Abstract
Background: The prognostic significance of follow-up (f/u) renal function for patients undergoing percutaneous coronary intervention (PCI) remains unknown. This study sought to investigate the prognostic implications of f/u renal function in patients undergoing PCI. Methods: A drug-eluting stent registry was used. We divided patients into 4 groups according to the change in the estimated glomerular filtration rate (eGFR) before PCI and 3–6 months after PCI. Patients with normal pre-PCI eGFR and f/u eGFR were assigned to group 1. Those with normal pre-PCI eGFR and abnormal f/u eGFR were assigned to group 2. Patients with abnormal pre-PCI eGFR and normal f/u eGFR were assigned to group 3. Patients with abnormal pre-PCI eGFR and f/u eGFR were allocated into group 4. Results: A total of 4,899 PCI patients were enrolled. The death rate in group 1, 2, 3, and 4 at 3 years was 2, 11, 4, and 9%, respectively. This showed significant differences between groups, except between groups 2 and 4. The prognosis of a group with aggravation from normal renal function was worse than that of a group with recovery from abnormal renal function. A prediction model that combines clinical risk factors and f/u eGFR has more power for predicting clinical outcomes than a combination of clinical risk factors and pre-PCI eGFR. Conclusion: Post-PCI eGFR was more accurate for predicting patient outcomes than pre-PCI eGFR.

Introduction
Renal impairment is a prevalent comorbid risk factor among patients with obstructive coronary artery disease undergoing percutaneous coronary intervention (PCI) [1]. Renal dysfunction is associated with systemic inflammation, endothelial dysfunction, accelerated atherosclerosis, and enhanced thrombogenicity, thus increasing the risk for cardiovascular and cerebrovascular ischemic
events [2]. Chronic kidney disease (CKD) is associated with adverse outcomes in those with existing cardiovascular disease [3]. However, most previous research has used the pre-PCI renal function to determine the prognosis of patients. Few studies have used the follow-up (f/u) renal function determined ≥3 months after PCI to evaluate the prognosis of patients. The glomerular filtration rate (GFR) is a sensitive measure of kidney function, but it is seldom measured directly in practice. Instead, the estimated (e)GFR is calculated using a formula, e.g., that from the Modification of Diet in Renal Disease (MDRD) study [4]. The objective of this study was to investigate the prognostic implication of f/u renal function in patients undergoing PCI. We also evaluated predictive factors for changes in renal function after PCI.

Methods

Study Population

This investigation was a retrospective, multicenter, observational study. Subjects were recruited from the cardiovascular catheterization database of Catholic Medical Center (Seoul, South Korea), consisting of 8 hospitals.

Serum creatinine was measured before index PCI and 3–6 months after index PCI. Patients were divided into 4 groups according to eGFR change pre-PCI and 3–6 months after PCI. Patients with normal pre-PCI eGFR and f/u eGFR were assigned to group 1. Those with normal pre-PCI eGFR and abnormal f/u eGFR were assigned to group 2. Patients with abnormal pre-PCI eGFR and normal f/u eGFR were assigned to group 3. Patients with abnormal pre-PCI eGFR and f/u eGFR were assigned to group 4.

Exclusion Criteria

Patients on dialysis before hospital admission, a f/u period of <3 months, or had no available data were excluded.

Definitions

Abnormal eGFR was considered based on a baseline eGFR <60 mL/min/1.73 m² according to the MDRD equation [4]. CKD was defined as eGFR <60 mL/min/1.73 m² for 3 months; this is the accepted cutoff value in the guidelines of the National Kidney Foundation Kidney Disease Outcomes Quality Initiative [5].

Patients were considered to have diabetes mellitus (DM) if they took DM medication, their fasting plasma glucose concentration was ≥126 mg/dL, or their 2 casual plasma glucose concentrations were ≥200 mg/dL. Systemic hypertension was defined as taking hypertension medication, systolic blood pressure (SBP) ≥140 mm Hg, or diastolic pressure ≥90 mm Hg. Hyperlipidemia was defined as taking a statin or a low-density lipoprotein cholesterol value ≥140 mg/dL. Smokers were defined as those who were either current or past smokers. Cerebrovascular accidents included both ischemic and hemorrhagic events. Shock was defined as SBP <90 mm Hg for >50 min or the need for supportive management to maintain SBP at >90 mm Hg.

Cardiac Intervention Techniques/Procedures

Each operator performed all procedures using standard cardiac interventional techniques. Patients who had not previously taken antiplatelet agents were administered loading doses of aspirin (300 mg) and clopidogrel (300–600 mg). Anticoagulation therapy during PCI was performed following current practice guidelines. All enrolled patients had PCI performed with a second-generation drug-eluting stent. The type of drug-eluting stent and glycoprotein IIb/IIIa receptor antagonist used were at the operator’s discretion.

Iso-osmolar agent (iodixanol) was used in all angiography procedures. In elective PCI, patients with CKD routinely received intravenous hydration with isotonic saline solution at 1 mL/kg/h for 12 h before the diagnostic procedure and 12 h after the procedure. In emergency PCI, hydration was performed during the diagnostic procedure using isotonic saline solution and continued at a rate of 1 mL/kg/h for at least 12 h. The operator determined the duration of dual antiplatelet therapy.

Study Outcomes

Study outcomes were all-cause death, cardiac death, recurrent myocardial infarction (MI), and target lesion revascularization (TLR). Death was considered to be of cardiac origin unless a definite noncardiac cause could be established. MI was defined as an elevation of CK-MB fraction or troponin T/troponin I higher than the upper limit of normal, with concomitant ischemic symptoms and electrocardiographic findings indicative of ischemia. TLR was defined as a repeat PCI of the lesion within 5 mm of stent deployment.

Data Collection

Demographic, clinical, laboratory, and angiographic data were collected using a web-based reporting system. All baseline and procedural coronary angiograms were reviewed at the core laboratory. We obtained additional information from the medical records at all 8 hospitals and through telephone contact. All outcomes were reported by the participating hospitals.

Statistical Analysis

Categorical variables are presented as numbers and percentages. They were compared using the χ² test. Continuous variables are expressed as mean ± standard deviation. They were analyzed using Student’s t test. Event rates were calculated based on Kaplan-Meier censoring estimates. The log-rank test was used to compare survival curves between groups. Hazard ratio (HR) and 95% confidence interval (CI) were generated using Cox regression. Adjusted covariates included variables listed in Table 1. To evaluate the independent effect of eGFR on clinical outcomes, we performed multivariable-adjusted Cox proportional hazard model analysis. The multivariate model included all parameters with a p value <0.20 in univariate analysis. The incremental prognostic value of pre-PCI and post-PCI eGFR, in addition to clinical risk factors, was assessed using the Brier score, Harrell’s C index, net reclassification improvement, and the integrated discrimination improvement index [6]. Clinical risk factors included age, sex, hypertension, DM, hyperlipidemia, a history of MI, a history of revascularization, and acute coronary syndrome. Statistical analyses were performed using R statistical software v3.2.5 (R Foundation for Statistical Computing, Vienna, Austria). All tests were 2-tailed, and p < 0.05 was considered statistically significant.
Prognostic Significance of f/u eGFR in PCI Patients

Results

From January 2011 to December 2013, a total of 4,899 out of 5,996 consecutive patients who underwent PCI with a drug-eluting stent were included (Fig. 1). The median f/u duration was 2.6 years (interquartile range [IQR] 1.7–3.8 years). The number of patients in groups 1, 2, 3, and 4 was 3,467, 403, 312, and 717, respectively. The mean age of patients was 63 ± 11 years. Male comprised 64%. Normal pre-PCI eGFR rate was 79% (3,870 patients), and abnormal eGFR rate 3–6 months after PCI was 23% (1,120 patients). The rate of normal pre-PCI eGFR that changed to abnormal post-PCI eGFR was 10% (403 patients). The rate of recovery of abnormal pre-PCI eGFR was 30% (312 patients).

Baseline, angiographic, procedural, and medication characteristics are summarized in Tables 1 and 2. Regarding baseline characteristics, group 1 included a significantly higher rate of young and male patients than the other groups. Group 1 also had fewer smokers, a lower prevalence of DM, hypertension, and cerebrovascular accident (CVA) history, and higher levels of eGFR and left ventricular ejection fraction (LVEF) than other groups. Group 4 showed a higher rate of DM than other groups. In terms of procedural characteristics, the left anterior descending (LAD) artery was the most often to be treated in all 4 groups. Group 1 used a larger diameter of stents than the other groups. As discharge medication, aspirin and thienopyridine were used for nearly all patients. Of P2Y12 receptor inhibitors, clopidogrel was mainly prescribed. Angiotensin-converting-enzyme inhibitor/angiotensin II receptor blocker, beta-blocker, and statin were used in more than half of the patients in all groups.

Figure 2 demonstrates all-cause death according to renal function changes. The all-cause death rate in groups 1, 2, 3, and 4 at 3 years was 2, 11, 4, and 9%, respectively, showing significant differences between groups except between groups 2 and 4 (group 1 vs. group 2, p < 0.001; group 1 vs. group 3, p = 0.009; group 1 vs. group 4, p < 0.001; group 2 vs. group 3, p = 0.004; group 2 vs. group 4, p = 0.796; group 3 vs. group 4, p = 0.004). The cardiac death rate in groups 1, 2, 3, and 4 at 3 years was 1, 4, 3, and 5%, respectively (group 1 vs. group 2, p < 0.001; group 1 vs. group 3, p = 0.006; group 1 vs. group 4, p < 0.001;
group 2 vs. group 3, \( p = 0.310 \); group 2 vs. group 4, \( p = 0.471 \); group 3 vs. group 4, \( p = 0.083 \). There were no significant differences in recurrent MI rate (2, 2, 4, and 2%, respectively, \( p = 0.142 \)) and TLR rate (15, 14, 17, and 11%, respectively, \( p = 0.179 \)). An adjusted HR for clinical outcomes showed that group 2 patients were at an excess risk of all-cause death but that their risk of cardiac death, target vessel MI, and TLR were comparable to those of group 3 patients (Table 3).

Independent predictors of CKD progression and renal recovery by multivariable analysis are presented in Table 4 (using variables from Table 1). Old age, male, DM, a CVA history, and low LVEF were significant predictors of the development of CKD after PCI in group 1 and

group 2 patients with normal pre-PCI eGFR. Young age and no DM were significant predictors of kidney function recovery after PCI in group 3 and group 4 patients with abnormal pre-PCI eGFR.

When pre-PCI and post PCI eGFR were added to the clinical risk factors for predicting all-cause death and cardiac death, the model with post-PCI eGFR showed the highest C index (0.749, 95% CI [0.736–0.761]; 0.744, 95% CI [0.731–0.756]) (Fig. 3). For cardiac death, the model with post-PCI eGFR showed significantly improved net reclassification improvement compared to the model with pre-PCI eGFR (Fig. 3).

Discussion

This study analyzed the prognostic implication of f/u eGFR for patients undergoing PCI using the observation registry. The first finding was that the eGFR 3–6 months after PCI was more accurate for predicting patient outcomes than pre-PCI eGFR. The second finding was that the prognosis of patients with normal pre-PCI and abnormal f/u (at 3–6 months) renal function was worse than that of patients with abnormal pre-PCI and normal f/u renal function. The third finding was that young age and no DM were significant predictors of recovery from initial renal dysfunction. Old age, male sex, DM, a CVA history, and a low LVEF were significant predictors of aggravated renal function.

It is widely known that pre-PCI renal function helps predict outcomes in PCI patients [7]. However, until now, no study has reported the prognosis of patients’ renal function 3–6 months after PCI. This investigation is the first to evaluate prognosis using f/u eGFR. We also demonstrated the clinical outcomes of PCI according to renal function change in a large unrestricted population, i.e., that reflects real-world practice.

Several studies have shown that abnormal renal function pre-PCI correlates with the occurrence of adverse events. This result could be due to poor general vessel conditions in patients with poor renal function. This might be partly explained by conditions like age, DM, and hypertension [8]. In addition, kidney failure speeds up the development of atherosclerosis. Thus, such patients might have more extensive coronary and peripheral artery disease, such as multivessel disease [9].

Pre-PCI renal dysfunction might be temporarily caused by multifactorial factors, including ischemic insult, in a healthy kidney. In other cases, CKD might have existed before. It might be further exacerbated by ischemia and

Prognostic Significance of f/u eGFR in PCI Patients

Fig. 3. Receiver-operating characteristics curves for predicting all-cause death and cardiac death. Brier score, discriminant function (C index), net reclassification improvement (NRI), and integrated discrimination index (IDI) were compared in 3 models. The reference model included clinical risk factors only, including age, sex, hypertension, diabetes mellitus, hyperlipidemia, a history of myocardial infarction, a history of revascularization, and acute coronary syndrome. Brier score, C index, NRI, and IDI values of models with clinical risk factors only, and pre-PCI eGFR or post-PCI eGFR in addition to clinical risk factor were compared. Among these, the model with the post-PCI showed the highest C index, NRI, and IDI values in all-cause death (a) and cardiac death (b). CI, confidence interval; eGFR, estimated glomerular filtration rate; PCI, percutaneous coronary intervention.

In both instances, normal kidneys usually recover after the insult, but the abnormal CKD finding remains. Recovery takes several weeks to months. It usually takes less than three months to recover [11, 12]. Kidney Disease Improving Global Outcomes (KDIGO) acute kidney injury (AKI) guidelines recommend that kidney function should be evaluated 3 months after an AKI episode to establish the presence and extent of CKD [13]. In this study, we used f/u eGFR after > 3 months; we could thus differentiate CKD and AKI.

Group 1 had a lower rate of all-cause and cardiac death than the other groups. We compared group 2 and group 3 regarding renal function changes after PCI. After adjusting for all variables listed in Table 1, we found a higher risk of all-cause death in group 3, but not of cardiac death, recurrent MI, or TLR. The prognosis of a group with aggravation from normal renal function was worse than that of a group with recovery from abnormal renal function.

In our analysis, young age and no DM were significant predictors of recovery from the initial kidney injury. However, the renal function of group 3 recovered to within a normal range after 3–6 months; the kidneys of patients in group 3 were thought to be susceptible to acute insult and prone to acute renal failure. Initially considered fully reversible, recent evidence has suggested that these events may promote disease progression in the longer term [14]. Recently, it was established that even milder forms of AKI not requiring dialysis are associated with both short- and long-term mortality [15, 16]. A previous CKD study showed no significant difference in the rate of TLR between CKD and non-CKD groups [17].

We found that predictive factors for the occurrence of CKD after PCI in group 1 and group 2 patients with normal pre-PCI eGFR were older age, male sex, DM, a CVA history, and a low LVEF. Recent studies have also shown that predictors of progression of CKD are old age, male sex, DM, heart failure, and stroke [18, 19]. The results of our study thus coincide with those of recent studies.

Although the biological mechanism linking CKD progression after AKI, as in group 2, has not fully been elucidated, it has been postulated that a combination of acute endothelial damage that leads to vascular dropout and nephron loss, followed by glomerular hypertrophy with the development of fibrosis might play a role [20]. DM is the most important contributor to CKD, and DM patients are at a greater risk of requiring hospitalization and experiencing AKI. Recent findings indicate that the rate of advanced CKD progression from AKI in DM patients is 3-fold higher than that in non-DM patients [21]. In terms of recovery from AKI, we found that younger non-DM young patients would recover.

When the scoring system was added to clinical risk factors, the model with the f/u eGFR showed the highest C index for all-cause death and cardiac death. In addition, f/u eGFR got better net reclassification improvement for both all-cause death and cardiac death when added to clinical risk factors. These results imply that f/u renal function can estimate patient risk after PCI better than pre-PCI renal function can. We recommend checking f/u eGFR after 3 months to predict the prognosis of patients undergoing PCI in clinical practice. In conclusion, f/u Post-PCI eGFR was more accurate for predicting patient outcomes than pre-PCI eGFR.

Our study has several limitations. First, we used a non-randomized, retrospective design. This might have affected our results due to allocation bias, uneven distribution of risk factors, and the possibility of unmeasured confounders. Second, we excluded some patients without information about f/u eGFR level after the procedure, which may have contributed to selection bias. Third, baseline CKD and prerenal AKI may have different implications in terms of prognosis. We checked only one eGFR value before PCI. A single-point value of eGFR could be affected by fluctuations due to hemodynamic factors, medication, etc. This could have caused misclassification, especially in patients with pre-PCI abnormal eGFR.
