ABSTRACT

The dynamic development of studies on neuroglia in recent years indicates its previously underestimated role in maintaining proper brain function, both in physiological and pathological conditions. The use of modern research methods such as single-cell techniques as well as in vivo and in vitro models enriched the state of our knowledge. The most important issues regarding the maturation and development of neuroglia include cooperation between glial cell groups and with neurons in neurogenesis, neuroregeneration, (re)myelination and how the early developmental roles
of glia contribute to nervous system dysfunction in neurodevelopmental and neurodegenerative disorders. There is still growing evidence emphasizing the importance of astroglia in maintaining the brain physiological homeostasis, regulation of immune response, cerebral blood flow, and involvement in the reactive neurogliosis, precisely adapted to the nature of pathological stimulus and the depth of tissue damage. The important issues related to the function of oligodendrocytes include explanation of the mechanisms of interaction between the glial cells and myelinated axons, important not only in myelination, but also in development of cognitive processes and memory. Further studies are required for understanding the mechanisms of demyelination occurring in several central nervous system (CNS) diseases. An interesting area of research is related with explanation on the NG2 glia function, characterized by significant proliferative potential and ability to differentiate in both in physiological conditions and in pathology, as well as the presence of synaptic neural glial connections, which are especially numerous during development. The increasing knowledge of microglia comprise the presence of specialised subsets of microglia, their role the myelination process and neurovascular unit functioning. We are only beginning to understand how microglia enter the brain and develop distinct functional states during ontogeny. This review summarises the current state of knowledge on the development and role in the CNS of different, heterogeneous cell populations defined by a common term neuroglia.

Key words: astrocytes, microglia, NG2 cells, neurovascular unit, oligodendrocytes

INTRODUCTION

The increasing evidence suggests previously overlooked, important role of neuroglia in the brain physiological and pathological processes (1, 2). This justifies the need to abandon the “neurocentric” perspective in understanding the nervous tissue functioning. In physiological conditions, the neuroglia participates in developmental processes including neuro- glio- and synaptogenesis, in control of metabolic processes, immune response and myelination of nerve fibres (3). It is also involved in the brain functional integration, through the modulation of neuroplasticity and shaping cognitive
and memory processes. Other important issues comprise gliotransmission and regulation of the cerebral blood flow. Following, a synthetic summary of the most important information regarding neuroglial development, morphology and function is presented. The neuroglial cells consist of three main types, astrocytes, oligodendrocytes and microglia.

GLIAL CELLS ORIGIN

Based on the developmental origin, two groups of central nervous system (CNS) glial cells can be distinguished: macroglia and microglia. Macroglia (i.e. astrocytes, oligodendrocytes), like neurons, originate from the epithelium of the neural tube (neuroectoderm). Microglia, in contrast, derive from mesoderm of the yolk sac wall (4, 5).

Macroglia

During the fourth week, embryonic disc follows morphological changes, as the result of ongoing differentiation of the germ layer cells. At that time, the neurulation takes place and, in a result, the neural tube (primordium for CNS) forms on the basis of neuroectodermal cells. After closing the anterior and posterior neuropores, the neural tube cells proliferate and follow differentiation into neurons and macroglial cells. The neural tube wall is formed by a pseudostratified epithelium with high rate of proliferation from the inner cavity side (future ventricles and central canal). Cytodifferentiation of the neural tube wall cells leads to an emergence of neurons and macroglia. Early glial cells called radial glial cells (glial progenitor cells) build pathways for neurons migration and are precursors for astrocytes and oligodendrocytes (5-7). It is also a time of neuronal functional differentiation into motoneurons and interneurons, and glia provide metabolic and structural support to these neurons (6, 7). Neuronal number during embryogenesis is modulated by a programmed cell death that is crucial for proper CNS development. Neuronal death is a result of a balance between the prosurvival and death-inducing factors, and glial cells are active players in this process (5). Since other types of glia, such as astrocytes and oligodendrocytes, are
generated during late embryogenesis after neuroblasts have produced most neurons, microglia constitute the main population of glial cells during early embryogenesis (5).

**Microglia**

Early entry and the brain colonization enables microglia to perform critical roles in regulating important events of early brain development e.g., neurons’ survival, phagocytosis of dying neurons, synaptogenesis, angiogenesis, axons development (8). Microglia originate from the embryonic erythromyeloid progenitors of the yolk sac, and not from the hematopoietic stem cells (9). These cells of the macrophage nature arise early in embryogenesis (during the fourth week) and invade the developing neural tube, where they differentiate as the result of factors action provided by their neural niche (10). Yolk sac is the embryonic membrane where the vasculogenesis process takes place. As the result of this process first embryonic vessels and blood cells are being formed (6, 7). Thus, from fourth to eighth week yolk sac is the place of the embryonic hematopoiesis. Primitive macrophages reach the blood vessels and also the neural tube (11, 12). Microglia constitute the first and main population of glial cells during early embryogenesis, thus, their differentiation is strongly linke to the neural tissue maturation. Once invading the forming central nervous system, in this early embryogenesis, the microglial cells expand via proliferation without input of foetal monocytes or bone marrow-derived progenitors during later developmental stages (9, 13). Thus, microglia self-renew via proliferation and are not replaced by bone marrow-derived cells in the healthy brain. Only in the case of injury, inflammation, disease or blood brain barrier break down, these cells are supported by infiltrating bone-marrow-derived monocytes (9, 13). Therefore, microglia show a high ability to proliferation during prenatal and postnatal stages to expand and distribute in the developing CNS, but in adult stage there is a decline in proliferation (14, 15).

In addition to microglia located inside the nervous tissue (parenchyma), there are CNS-associated macrophages located in meninges, perivascular area, and choroid plexus that also originate from the yolk sac progenitors (16). Yolk-sac primary macrophages are heterogenous even before brain colonisation. However, role of these other macrophages remains largely unknown (17). Only choroid plexus macrophages are replaced over time by the circulating monocytes (16).
GLIAL CELLS CHARACTERISTIC

Astrocytes

Apart from the star-shaped cellular body, reflected in the name of this class of neuroglia, characteristic features of the astrocytes include presence of the intermediate filaments (e.g., glial fibrillary acidic protein and vimentin) building their cytoskeleton, perivascular projections and gap junctions, and presence of glutamate and GABA transporters (18-20). Among their characteristic features are also specific properties of energy metabolism and lack of electrical excitability (21, 22). Apart from the protoplasmic and fibrous astrocytes, there are several other types distinguished, defined by different structure and immunocytochemical characteristics (23). The differences in the morphology and biochemical features reflect considerable variability in astrocytic function, which is still only partially disclosed.

In physiological conditions, astrocytes have several functions mainly related with maintaining the physiological homeostasis (24-26). Among them, the most important are: regulation of metabolic processes in the brain tissue (e.g., regulation of glucose metabolism, ion concentration, water content, and pH), structural support (creating functional barriers, territorial domains and syncytial structures), brain development (proliferation, gliogenesis, neuroplasticity), intercellular communication (gliotransmission, regulation of synaptic transmission and plasticity), neuroprotection and brain defense (regulation of cerebral blood flow, protection against glutamatergic excitotoxicity, and inflammatory response).

One of the most important features of astrocytes, which determines their function in pathological conditions, is greater than in the case of other neuroglial subpopulations resistance to decrease in oxygen and glucose concentrations (27). This enables preserving anaerobic glycolysis and ATP production in the area of brain damage and, consequently, supporting the neuronal metabolic functions (28). Due to the abovementioned features, astrocytes are involved in processes initiated in the brain tissue by pathological stimuli and defined as the reactive neurogliosis (26). This neuroglial response comprises the morphological changes, changes in gene expression,
activation of signaling pathways, activation of the inflammatory reactions, and interactions among the various neuroglial populations initiated by the damaging factor (26, 29, 30). However, on the contrary to the previously accepted views, it is not regarded as a stereotypical reaction independent of the nature of the pathological stimulus (25, 29, 31). The astrocytic response is multipotent and context-dependent, optimally adapted to the type of injury, its intensity and the time passed since its initiation (25, 26, 32). The processes involved in the reactive neurogliosis are both of destructive and protective character (32, 33). Each of them reaches its maximal intensity at the specific time-point determining the further fate of the damaged tissue, as well as potential therapeutic measures. The destructive effects of astrogliosis include an exacerbation of the inflammatory response resulting from pro-inflammatory cytokine production, release of reactive oxygen species and excitotoxic glutamate, and impairment of the blood-brain barrier (BBB) function (25, 34). The protective effects include an excitotoxic glutamate uptake, protection against the oxidative stress by free radical scavenging, the BBB repair and reduction of the vasogenic oedema, and neurotrophin release (25, 35, 36). Another characteristic feature of the reactive neurogliosis is presence of phenotypical characteristics not observed in the resting conditions and an expression of several antigens typical for the earlier stages of the cellular lineage development (37-39). All these processes enable restoration of the functions impaired by the pathological stimuli and demarcation of the destructive effects of damage, meanwhile protecting the intact brain tissue areas. The fact that astrocytes communicate with neurons and the vascular system after injury makes them potentially useful in future regenerative therapeutic strategies.

**Oligodendrocytes**

The morphological classification of oligodendrocytes is based on a diversity of their body shapes, number of processes, and size of myelinated axons (40, 41). According to these criteria, four morphological types of oligodendrocytes are distinguished. Additionally, the non-myelinating oligodendrocytes, such as perineuronal satellite oligodendrocytes and, according to some researchers, NG2 glial cells can be identified (42, 43). The most important function of oligodendrocytes is production of myelin sheath. However, the number of the neuronal extensions myelinated by a single oligodendrocyte unit may reach up to 30 axons (44). However, this number shows great
variability. The close relationship between the oligodendrocyte and the myelinated fragments of the axons enables an interaction, that occurs through the ligand- and voltage-gated ion channels and receptors, important for communication between oligodendrocytes and neurons (45-47). This direct structural relationship affects, on the one hand, the course of the myelination process and, on the other hand, the conduction of the action potential along the axon. The mutual contact between the oligodendrocyte and neuronal axon determines the maintenance of the physiological efficiency of oligodendrocytes, protecting them against damage resulting from the excessive concentration of neurotransmitters or the excessive activity of ion channels (45, 46). It has been reported that effectiveness of this communication is the highest in the oligodendrocyte progenitor cells (OPC) and gradually decreases during the ontogenic development (48).

In pathological conditions, oligodendrocyte functional impairment is manifested by a demyelination. It might be a result of improper immunological response induced by external and internal stimuli occurring in the course of demyelinating diseases (e.g., multiple sclerosis) (49). The myelin damage has also been demonstrated during aging and in some neuropsychological illnesses, such as schizophrenia or bipolar disorder, as well as in the course of Alzheimer’s disease and cognitive disorders (50-52).

Microglia

In the prenatal and early postnatal phase, microglia actively participate in brain development by stimulating neurogenesis and gliogenesis (e.g., oligodendrocytes), and the brain vasculature. Microglia regulate the neural circuit wiring, apoptosis and survival of neurons, synapse formation and functioning, and myelination (5, 8). Thus, microglia are considered either a causal or a contributing factor to almost all brain disorders, from neurodevelopmental disorders to neurodegeneration. In humans and mice, microglia represent around 10% of the adult CNS cells, with variable cell density across distinct CNS regions (53, 54). We are only starting to understand how microglia enter the brain and develop distinct functional states during ontogeny.

Under homeostatic conditions microglia are long-lived, self-renewing cells that constantly control the CNS environment (9, 13). Little is known about microglia specific role in the brain during normal growth and development. Microglia activation is
a common feature in neurological disorders based on inflammation, demyelination or neuronal structure degeneration, and also in glioma development (4, 9, 13). Microglia are the glial cells that form the first line of immune defense in the brain and spinal cord. Tissue damage induces activation of microglia cells which secrete a broad range of cytokines with either pro- or anti-inflammatory properties (5, 13). Activated microglia can influence other glial cells and increase the BBB permeability (5, 13). Thus, activated microglia enhance their phagocytic functions in order to clear the damaged tissue from remnants of myelin, cellular debris, apoptotic bodies, and pathogens (5, 8).

Microglia have been distinguished based on their morphology and surface molecules presence which proves that they are as a heterogeneous cell population within the CNS (55). Additionally, one can observe a variety of biologically important functions of these cells, supported by the presence of specialised subsets of microglia. It has been postulated that there are three microglial developmental stages: early microglia (high rate of proliferation and differentiation), pre-microglia linked to neuronal development, and adult microglia (56). Animal studies using mice model of brain development have shown that early during postnatal development a CD11c+ microglia are involved in the myelination process (57, 58), and that this cell population is of special importance in progress of different CNS diseases and during aging (56).

There have been trials to define a precise molecular signature of microglial cells (5, 8). Microglia have a unique gene signature determined by the microglia-specific genes, such as Tmem119, P2ry12, Sall1, and Olfml3 (59). Microglia also express many genes shared by macrophages, including CD11b, CD45, and CX3CR1 (56, 59). Results of animal studies have indicated that microglia subtypes emerge in brain regions or disease development (60). Interestingly, there has been observed a regional heterogeneity of microglia in the human brain (61). Each brain region represents a distinct niche (i.e. has its own neuronal populations, glial cells content, extracellular matrix components). During brain angiogenesis, microglia secret factors that influence vascular growth (62).

Two signaling pathways are crucial for microglial development: one involves colony stimulating factor 1 receptor (CSF1R) and the second one — transforming growth factor beta (TGF-beta). Studies have shown that deletion or inhibition of the
CSF1R during mice development results in loss of microglia (14, 63). CSF1R has two ligands, interleukin 34 (IL-34) and CSF1. Both are expressed in the CNS, but each of them has a different source established postnatally e.g., gray matter microglia depend on neuronal IL-34 production, while white matter microglia depend on CSF1 secreted by astrocytes after birth (14, 63). Loss of TGF-beta signaling in adult microglia results in their hyperactivation after birth and impairment of microglial expansion throughout the developing CNS (14, 63). Thus, microglial cells need neurons to survive and differentiate. Neurons secret e.g., the cytokines IL-34 and CSF1 that influence the CSF1R pathway, as well as ligands for TGF-beta signaling (64).

Another major factor influencing microglial biology is the gut microbiome. Results of studies in the germ-free mice have shown a maturation disturbances of adult microglia (14). Signals from the microbiome affect microglia mainly during postnatal development, whereas embryonic microglia are less sensitive to the microbiota (14, 63).

Like other tissue-resident macrophages, microglia phagocytize cell debris, respond to inflammatory factors, and patrol the local microenvironment. Microglia influence the nervous tissue through a different cellular functions controlled by intrinsic and extrinsic factors. During development, microglia participate in synaptogenesis, modulate axonal growth, secrete factors that support the postnatal survival of the cortical neurons e.g., insulin-like growth factor 1 (IGF-1). Microglia also are involved in the physiological functions in the adult CNS, as they constantly control their environment.

Animal studies have shown that amoeboid microglia in white matter are essential for proper oligodendrocyte homeostasis and myelination (57, 58). Wlodarczyk et al. (58) discovered a new role for of CD11c+ microglia in promoting the CNS myelination. The molecule CD11c is a classic dendritic cell surface marker and only very few microglial cells in the normal adult brain express a detectable level of this protein. This subset of microglia also express sevenfold more mRNA for IGF-1 than their CD11c counterparts, and it has significantly higher levels compared with neurons, astrocytes, and oligodendrocyte precursor cells (58). This population of microglia predominates in the primary areas of the brain myelination and its selective depletion provides to myelin
formation disturbances (58). It has also been suggested that early after birth the white matter microglial cells differ from the grey matter microglial cells (57).

**NG2 cells**

NG2 glial cells are classified as a distinct fourth population of neuroglia, accounting for approximately 5% of neuroglial population and identified by the co-expression of chondroitin sulphate proteoglycan NG2 and platelet-derived growth factor receptor alfa (42, 65). Most of them are thought to represent oligodendrocyte lineage (66, 67). Some authors consider them to be the OPC, sometimes even using the terms OPC and NG2 glia interchangeably. In the adult brain they remain as the NG2 glial cells or differentiate into oligodendrocytes, although this feature varies among the brain areas (42, 65).

The most important features of NG2 glia are the significant proliferative capacity and differentiation potential still present in the adult brain (68-70). In physiological conditions, they allow to maintain a stable number of NG2 cells and oligodendrocytes (42, 65). Other functions of NG2 cells in physiological conditions include: regulation of the cell migration, re-myelination and efficiency of synaptic conduction, and keeping the energetic metabolism at the adequate level (71-73). The NG2 glia form synapses receiving the GABA-ergic and glutamatergic neuronal inputs (74). The role of the neuro-glial synapses is most probably related to increase of proliferation and oligodendrocyte differentiation (74). Another characteristic feature of the NG2 neuroglia is an occurrence of spontaneous and evoked synaptic currents, although their function is unknown (75).

The most important features of NG2 glia in pathological conditions are: the significant proliferative potential and differentiation ability preserved in adulthood, which enable their contribution to the re-population of different neuroglial classes reduced due to destructive processes in the CNS (76, 77). This role has been demonstrated in many experimental models of brain lesion, both in vitro and in vivo (69, 77-80). The ability of NG2 cells to differentiate into astrocytes and oligodendrocytes (70, 81), as well as their contribution to increasing NG2 glia population have been proved by several authors (42, 65). However, the NG2 cells ability to differentiate into neurons, suggested by some authors, has not been commonly accepted (82, 83).
Reassumingly, the morphological features of the NG2 glia response and its proliferation potential depend on the type of pathological stimulus and degree of tissue damage (77). The function of NG2 glia in pathological conditions is only partially understood and requires further intensive research. The proliferative and differentiative potential of NG2 glia could be attractive for development of regenerative medicine therapeutic strategies.

**NEUROVASCULAR UNIT**

Regulation of physiological processes in the CNS requires involvement of all structural components of the nervous tissue. This is particularly evident in the case of the regulation of cerebral blood flow, characterised by enormous dynamics and requiring adaptation of changes to the current biochemical conditions in the brain, as well as to the physiological parameters, determining the state of the circulatory system (84).

The concept of the neurovascular unit (NVU) has proven useful in studies on the structure and function of the brain tissue in physiological and pathological conditions (85-87). This theoretical model comprehensively describes morphological and functional relationships occurring among three main components of brain tissue: neurons, neuroglia and cerebral vessels. Apart from neurons, the NVU consists of the vascular endothelial cells, smooth muscle cells of the vascular wall, pericytes, astrocytes and perivascular macrophages (62, 88, 89). The unquestionable value of the NVU model in explaining the essence of many physiological and pathological processes, as well as its usefulness in elucidating the complex regulatory mechanisms occurring between its components, results from the interaction of several structures. Among them one could encounter: tripartite synapses (ensuring the possibility of the synaptic activity modulation by the astrocyte) (90, 91), astrocytic perivascular end-feet (enabling direct action of the astrocyte on the vascular wall) (92), and vascular tight junctions (being an essential component of the BBB) (88). Astrocytes control the maintenance of these tight-junctions by secreting factors e.g., sonic hedgehog protein (Shh), beta-catenin. However, the activated astrocytes can disrupt the local BBB allowing an entry of the peripheral immune cells. The efficient functioning of the NVU is also a result of action...
the signaling systems based on gliotransmission (93) and Ca\textsuperscript{2+} oscillations (94-96). The NVU is characterised by involvement of its elements in numerous biochemical processes, heterogeneous resistance of its constituents to metabolic disorders occurring in the course of CNS diseases, differentiated participation in the immune response induced by pathological stimuli and, finally, by different proliferative and regenerative potential of the cellular lineages (85, 86). The NVU concept has proven to be very useful in research on several issues, such as regulation of the cerebral blood flow, status of the BBB, dysfunctions of the neurotransmitter systems and signaling pathways. It has also proven its value in the studies on coexistence of different pathological processes, as well as diseases at different stages in patients of various age, such as atherosclerosis, hyperlipidaemia, Alzheimer’s, cardiovascular and inflammatory diseases (85, 87, 96, 97). Steliga et al. (98) have also suggested that the NVU could be a source of biomarkers useful for cerebral stroke diagnostics.

The crosstalk between microglia and astrocytes in the BBB is crucial during inflammatory processes in the CNS. Microglia and astrocytes are activated into the pro-inflammatory phenotype and the anti-inflammatory phenotype (99, 100). Activated into the M1 phenotype microglia produce pro-inflammatory factors, such as IL-1 and TNF-alfa that activate astrocytes. Subsequently, microglia change morphology i.e. take an amoeboid shape and increase ability to phagocytosis (100). As a macrophages, microglial cells function also in M2 phenotype secreting anti-inflammatory factors, such as IL-10, TGF-beta. In general, the M1-like phenotype is considered to be associated with tissue destruction (including NVU), while the M2-like phenotype is involved in repair and regeneration (62, 100). Experimental trials have been taken to inhibit the activity of the proinflammatory phenotype of microglia and augment the activity of the anti-inflammatory phenotype of microglia e.g., in stroke (101).

**CONCLUSIONS**

The last decade of research has shed a new light on glial identity and activities. It is now a well-established fact that glial cells are a very heterogenous group of the CNS cells interacting with each other and having multiple interactions with other CNS elements to control their development and functioning. Glial cells isolated from
different brain regions show an age- and region-dependent differences in transcriptomic profiles. It has been suggested the appearance of homeostatic and reactive glial subtypes could be of great importance for understanding many CNS pathologies. Thus, the molecular characteristic of a particular glial subtype in its anatomical environment is a key to understand glial cells role in both homeostatic and pathological conditions.
