INTRODUCTION

Cutaneous tuberculosis includes all cutaneous manifestations due to mycobacteria of the tuberculosis complex: Mycobacterium tuberculosis, Mycobacterium bovis, and Mycobacterium africanum [1]. It is rare, representing 2% of cases of extrapulmonary tuberculosis [2-4]. Its clinical forms are highly numerous and much more poorly understood than in the past [5,6]. Diagnosis is often difficult due to the polymorphism of both clinical and histological pictures [3,4,6,7]. Herein, we report a case of cutaneous tuberculosis in its warty form located on the nose.

CASE REPORT

This was a 57-year-old housewife who consulted on March 10, 2018, for a keratotic lesion located on the nose and evolving for three months. A notion of contagion with a case of pulmonary tuberculosis was found during interrogation as well as a notion of evening fever and weight loss. A treatment combining metronidazole at a dose of 2 g/day per os for one month and traditional herbal medicine by local application had been instituted without success. On physical examination, the patient was in good general condition. A dermatological examination revealed a blackish, papillomatous patch invading almost the entire nose, with a keratotic surface spreading over the wings of the nose. The diagnosis of verrucous tuberculosis was reached on the basis of epidemiological, clinical, and paraclinical arguments. Under anti-tuberculosis treatment for six months, the lesion had healed without sequelae. The diagnosis of verrucous cutaneous tuberculosis must be established in the presence of any chronic and crusty lesion. The management responds to the treatment protocol for all forms of tuberculosis.

without caseous necrosis. Intradermal reaction to tuberculin (IDR) was negative. Dermal smear showed a Leishman body. Bacteriological and mycological examinations were negative as well. Hematologically, the sedimentation rate was elevated to 79 mm in the first hour and the blood count was normal. Blood sugar and the exploration of kidney function were also normal. Retroviral serology was negative. An AP chest X-ray was normal (Fig. 2). The diagnosis of warty cutaneous tuberculosis was retained on the basis of epidemiological, clinical, and paraclinical arguments. The patient was started on anti-tuberculosis treatment according to the protocol for the treatment of all forms of tuberculosis. It is first quadruple therapy (isoniazid at 3–5 mg/kg/d, rifampicin at 10 mg/kg/d, ethambutol at 15–20 mg/kg/d, and pyrazinamide at 20–30 mg/kg/d) for two months, then dual therapy (isoniazid at 300 mg/d and rifampicin at 400 mg/d) for four months. Local treatment with a keratolytic (3% salicylated petroleum jelly) and fusidic acid was included. Significant lysis of the keratosis was noted at month three of treatment (Fig. 3), and clinical healing without sequelae was noted at month six of treatment with a two-year follow-up (Fig. 4).

**DISCUSSION**

Warty cutaneous tuberculosis results from skin re-inoculation of Koch’s bacillus in a previously sensitized subject [5,7-9], yet this notion of re-inoculation was not reported in our patient. As in the case of our observation, a lesion most often results in one or more papillomatous, keratotic, painless patches of progressive extension [5,10]. Unlike our case, in which the topography was nasal, a lesion is preferentially located in the extremities, especially in the hands and face, yet also in the perianal region [5,7,10], and may
The tuberculin skin test was also positive in several studies [5,8]. It was negative in our patient. Cultures are most often negative, making the diagnosis difficult [5,10]. It is in such a situation that gene amplification by PCR is highly necessary [12], which was not conducted in our case due to the lack of a technical platform. The diagnosis of warty cutaneous tuberculosis was retained in a combination of the following arguments: the notion of contagion, the appearance of the lesion, the elevation of the SV, the aspect of the tuberculoid granuloma without caseous necrosis on histology, the unsuccessful evolution following previous treatment (metronidazole at 2 g/d), despite the negativity of the rest of the assessment. In our patient, the recovery obtained with anti-tuberculosis treatment retrospectively constituted the strongest argument in favor of the diagnosis of tuberculosis, as in several other studies [12,13].

CONCLUSION

Warty cutaneous tuberculosis, despite its rarity, should be considered in the presence of any chronic skin disease resistant to conventional local treatment, because of its polymorphism. The difficulty of obtaining bacteriological confirmation in our context (direct examination, culture, polymerase chain reaction (PCR)) requires collecting a conjunction of anamnestic, clinical, and histological arguments.

The absence of caseous necrosis on histopathological examination should not exclude the diagnosis, as it is most often found in multiple non-specific cases with infiltrates of various compositions and arrangements. A well-conducted treatment with anti-tuberculosis drugs without resistance usually progresses toward healing, sometimes without sequelae. Such a response to a specific anti-tuberculosis treatment constitutes a major diagnostic argument.

Consent

The examination of the patient was conducted according to the principles of the Declaration of Helsinki.

The authors certify that they have obtained all appropriate patient consent forms, in which the patient has consent for images and other clinical information to be included in the journal. The patients understand that their names and initials will not be published and due effort will be made to conceal their identity, but that anonymity cannot be guaranteed.
