Abstract
Objective: Carbapenem-resistant Enterobacteriaceae (CRE) are among the most severe threats to public and clinical health because of their high levels of resistance to various antibiotics. We assessed the efficacy of combination therapy with meropenem (MEM) and cefmetazole (CMZ) against Imipenemase (IMP)-producing CRE, using the checkerboard method and time-killing assay on 13 Enterobacteriaceae isolates harboring blaIMP-1 (4 Enterobacter hormaechei, 5 Escherichia coli, and 4 Klebsiella pneumoniae isolates) and 13 isolates harboring blaIMP-6 (8 E. coli and 5 K. pneumoniae isolates).

Results: Minimum inhibitory concentrations (MICs) of MEM and CMZ ranged from 2 to 64 and 64 to 2048 μg/mL, respectively. Checkerboard method demonstrated the synergy of the MEM/CMZ combination in all the tested IMP-producing CRE isolates, and the time-kill assay indicated a bactericidal effect for both blaIMP-1 and blaIMP-6 positive CRE when MEM/CMZ combination was used. In vitro, the MEM/CMZ combination was potentially effective against IMP-1- or IMP-6-producing CRE. Further investigations including in vivo animal studies and clinical studies are warranted to corroborate the clinical utility of the novel combination therapy.

Keywords: Carbapenem-resistant Enterobacteriaceae, Carbapenemase-producing Enterobacteriaceae, Cephamycin, Cefmetazole, IMP

Introduction
Carbapenems are the last-resort antibiotics for the treatment of various infections caused by multidrug-resistant gram-negative bacteria. The wide global dissemination of carbapenem-resistant Enterobacteriaceae (CRE) is a serious threat to global public health and is a major concern to clinicians. Carbapenem resistance is mainly due to the production of carbapenemases whose genes are encoded on plasmids that are transmitted easily across bacterial species, which has resulted in the rapid spread of CRE worldwide [1].
Carbapenemases are categorized into mainly three classes (classes A, B, and D) of the Amber β-lactamase classification. The class A Klebsiella pneumoniae carbapenemases (KPC) are one of the most prevalent carbapenemases. The class D Oxacillin-hydrolysing (OXA)-48 carbapenemase producers have disseminated globally. Class B metallo-β-lactamas (MBLs) mainly comprise the Verona Integron-Mediated (VIM)-, Imipenemase (IMP)-, and New Delhi Metallo-beta-lactamase (NDM)-types. Of these, NDM producers have rapidly spread worldwide since the first reports of their emergence in 2009 [1]. Despite their global dissemination, KPCs, OXAs, and NDMs are still not common in Japan, where...
IMP-1 and IMP-6 are the exclusively predominant carbapenemases [2, 3].

Treatment options for patients infected with carbapenemase-producing Enterobacteriaceae (CPE) are limited. For class A carbapenemases, such as KPC, a double-carbapenem therapy has been used [4]. Additionally, ceftazidime/avibactam combination, which is officially approved in Europe and the United States but not in Japan, has exhibited potent activity against OXA-48 producing gram-negative organisms [5]. However, MBL producers are resistant to these new treatments, and few studies have explored treatment strategies for MBL-producing Enterobacteriaceae [5, 6].

In a previous study, we demonstrated the in vitro efficacy of the combination of meropenem (MEM) and cefmetazole (CMZ) against KPC producers [7]. In this study, we investigated the in vitro activity of the MEM/CMZ combination therapy against IMP-producing CRE.

**Main text**

**Methods**

We used 13 Enterobacteriaceae isolates harboring 

\[
\text{bla}_{\text{IMP-1}} \quad (4 \text{ Enterobacter hormaechei, 5 Escherichia coli, and 4 Klebsiella pneumoniae}) \text{ provided by Toho University, and 13 Enterobacteriaceae isolates harboring } \text{bla}_{\text{IMP-6}} \quad (8 \text{ E. coli and 5 K. pneumoniae}) \text{ obtained in our previous CRE surveillance in Osaka, Japan [2]. E. hormaechei isolates belonging to Enterobacter cloacae complex were included in this analysis as one of } \text{bla}_{\text{IMP-1}} \text{ representative carriers, which were detected in an outbreak reported in Tokyo, Japan [3]. Through the experiments explained below, we used meropenem trihydrate (Tokyo Chemical Industry, Japan, Tokyo) and cefmetazole sodium salt (Sigma-Aldrich, Saint Louis, MO, United States) as antibiotic agents.}
\]

We determined minimum inhibitory concentrations (MICs) of MEM and CMZ by the broth microdilution method based on the Clinical and Laboratory Standards Institute (CLSI) document M07-A10 [8]. Bacterial growth was evaluated by visible observation for turbidity. Briefly, we inoculated \(5 \times 10^5\) colony forming units (CFU)/mL of bacterial suspension into cation-adjusted ambient air for 18 h. MIC was defined as the lowest concentration of the tested antimicrobial that completely inhibited the growth of bacteria.

Details of the checkerboard method and time-killing assay have been presented previously [7]. In the checkerboard method, synergistic effect between MEM and CMZ against IMP-1 or IMP-6 producers was quantified by calculating the fractional inhibitory concentration (FIC) index. FIC index value \(\leq 0.5\) was defined as synergy, \(> 0.5 \) to \(\leq 4.0\) as indifferent, and \(> 4.0\) as antagonistic. The assay was performed in duplicate. In case a synergistic effect was observed, MEM MIC fold-reduction was determined based on the lowest FIC index.

We conducted time-killing assays using the following two E. coli isolates: TUM13773 carrying \(\text{bla}_{\text{IMP-1}}\) and E109 carrying \(\text{bla}_{\text{IMP-6}}\). During these assays, each isolate was incubated in Muller-Hinton II broth devoid of antibiotic (control) and with MEM, CMZ, or MEM/CMZ combination at the concentration of 25% of the MIC for individual isolates. CFUs of bacteria at 3, 6, 9, and 24 h after beginning the treatment were counted. The averages of CFUs were calculated from duplicated assays. We defined an efficacy of the combination therapy as bactericidal when \(\geq 3 \log_{10} \text{CFU/mL}\) reduction compared to the initial bacterial count was observed.

**Results**

MIC ranges of MEM and CMZ for isolates harboring \(\text{bla}_{\text{IMP-1}}\) were 2 to 8 \(\mu\text{g/mL}\) and 64 to 2048 \(\mu\text{g/mL}\), respectively. Similarly, those harboring \(\text{bla}_{\text{IMP-6}}\) ranged from 16 to 32 \(\mu\text{g/mL}\) and from 64 to 1024 \(\mu\text{g/mL}\), respectively (Table 1). No isolates were susceptible to both MEM and CMZ based on the CLSI breakpoint values [9].

The checkerboard method showed that the combination of MEM and CMZ was synergistically active against all the tested IMP-producing CRE isolates (Table 1). MEM MICs in the combination achieved 4- to 32-fold reduction of the MIC of MEM alone.

In the time-killing assays, the viable bacteria treated with each antibiotic alone regrew at 24 h (Fig. 1). Contrarily, upon using the combination of 0.25 \(\times\) MIC MEM and 0.25 \(\times\) MIC CMZ, no growth was detected at 9 h and 24 h, indicating a bactericidal effect against the tested isolates.

**Discussion**

We herein demonstrated the in vitro efficacy of MEM in combination with CMZ against IMP-producing CRE isolates. In addition to the double-carbapenem therapy [4] and ceftazidime/avibactam [5], newer \(\beta\)-lactamase inhibitors including relebactam (MK-7655), nacubactam (OP0595), zidebactam (WCK 5107), and vaborbactam (RPX7009) have been developed to treat CPE that produce serine-carbapenemases [10]. On the other hand, there is less available treatment option for infections caused by MBL-producing CRE.

Still much remains to be done, this investigation is very novel to the literature, in that it was intended to corroborate the potency of CMZ to cancel the function of IMP-type carbapenemases. CMZ is one of the established antimicrobials with accumulated data of its use. It is a cephemycin antibiotic that is stable against...

CMZ cefmetazole, MEM meropenem

FIC index was measured in duplication. FIC index was calculated in following formula; FIC index = (MIC of MEM measured in combination with CMZ)/(MIC of MEM only) + (MIC of CMZ measured in combination with MEM)/(MIC of CMZ only). FIC index ≤ 0.5 was defined as synergy, > 0.5 to ≤ 4.0 as indifferent, and > 4.0 as antagonistic. MEM MIC fold-reduction by CMZ was calculated at the lowest FIC index.

**Fig. 1** Time kill curves for IMP-1- or IMP-6-producing \text{E. coli} isolates with MEM or CMZ only, or both MEM and CMZ. \text{E. coli} isolate TUM13773 carrying \( \text{bla}_{\text{IMP-1}} \), \text{E. coli} isolate E109 carrying \( \text{bla}_{\text{IMP-6}} \), were incubated in Mueller–Hinton II Broth (black circle) or supplemented with MEM (black up-pointing triangle), with CMZ (black diamond) or with combination of MEM and CMZ (square) at 37 °C. All the antibiotics were used at concentrations of 25% of their MIC for individual isolates. Viable cells per milliliter before incubation and after incubation for 3, 6, 9, and 24 h were counted on Muller Hinton II agar plates after overnight incubation at 37 °C. Assays were performed in duplicate and the logarithm of the average CFU/mL was plotted.
extended-spectrum β-lactamases (ESBLs) [11], but is hydrolyzed by carbapenemases, including IMPs [12]. Presently, CRE isolates that produced IMPs were highly resistant to CMZ, with MICs ranging 64 to 2048 μg/mL. These findings may indicate a high affinity of CMZ to IMP-type carbapenemases, and is consistent with our hypothesis that CMZ binds avidly to the carbapenemases, helping MEM exert its bactericidal activity, as seen in double-carbapenem therapy [4]. To demonstrate the superiority of CMZ to MEM in terms of affinity to IMP-type carbapenemases, we need to perform a kinetic assay in future study. ESBL-producing Enterobacteriaceae have globally disseminated [12] and CRE isolates co-harbouring genes encoding ESBLs and carbapenemases have been previously described [13, 14]. Particularly, blaIMP-6 was reported to disseminate mainly through the horizontal transmission of the prevalent plasmid, pKPI-6, which simultaneously carries blaIMP-6 and blaCTX-M [15]. The MEM and CMZ combination therapy would be a ready-to-apply, cost-effective strategy for IMP-producing CRE even against producing ESBLs, compared to the newer β-lactamase inhibitors.

Limitations

However, several limitations remain to be overcome prior to clinical use. First, the CMZ concentrations tested in this study exceed the serum levels attainable in humans. Second, as shown in our previous study [7], an inoculum effect may exist in this combination therapy, possibly resulting in treatment failure using a high bacterial inoculum. Third, various antimicrobial resistance mechanisms, such as AmpC-type beta-lactamases, efflux pumps, and porin loss, may influence the inhibitory activity of CMZ. Despite these limitations, the collective data from this study demonstrate a preferential effect of MEM and CMZ when used in combination against IMP-producing CRE in vitro. Faced with the limited availability of new antimicrobials, the revived use of an existing antimicrobial agent could provide effective treatment. In vivo experiments as well as pharmacokinetic and pharmacodynamic studies are required before the clinical application of the new combination therapy.
