This study investigated the ability of cerium hydroxide (CE) to adsorb phosphate, and compared it to the aluminum compounds boehmite (BE) and gibbsite (GB), which possess high phosphate adsorption ability. Specific surface area, number of hydroxyl groups, and amount of phosphate adsorbed were measured. Results indicated that specific surface area increased in the order GB < CE < BE, number of hydroxyl groups increased GB < BE < CE, and amount of phosphate adsorbed increased GB < BE < CE. These results showed that the adsorption mechanism of phosphate using CE was more closely related to chemical factors involved in the exchange of phosphate with hydroxyl groups onto CE than to physical factors such as specific surface area. Keywords: Cerium hydroxide; Phosphate; Ion exchange

I. INTRODUCTION

Phosphate has received attention because of its role in eutrophication and its limited abundance in nature. Methods for the removal and reuse of phosphate have been reported. For example, layered double hydroxides (LDHs) [1–4], inorganic materials including metal oxide hydroxides [5], metal oxides [6], and enhanced biological phosphorus removal (EBPR) processes [7] have been investigated. The adsorption mechanism of these methods involved ion exchange, ligand exchange with surface hydroxyl groups to create inner-sphere complexation, bonding between adsorbed phosphate and adsorptive sites on the surface, dissolution-coagulation, and surface precipitation. A previous report described the phosphate adsorption ability of boehmite (BE) and gibbsite (GB), which involves an adsorption mechanism of ion exchange with hydroxyl groups and the surface [8–11]. BE and GB also possessed the ability to adsorb arsenic and chromium ions [12, 13].

However, cerium is the most abundant of the rare earth elements in the earth’s crust, greater than that of lead (16 mg/g) and zinc (40 mg/g). Considering the residual amount of rare earth elements in the earth’s crust, it is likely they will be mined for another 1200 years [14]. Cerium is used as an abradant, as a decolorization agent for glass, and as a catalyst, especially for water purification. In particular, adsorption of arsenic by cerium has been reported [15, 16]. Cerium can maintain hydroxyl group on its surface as well as BE and GB. However, there are no reports regarding the adsorption of phosphate by cerium.

In this study, the ability of cerium to adsorb phosphate was investigated because cerium can maintain hydroxyl groups on its surface and has an arsenic adsorption ability similar to that of BE and GB.

II. EXPERIMENTAL

A. Materials

AD220NS (Tomita Pharmaceutical Co., Ltd., Japan) was used as BE. For the BE, noncrystalline aluminum hydroxide was placed in an aqueous medium, and after heat treatment at 90-100°C for 1-3 h, the aluminum oxyhydroxide obtained was spray-dried. Its chemical composition was 69.5% Al2O3, with less than 0.1% Cl− and less than 0.8% SO42−. Loss of mass upon drying, pH, mean particle size, and pore volume were 7.8%, 8.2, 100 μm, and 0.402 mL/g, respectively. GB (GBH-42M) was purchased from Showa Denko (Japan). Its adhesion moisture was 0.23%, and the composition was 99.6% Al(OH)3, 0.01% Fe2O3, 0.01% SiO2, 0.33% Na2O and 0.05% ω-Na2O. Mean particle size, bulk density (light), bulk density (heavy), and moisture adsorption capacity were 1.1 μm, 0.2 g/cm³, 0.5 g/cm³, and 0.90%, respectively. Cerium hydroxide (CE) was purchased from Wako Pure Chemical Industries Co., Ltd. CE was included as CeO2 at 80-87%; solubility was good in acidic solution, but was poor in alkaline solution.

The number of hydroxyl groups was calculated from the amount of adsorbed fluoride ion as follows [17]: 1.25 g of adsorbent was added to 50 mL of 0.01 mol/L NaF solution at pH 4.6, which was then adjusted using 0.2 mol/L acetic acid and 0.2 mol/L sodium acetate buffer. The solution was shaken at 25°C for 24 h at 100 rpm and then filtrated using a 0.45-μm membrane filter. The concentration of fluoride ions in the filtrated solution was measured [18], and the amount of fluoride ion adsorbed onto adsorbent

was calculated. Specific surface area was measured using NOVA4200e (Quantachrome Co., Ltd. Japan).

**B. Adsorption of phosphate**

Potassium dihydrogenphosphate was purchased from Wako Pure Chemical Industries Co., Ltd. The amount of phosphate adsorbed was measured by the following procedure: 0.05 g of adsorbent was added to 50 mL of phosphate solution at an initial concentration 1110-1150 mg/L. The solution was shaken at 25°C for 24 h at 100 rpm and then was filtrated using a 0.45-μm membrane filter. The concentration of phosphate was measured using DR/890 (HACH, U.S.A.). The amount of phosphate adsorbed onto the adsorbent was calculated using the concentrations before and after adsorption as follows:

$$X = (C_0 - C)V/M,$$

where $X$ is the amount of phosphate adsorbed (mg/g), $C_0$ is the concentration before adsorption (mg/L), $C$ is the concentration after adsorption (mg/L), $V$ is the solvent volume (L), and $M$ is the mass of adsorbent (g).

**III. RESULTS AND DISCUSSION**

The specific surface area, number of hydroxyl groups, and number of hydroxyl groups per unit of BE, GB, and CE are shown in Table I. Results indicated that specific surface area increased in the order GB < CE < BE, while the number of hydroxyl groups increased in the order GB < BE < CE. Reports have demonstrated that the amount of phosphate adsorbed using untreated BE was greater than that using untreated GB, and adsorption of phosphate was related to specific surface area and the number of hydroxyl groups on the surface [8, 9]. The data in Fig. 1 shows that the amount of phosphate adsorbed by BE, GB, and CE was 40.47, 3.50, and 96.64 mg/g, respectively. This indicates that adsorption of phosphate using CE was more closely related to chemical factors involving exchange of phosphate with hydroxyl groups on the surface than to physical factors such as specific surface area. In addition, a comparison of the number of hydroxyl groups on the surface per unit with the amount of phosphate adsorbed and the amount of phosphate adsorbed by GB, the number of hydroxyl groups on the surface reached a maximum of 0.036 mmol/m², lower than that found with other adsorbents. However, this is probably a suitable number of hydroxyl groups on the surface, because of the difficulty in the ion exchange of phosphate and the potential for steric hindrance. The pH of the solution after adsorption of phosphate shifted to basic. Moreover, the relationship between the number of hydroxyl groups on the surface and the amount of phosphate adsorbed by CE (Fig. 2) indicated that the main adsorption mechanism of phosphate adsorption was ion exchange between phosphate and the hydroxyl groups on the surface (Figure 3 shows surface reaction between phosphate and number of hydroxyl groups on the surface). The linear equation in Fig. 2 indicated that 1:1 ion exchange occurred between phosphate and hydroxyl groups on the surface. The characteristics of CE and the adsorption mechanism of phosphate using CE also were investigated in detail.
IV. CONCLUSIONS

Among BE, GB, and CE, the specific surface area of BE was greatest, and the number of hydroxyl groups of CE was the greatest. The amount of phosphate adsorbed increased in the order GB < BE < CE. The adsorption mechanism of phosphate using CE was more closely related to the number of hydroxyl groups than to specific surface area. Moreover, measurement of the number of hydroxyl groups per unit indicated that a suitable number of hydroxyl groups were present on the surface compared to the amount of phosphate adsorbed. The relationship between the number of hydroxyl groups on the surface and the amount of phosphate adsorbed by CE indicated that the main adsorption mechanism of phosphate was ion exchange with hydroxyl groups on the surface.
