known unconditionally.
Acknowledgements

I thank Arvind and Manindra for inviting me to contribute to this volume in honour of Somenath Biswas, a wonderful professional colleague and friend.

I thank CEFIPRA for supporting an Indo-French collaboration (project 4702-1); many of my ideas for how to present this survey were crystallised during my visit to University of Paris-Diderot during May-June 2012.

I have picked material I find interesting, and have not really attempted an exhaustive coverage. I apologize in advance to those whose favourite results I have omitted.

I gratefully acknowledge many insightful discussions with Eric Allender, V Arvind, Hervé Fournier, Bruno Grenet, Nutan Limaye, Guillaume Malod, Stefan Mengel, Sylvain Perifel, B V Raghavendra Rao, Nitin Saurabh, Kartek Sreenivasaiah, Srikanth Srinivasan, V Vinay. I thank the organisers of the Dagstuhl Seminars on Circuits, Logic and Games (Feb 2010) and Computational Counting (Dec 2010) for inviting me and giving me the opportunity to discuss these topics. The survey by Pascal Koiran at the Dagstuhl seminar on Computational Counting in Dec 2010 was particularly helpful.
