Abstract

We have calculated Heisenberg exchange parameters for bcc-Fe, fcc-Co, and fcc-Ni using the non-relativistic spin-polarized Green function technique within the tight-binding linear muffin-tin orbital method and by employing the magnetic force theorem to calculate total energy changes associated with a local rotation of magnetization directions. We have also determined spin-wave stiffness constants and found the dispersion curves for metals in question employing the Fourier transform of calculated Heisenberg exchange parameters. Detailed analysis of convergence properties of the underlying lattice sums was carried out and a regularization procedure for calculation of the spin-wave stiffness constant was suggested. Curie temperatures were calculated both in the mean-field approximation and within the Green function random phase approximation. The latter results were found to be in a better agreement with available experimental data.

I. INTRODUCTION

The quantitative description of thermodynamic properties of magnetic metals is challenging solid state theorists since decades. Thanks to the development of density functional theory and its implementation into ab initio computational schemes, an excellent understanding of their ground state (i.e., at $T = 0$ K) has been achieved. On the other hand, most of the progress towards a description of magnetic metals at non-zero temperature has been based upon models in which the electronic structure is oversimplified and described in terms of empirical parameters. Although this approach has the great merit of emphasizing the relevant mechanisms and concepts, it cannot properly take into account the complex details of the electronic structure and is therefore unable to yield quantitative predictions.
of the relevant physical quantities such as spin-wave stiffness, Curie temperature \( T_C \), etc., for comparison with experimental data.

It is therefore of a great importance to develop an \textit{ab initio}, parameter-free, scheme for the description of ferromagnetic metals at \( T > 0 \) K. Such an approach must be able to go beyond the ground state and to take into account excited states, in particular the magnetic excitations responsible for the decrease of the magnetization with temperature and for the phase transition at \( T = T_C \). Although density functional theory can be formally extended to non-zero temperature, there exists at present no practical scheme allowing to implement it. One therefore has to rely on approximate approaches. The approximations to be performed must be chosen on the basis of physical arguments.

In itinerant ferromagnets, it is well known that magnetic excitations are basically of two different types: (i) Stoner excitations, in which an electron is excited from an occupied state of the majority-spin band to an empty state of the minority-spin band and creates an electron-hole pair of triplet spin. They are associated with longitudinal fluctuations of the magnetization; (ii) the spin-waves or magnons, which correspond to collective transverse fluctuations of the direction of the magnetization. Near the bottom of the excitation spectrum, the density of states of magnons is considerably larger than that of corresponding Stoner excitations, so that the thermodynamics in the low-temperature regime is completely dominated by magnons and Stoner excitations can be neglected. Therefore it seems reasonable to extend this approximation up to the Curie temperature, and to estimate the latter by neglecting Stoner excitations. This is a good approximation for ferromagnets with a large exchange splitting such as Fe and Co, but it is less justified for Ni which has a small exchange splitting.

The purpose of the present paper is to describe the spin-wave properties of transition metal itinerant ferromagnets at \textit{ab initio} level. With thermodynamic properties in mind, we are primarily interested in the long-wavelength magnons with the lowest energy. We shall adopt the \textit{adiabatic approximation} in which the precession of the magnetization due to a spin-wave is neglected when calculating the associated change of electronic energy. Clearly, the condition of validity of this approximation is that the precession time of the magnetization should be large as compared to characteristic times of electronic motion, namely, the hopping time of an electron from a given site to a neighboring one, and the precession time of the spin of an electron subject to the exchange field. In other words, the spin-wave energies should be small as compared to the band width and to the exchange splitting. This approximation becomes exact in the limit of long wavelength magnons, so that the spin-wave stiffnesses constant calculated in this way are in principle exact.

This procedure corresponds to a mapping of the itinerant electron system onto an effective Heisenberg Hamiltonian with classical spins

\[
H_{\text{eff}} = - \sum_{i \neq j} J_{ij} \mathbf{e}_i \cdot \mathbf{e}_j ,
\]

where \( J_{ij} \) is the exchange interaction energy between two particular sites \((i, j)\), and \( \mathbf{e}_i, \mathbf{e}_j \) are unit vectors pointing in the direction of local magnetic moments at sites \((i, j)\), respectively. The same point of view has been adopted in various papers recently published on the same topic \([1, 4]\).
The procedure for performing the above mapping onto an effective Heisenberg Hamiltonian relies on the constrained density functional theory [15], which allows to obtain the ground state energy for a system subject to certain constraints. In the case of magnetic interactions, the constraint consists in imposing a given configuration of spin-polarization directions, namely, along \( \mathbf{e}_i \) within the atomic cell \( i \). Note that \textit{intracell} non-collinearity of the spin-polarization is neglected since we are primarily interested in low-energy excitations due to \textit{intercell} non-collinearity.

Once the exchange parameters \( J_{ij} \) are obtained, the spin-dynamics [4,16,17] can be determined from the effective Hamiltonian (1) and one obtains the result known from spin-wave theories of localized ferromagnets: the spin-wave energy \( E(q) \) is related to the exchange parameters \( J_{ij} \) by a simple Fourier transformation

\[
E(q) = \frac{4\mu_B}{M} \sum_{j \neq 0} J_{0j}(1 - \exp(iq \cdot \mathbf{R}_{0j})),
\]

where \( \mathbf{R}_{0j} = \mathbf{R}_0 - \mathbf{R}_j \) denote lattice vectors in the real space, \( q \) is a vector in the corresponding Brillouin zone, and \( M \) is the magnetic moment per atom (\( \mu_B \) is the Bohr magneton).

There are basically two approaches to calculate the exchange parameters and spin-wave energies. The first one which we adopt in the present paper, referred to as the real-space approach, consists in calculating directly \( J_{ij} \) by employing the change of energy associated with a constrained rotation of the spin-polarization axes in cells \( i \) and \( j \) [2]. In the framework of the so-called magnetic force-theorem [2,18] the change of the total energy of the system can be approximated by the corresponding change of one-particle energies which significantly simplifies calculations. The spin-wave energies are then obtained from Eq. (2). In the second approach, referred to as the frozen magnon approach, one chooses the constrained spin-polarization configuration to be the one of a spin-wave with the wave vector \( q \) and computes \( E(q) \) directly by employing the generalized Bloch theorem for a spin-spiral configuration [19]. Like the above one, approach can be implemented with or without using the magnetic force-theorem. Both the real-space approach and the frozen magnon approach can be implemented by using either a finite or an infinitesimal rotation, the latter choice is usually preferable. The exchange parameters \( J_{ij} \) are then obtained by inverting Eq. (2). One should also mention a first-principles theory of spin-fluctuations (the so-called disordered local moment picture) based on the idea of a generalized Onsager cavity field [20].

The spin-wave stiffness \( D \) is given by the curvature of the spin-wave dispersion \( E(q) \) at \( q = 0 \). Although its calculation is \textit{in principle} straightforward in the real-space approach, we shall show that serious difficulties arise due to the Ruderman-Kittel-Kasuya-Yoshida (RKKY) character of magnetic interactions in metallic systems. These difficulties have been underestimated in a number of previous studies [2,4,13,14], and the claimed agreement with experiment is thus fortuitous. We shall present a procedure allowing to overcome these difficulties. In addition, we shall demonstrate that the evaluation of the spin-wave dispersion \( E(q) \) in the real-space approach has to be also done carefully with respect to the convergency of results with the number of shells included.

Finally, to obtain thermodynamic quantities such as the Curie temperature, we apply statistical mechanics to the effective Hamiltonian (1). In the present paper, we use two different approaches to compute the Curie temperature. The first one is the commonly
used mean field approximation (MFA). The limitations of this method are well known: it is correct only in the limit of high temperatures (above $T_C$), and it fails to describe the low-temperature collective excitations (spin-waves). The second approach is the Green function method within the random phase approximation (RPA) \[21–26\]. The RPA is valid not only for high temperatures, but also at low temperatures, and it describes correctly the collective excitations (spin-waves). In the intermediate regime (around $T_C$), it represents a rather good approximation which may be viewed as an interpolation between the high and low temperature regimes. It usually yields a better estimate of the Curie temperature as compared to the MFA. It should be noted, however, that both the MFA and RPA fail to describe correctly the critical behavior and yield in particular incorrect critical exponents.

II. FORMALISM

The site-off diagonal exchange interactions $J_{ij}$ are calculated using the expression \[2\]

$$J_{ij} = \frac{1}{4\pi} \text{Im} \int_C \text{tr}_L \left[(P^\uparrow_i(z) - P^\downarrow_i(z)) g^{\uparrow}_{ij}(z) (P^\uparrow_j(z) - P^\downarrow_j(z)) g^{\downarrow}_{ji}(z)\right] \, dz, \quad (3)$$

which is evaluated in the framework of the first-principles tight-binding linear muffin-tin orbital method (TB-LMTO) \[27\]. Here $\text{tr}_L$ denotes the trace over the angular momentum $L = (\ell m)$, energy integration is performed in the upper half of the complex energy plane over a contour $C$ starting below the bottom of the valence band and ending at the Fermi energy, $P^\sigma_i(z)$ are diagonal matrices of the so-called potential functions of the TB-LMTO method for a given spin direction $\sigma = \uparrow, \downarrow$ with elements $P^\sigma_{i,L}(z)$, and $g^\sigma_{ij}(z)$ are the so-called auxiliary Green function matrices with elements $g^\sigma_{iL,jL'}(z)$ \[28\] defined as

$$[g^\sigma(z)]^{-1}_{iL,jL'} = P^\sigma_{i,L}(z) \delta_{LL'} \delta_{ij} - S_{ij,L,L'}. \quad (4)$$

We have also introduced the spin-independent screened structure constant matrix $S_{ij}$ with elements $S_{iL,jL'}$ which characterizes the underlying lattice within the TB-LMTO approach \[28\].

Calculated exchange parameters were further employed to estimate the spin-wave spectrum $E(q)$ as given by Eq. (2). For cubic systems and in the range of small $q$ we have

$$E(q) = D q^2, \quad (5)$$

where $q = |q|$. The spin-wave stiffness coefficient $D$ can be expressed directly in terms of the exchange parameters $J_{0j}$ as \[2\]

$$D = \frac{2\mu_B^2}{3M} \sum_j J_{0j} R_{0j}^2, \quad (6)$$

where $R_{0j} = |R_{0j}|$. The summation in Eq. (3) runs over all sites but in practice the above sum has to be terminated at some maximal value of $R_{0j} = R_{max}$. There is a lot of misunderstanding in the literature as concerns the use of Eq. (3). Several calculations were done with $R_{max}$ corresponding to the first few coordination shells \[2,13,14\]. In other
calculations, the authors realized the problem of the termination of \( R_{max} \) but they did not suggest an appropriate method to perform the sum (\( \sum \)) in the direct space. We will demonstrate that terminating the sum in Eq. (5) after some value of \( R_{max} \) is fundamentally incorrect because it represents a non-converging quantity and we will show how to resolve this problem from a numerical point of view. The reason for such behavior is the long-range oscillatory character of \( J_{ij} \) with the distance \( R_{ij} \) in ferromagnetic metals.

Alternatively, it is possible to evaluate \( E(q) \) directly in the reciprocal space as

\[
E(q) = \frac{4\mu_B}{M} (J(0) - J(q)),
\]

(7)

and to determine the spin-stiffness constant as a second derivative of \( E(q) \) with respect to \( q \).

Calculated exchange parameters can be also used to determine Curie temperatures of considered metals. Within the MFA

\[
k_B T_C^{MFA} = \frac{2}{3} \sum_{j \neq 0} J_{0j} = \frac{M}{6\mu_B} \frac{1}{N} \sum_{q} E(q),
\]

(8)

where \( E(q) \) is the spin-wave energy. We have calculated \( T_C^{MFA} \) directly from the expression \( k_B T_C^{MFA} = 2J_0/3 \), where

\[
J_0 \equiv \sum_{i \neq 0} J_{0i} = -\frac{1}{4\pi} \int_C \text{Im} \sum_{k} \text{tr}_L \left[(P^i_0(z) - P^i_0(z)) g^i(k + q, z) (P^i_0(z) - P^i_0(z)) g^i(k, z) \right] \, dz,
\]

(9)

The expression for the Curie temperature within the GF-RPA approach is

\[
\frac{1}{k_B T_C^{RPA}} = \frac{6\mu_B}{M} \frac{1}{N} \sum_{q} \frac{1}{E(q)}.
\]

(10)

The integrand in (11) is singular for \( q = 0 \). We have therefore calculated \( T_C^{RPA} \) using the expression

\[
\frac{1}{k_B T_C^{RPA}} = -\lim_{z \to 0} \frac{6\mu_B}{M} \text{Re} G_m(z),
\]

(11)

\[
G_m(z) = \frac{1}{N} \sum_{q} \frac{1}{z - E(q)}.
\]

The quantity \( G_m(z) \) is the magnon Green function corresponding to the dispersion law \( E(q) \) and it was evaluated for energies \( z \) in the complex energy plane and its value for \( z = 0 \) was obtained using the analytical deconvolution technique. It should be noted that the MFA and the RPA differ essentially in the way in which they weight various \( J_{ij} \), namely more distant neighbors play a more important role in the RPA as compared to the MFA. It is seen from Eqs. (8,10) that \( T_C^{MFA} \) and \( T_C^{RPA} \) are given as the arithmetic and harmonic averages of the spin-wave energies \( E(q) \), respectively, and therefore it holds \( T_C^{MFA} > T_C^{RPA} \).
III. RESULTS AND DISCUSSION

A. Details of calculations

Potential functions and Green functions which appear in Eq. (3) were determined within the non-relativistic TB-LMTO method in the so-called orthogonal representation \cite{28} assuming the experimental lattice constants and the exchange potential in the form suggested by Vosko-Wilk-Nusair \cite{30}. It should be noted that some calculations, in particular for $T_C^{MFA}$, were also done using the scalar-relativistic formulation. The contour integral along the path $C$ which starts below the lowest occupied band and ends at the Fermi energy (we assume zero temperature) was calculated following the scheme described in \cite{28} which employs the Gaussian quadrature method. Twenty energy nodes were used on the semi-circle in the upper part of the complex energy plane. The integration over the full Brillouin zone was performed very carefully to obtain well-converged results even for very distant coordination shells (up to 172-nd shell for fcc lattice and the 195-th shell for bcc lattice). In particular, we have used up to $5 \times 10^6 \mathbf{k}$-points in the full Brillouin zone for the energy point on the contour $C$ closest to the Fermi energy, and the number of $\mathbf{k}$-points then progressively decreased for more distant points, and for points close to the bottom of the band.

B. Effective Heisenberg exchange parameters

We will first discuss qualitatively the dependence of $J_{ij}$ on the distance $R_{ij} = |\mathbf{R}_i - \mathbf{R}_j|$. In the limit of large values of $R_{ij}$ the expression (3) can be evaluated analytically by means of the stationary phase approximation \cite{31}. For simplicity we consider here a single-band model but the results can be generalized also to the multiband case (see Ref. \cite{32}). For a large $R_{ij}$ behaves $g_{ij}^\sigma$ as

$$g_{ij}^\sigma(E + i0^+) \propto \frac{\exp \left[ i (\mathbf{k}^\sigma \cdot \mathbf{R}_{ij} + \Phi^\sigma) \right]}{R_{ij}},$$

(12)

where $\mathbf{k}^\sigma$ is the wave vector of energy $E$ in a direction such that the associated group velocity $\nabla_k E^\sigma(\mathbf{k})$ is parallel to $\mathbf{R}_{ij}$, and $\Phi^\sigma$ denotes a corresponding phase factor. The energy integration in (3) yields additional factor of $1/R_{ij}$ \cite{31} and one obtains

$$J_{ij} \propto \text{Im} \frac{\exp \left[ i (\mathbf{k}_F^\uparrow + \mathbf{k}_F^\downarrow) \cdot \mathbf{R}_{ij} + \Phi^\uparrow + \Phi^\downarrow \right]}{R_{ij}^3}.$$ (13)

For a weak ferromagnet both Fermi wave vectors $\mathbf{k}_F^\uparrow$ and $\mathbf{k}_F^\downarrow$ are real and one obtains a characteristic RKKY-like behavior

$$J_{ij} \propto \sin \left[ (\mathbf{k}_F^\uparrow + \mathbf{k}_F^\downarrow) \cdot \mathbf{R}_{ij} + \Phi^\uparrow + \Phi^\downarrow \right],$$

(14)

i.e., the exchange interaction has an oscillatory character with an envelope decaying as $1/R_{ij}^3$. On the other hand, for a strong ferromagnet with a fully occupied majority band
the corresponding Fermi wave vector is imaginary, namely \( \mathbf{k}_F^\uparrow = i \kappa^\uparrow_F \) and one obtains an exponentially damped RKKY behavior

\[
J_{ij} \propto \frac{\sin(\mathbf{k}_F^\uparrow \cdot \mathbf{R}_{ij} + \Phi^\uparrow + \Phi^\downarrow) \exp(-\kappa^\uparrow_F \cdot \mathbf{R}_{ij})}{R_{ij}^3}.
\] (15)

The qualitative features of these RKKY-type oscillations of \( J_{ij} \) will not be changed in realistic ferromagnets. For a weak ferromagnet, like Fe, one expects a pronounced RKKY character giving rise to strong Kohn anomalies in the spin-wave spectrum. On the other hand, for Co and Ni which are almost strong ferromagnets one expects a less pronounced RKKY character, less visible Kohn anomalies in the spin-wave spectrum (see Sec. III C), and faster decay of \( J_{ij} \) with a distance \( R_{ij} \). It should be noted that due to the \( sp-d \) hybridization no itinerant ferromagnet is a truly strong ferromagnet.

The calculated Heisenberg exchange parameters \( J_{ij} \) for bcc-Fe, fcc-Co, and fcc-Ni are presented in the Table I for the first ten shells. The exchange parameters \( J_{ij} \) remain non-negligible over a very long range along the [111]-direction, and change from ferromagnetic to antiferromagnetic couplings already for the third nearest-neighbors (NN). In case of Co this change appears only for the 4th NN whereas Ni remains ferromagnetic up to the 5th NN. It should be noted a short range of \( J_{ij} \) for the case of Ni, being essentially a decreasing function of the distance with the exception of the second NN. Such behavior is in a qualitative agreement with conclusions obtained from the asymptotic behavior of \( J_{ij} \) with distance discussed above, in particular with the fact that bcc-Fe is a weak ferromagnet while fcc-Co and, in particular, fcc-Ni are almost strong ferromagnets. There have been several previous calculations of \( J_{ij} \)'s for Fe and Ni [2,5,7,11,26]. Present calculations agree well with calculations of Refs. [2,5,11] and there is also a reasonable agreement with results of Refs. [25]. It should be mentioned that \( J_{ij} \) for both fcc-Co and hcp-Co were determined and they agree quite well with each other [6] (see also Table III below). Finally, we have also verified numerically the validity of important sum rule, namely \( J_0 = \sum_{i \neq 0} J_{0i} \). The sum fluctuates with the number of shells very weakly for, say, more than 50 shells.

C. Dispersion relations

Calculated magnons energy spectra \( E(\mathbf{q}) \) along the high symmetry directions of the Brillouin zone are presented in Figs. 1a–c together with available experimental data [38, 39]. We have used all calculated shells to determine \( E(\mathbf{q}) \), namely 195 and 172 shells for bcc- and fcc-metals, respectively. Corresponding plot of \( E(\mathbf{q}) \) for fcc-Ni exhibits parabolic, almost isotropic behavior for long wavelengths and a similar behavior is also found for fcc-Co. On the contrary, in bcc-Fe we observe some anisotropy of \( E(\mathbf{q}) \), i.e., \( E(\mathbf{q}) \) increases faster along the \( \Gamma - N \) direction and more slowly along the \( \Gamma - P \) direction. In agreement with Refs. [4,10] we observe a local minima around the point \( H \) along \( \Gamma - H \) and \( H - N \) directions in the range of short wavelengths. They are indications of the so-called Kohn anomalies [4] which are due to long-range interactions mediated by the RKKY interactions similarly like Kohn-Migdal anomalies in phonon spectra are due to long-range interactions mediated by Friedel oscillations. It should be mentioned that minima in dispersion curve of bcc-Fe appear only if the summation in (2) is done over a sufficiently large number of shells, in the present case for
more than 45 shells. A similar observation concerning of the spin-wave spectra of bcc-Fe was also done by Wang et al. [26] where authors used the fluctuating band theory method using semiempirical approach based on a fitting procedure for parameters of the Hamiltonian. On the other hand in a recent paper by Brown et al. [6] above-mentioned Kohn-anomalies in the behavior of spin-wave spectra of bcc-Fe were not found, possibly because the spin-wave dispersion was obtained as an average over all directions in the \( q \)-space.

Present results for dispersion relations compare well with available experimental data of measured spin-wave spectra for Fe and Ni [33–35]. For low-lying part of spectra there is also a good agreement of present results for dispersion relations with those of Refs. [4,7] obtained using the frozen magnon approach. There are, however, differences for a higher part of spectra, in particular for the magnon bandwidth of bcc-Fe which can be identified with the value of \( E(q) \) evaluated at the high-symmetry point \( q = H \) in the bcc-Brillouin zone. The origin of this disagreement is unclear. We have carefully checked the convergence of the magnon dispersion laws \( E(q) \) with the number of shells included in Eq. (2) and it was found to be weak for 50 – 70 shells and more. However, if the number of shells is small the differences may be pronounced, e.g., our scalar-relativistic calculations give for the bcc-Fe magnon bandwiths the values of 441 meV and 550 meV for 15 and 172 shells, respectively. The former value agrees incidentally very well with that given in Refs. [4,7]. On the other hand, even small differences in values of \( E(q) \) are strongly amplified when one evaluates the second derivative of \( E(q) \) with respect to \( q \), i.e., the spin-wave stiffness constant. One should keep in mind, however, that the above discussion is somehow academic, for it concerns an energy region where the adiabatic approximation ceases to be a good one, so that spin-waves are no longer well defined because of their strong damping due to Stoner excitations (see e.g. [5]). The results of theoretical calculations based upon the adiabatic approximation can be thus compared with each other, but not with experimental data. It should be pointed out that the influence of deviations in the calculation of magnon spectra for large values of \( q \) of the Curie temperature is minimized for its RPA value as compared to its MFA value (see Eqs. [8,11]).

**D. Spin-wave stiffness constant**

As was already mentioned the sum in (3) does not converge due to the characteristic RKKY behavior (14) and, therefore, Eq. (3) cannot be used directly to obtain reliable values for the spin-wave stiffness constant. This is demonstrated in Fig. 2 where the dependence of calculated spin-wave stiffness constants on the parameter \( R_{\text{max}} \) in Eq. (3) is plotted. The oscillatory character of \( D \) versus \( R_{\text{max}} \) persists for large values of \( R_{\text{max}} \) for the case of bcc-Fe and even negative values of spin-wave stiffness constants were obtained for some values of \( R_{\text{max}} \). To resolve this difficulty we suggest to regularize the expression (3) by substituting it by the formally equivalent expression which is, however, numerically convergent

\[
D = \lim_{\eta \to 0} D(\eta),
\]

\[
D(\eta) = \lim_{R_{\text{max}} \to \infty} \frac{2 \mu_B}{3M} \sum_{0 < R_{0j} \leq R_{\text{max}}} J_{0j} R_{0j}^2 \exp(-\eta R_{0j}/a).
\] (16)
The quantity $\eta$ plays a role of a damping parameter which makes the sum over $R_{ij}$ absolutely convergent as it is seen from Fig. 3. The quantity $D(\eta)$ is thus an analytical function of the variable $\eta$ for any value $\eta > 0$ and can be extrapolated to the value $\eta = 0$. To show that the limit for $\eta \to 0$ is indeed finite and that our scheme is mathematically sound, let us consider as an example a typical RKKY interaction $J(R) \propto \sin(kR + \Phi)/R^3$. For large $R$ we can employ Eq. (14) and substitute the sum in (6) by a corresponding integral. We obtain

$$\lim_{\eta \to 0} D(\eta) \propto 4\pi \int_{R_0}^{\infty} R^2 \frac{\sin(kR + \Phi)}{R^3} dR = -\cos(\Phi) \text{si}(kR_0) - \sin(\Phi) \text{ci}(kR_0),$$

where $\text{si}$ and $\text{ci}$ are integral sine and cosine, respectively. The integral is indeed finite.

We therefore perform calculations for a set of values $\eta \in (\eta_{\text{min}}, \eta_{\text{max}})$ for which $D(\eta)$ is a smooth function with a well pronounced limit for large $R_{\text{max}}$. The limit $\eta = 0$ is then determined at the end of calculations by a quadratic least-square extrapolation method. Typically, 5-15 values of $\eta$ was used for $\eta_{\text{min}} \approx 0.5 - 0.6$ and $\eta_{\text{max}} \approx 0.9 - 1.2$ with a relative error of order of a few per cent. In calculations we have used $R_{\text{max}} = 7a$ for fcc and $9a$ for bcc, where $a$ denotes the corresponding lattice constant. It should be noted that measurements refer to the hcp-Co while the present calculations were performed for fcc-Co. A similar accuracy between calculated and measured spin-wave stiffness constants was obtained by Halilov et al. [4] using the frozen-magnon approach. Our results are also in a good agreement with those obtained by van Schilfgaarde and Antropov [7] using the spin-spiral calculations to overcome the problem of evaluation of $D$ from Eq. (6). On the other hand, this problem was overlooked in Refs. [2,13,14] so that a good agreement of $D$, calculated for a small number of coordination shells, with experimental data seems to be fortuitous. Finally, results of Brown et al. [6] obtained by the layer Korringa-Kohn-Rostoker (KKR) method in the frozen potential approximation are underestimated for all metals and the best agreement is obtained for Ni.

### E. Curie temperature

Several attempts have been made to evaluate Curie temperatures of magnetic transition metals [4,7,12,39,40] most of them based on the MFA. The MFA as a rule overestimates values of Curie temperatures (with exception of fcc-Ni with values substantially underestimated). We will show that an alternative method based on the Green function approach in the framework of the RPA [22-25] can give a better agreement with experimental data. The RPA Curie temperatures were calculated from Eq. (11) by employing the method of analytical deconvolution [29]. In order to test the accuracy of this procedure we compare the present numerical results for the ratio $T_{C}^{\text{MFA}}/T_{C}^{\text{RPA}}$ obtained for the nearest-neighbor Heisenberg model with the exact results [22,23]: we obtain 1.33 (fcc) and 1.37 (bcc) as compared to exact values 1.34 and 1.39, respectively, i.e., a numerical procedure agrees with
exact results within one per cent accuracy. Calculated values of Curie temperatures for both the MFA and RPA as well as corresponding experimental data are summarized in Table II. Mean-field values of Curie temperatures are overestimated for Fe and Co, but underestimated for Ni in agreement with other calculations [4,7]. On the other hand, the results obtained using the RPA approach are in a good agreement with experiment for both fcc-Co and bcc-Fe, while the results for fcc-Ni are even more underestimated. This is in agreement with the fact mentioned in Sec. II, namely that $T_{C}^{RPA} < T_{C}^{MFA}$. The present results for Fe and Ni are in a good agreement with results of Ref. [20] using the spin-fluctuation theory and an improved statistical treatment in the framework of the Onsager cavity-field method.

The calculated ratio $T_{C}^{MFA} / T_{C}^{RPA}$ is 1.49, 1.25, 1.13 for bcc-Fe, fcc-Co, and fcc-Ni, respectively. The values differ from those obtained for the first-nearest neighbor Heisenberg model due to non-negligible next-nearest neighbors in realistic ferromagnets and their oscillatory behavior with the shell number.

The last point concerns the relevance of relativistic corrections for the evaluation of the exchange parameters and related quantities. The simplest quantity to evaluate is the MFA value of the Curie temperature (see Eq. (9)). Results for ferromagnetic metals (including hcp-Co) are summarized in Table III by comparing the non-relativistic and scalar-relativistic values. One can conclude that scalar-relativistic corrections are not important for fcc-Co and hcp-Co but their effect is non-negligible for fcc-Ni and bcc-Fe. The scalar-relativistic corrections generally shifts sp-bands downwards as compared to the d-band complex while the changes of magnetic moments are generally very small (a similar exchange splitting). One can thus ascribe above changes mostly to the modifications of the density of states at the Fermi energy (the site-diagonal blocks of the Green function in Eq. (9)). Results also show only a weak dependence of the calculated $T_{C}^{MFA}$ on the structure (hcp-Co vs fcc-Co).

F. Comparison between the real-space and frozen magnon approaches

The real-space and frozen magnon approaches are formally equivalent to each other. The quantities that are directly calculated (the $J_{ij}$s in the former case, the $E(q)$’s in the latter) are related to each other by a Fourier transformation. Therefore, the pros and cons of both approaches concern mainly their computational efficiency.

The computational effort needed to obtain one $J_{ij}$ parameter within the real-space approach is approximately the same as to compute one magnon energy $E(q)$ within the frozen magnon approach: in both cases a fine Brillouin zone integration is required.

Therefore, it is quite clear that if one is primarily interested in spin-wave dispersion curves (for a moderate number of $q$ points), or in the spin-wave stiffness $D$, the frozen magnon approach is superior, for it does require to perform a Fourier transformation and the delicate analysis explained in Sec. III D. We have shown, however, although less direct and computationally more demanding, the real-space approach performs well also.

On the other, if one is interested in the Curie temperature, the real-space approach is more efficient. This obvious if ones uses the mean-field approximation. Indeed, $T_{C}^{MFA}$ is obtained from a single real-space calculation, by using the sum rule (3), whereas many $E(q)$’s are needed to obtain $T_{C}^{MFA}$ from Eq. (8) within the frozen magnon approach. Also if one uses the RPA, the real-space approach is more efficient. For both approaches, the
integral over $\mathbf{q}$ in Eq. (10) needs to be performed accurately, with paying great attention to the divergence of the integrant at $\mathbf{q} = 0$. A very high density of $\mathbf{q}$ points is required there, in order to have a satisfactory convergence. Within the frozen-magnon approach, each of the $E(\mathbf{q})$’s requires the same computational effort. In contrast, within the real-space approach, less than 200 $J_{ij}$’s are sufficient to obtain a parametrization of $E(\mathbf{q})$ over the full Brillouin zone, which considerably reduces the computational effort.

A further very important advantage of the real-space approach is its straightforward application to systems with broken translational symmetry like, e.g., substitutional alloys, surfaces, overlayers, and multilayers. This is an important advantage keeping in mind the relevance and yet not fully understood character of exchange interactions at metal interfaces and surfaces. The reciprocal-space approach can be applied to ideal surfaces, but it is numerically demanding, and its application to system with substitutional disorder and/or to finite magnetic clusters is practically impossible. Finally, the dependence of exchange parameters $J_{ij}$ on the distance also gives an important information about the nature of the magnetic state (RKKY-like interactions) and this dependence is again straightforwardly determined by the real-space method while in the reciprocal-space method $J_{ij}$’s have to be determined by inverting Eq. (2).

IV. SUMMARY

We have calculated Heisenberg exchange parameters of bcc-Fe, fcc-Co, and fcc-Ni in real space from first-principles by employing the magnetic force theorem. We have determined dispersion curves of magnetic excitations along high-symmetry directions in the Brillouin zone, spin-wave stiffness constants, and Curie temperatures of considered metals on the same footing, namely all based on calculated values of exchange parameters $J_{ij}$. Dispersion curves of bcc Fe exhibit an anisotropic behavior in the range of long wavelengths, with peculiar minima for short wavelengths in the [100]-direction which are due to a relatively strong exchange oscillations in this metal. We have presented a method of evaluation of the spin-wave stiffness constants which yields converged values, in contrast to previous results in the literature. Calculated spin-wave stiffness constants agree reasonably well with available experimental data for Co and Fe, while agreement is rather poor for Ni. Present calculations agree also well with available experimental data for magnon dispersion law of bcc-Fe. We have also evaluated Curie temperatures of metals in question using the mean-field approximation and the Green function random phase approximation. We have found that in the latter case a good agreement with the experiment is obtained for Co and Fe, while less satisfactory results are obtained for Ni, where the role of the Stoner excitations is much more important as compared to Co and Fe. In addition, the adiabatic approximation is less justified for Ni, and, possibly, correlation effects beyond the local density approximation play the more important role for this ferromagnet.

In conclusion, we have demonstrated that the real-space approach is able to determine the low-lying excitations in ferromagnetic metals with an accuracy comparable to the reciprocal-space approach. This justifies the use of the real-space approach for more interesting and complex systems with violated translational symmetry where the reciprocal-space approach is of the limited use. In particular, a first promising application of the real-space approach
to the problem of the oscillatory Curie temperature of two-dimensional ferromagnets has been recently published [41].

TABLE II. Calculated spin-wave stiffness constants ($D_{th}$) and Curie temperatures ($T_{C}^{MFA}$ and $T_{C}^{RPA}$) and their comparison with experimental values $D_{ex}$ and $T_{C}^{ex}$.

| Metal | $D_{th}$[meV·Å²] | $D_{ex}$[meV·Å²] | $T_{C}^{MFA}$[K] | $T_{C}^{RPA}$[K] | $T_{C}^{ex}$[K] |
|-------|-----------------|-----------------|----------------|----------------|---------------|
| Fe (bcc) | 250 ± 7 | 280⁹, 330¹⁰ | 1414 | 950 ± 2 | 1044 − 1045 |
| Co (fcc) | 663 ± 6 | 580⁹, 510¹¹ | 1645 | 1311 ± 4 | 1388 − 1398¹² |
| Ni (fcc) | 756 ± 29 | 555⁹, 422¹² | 397 | 350 ± 2 | 624 − 631 |

¹²Data refer to hcp Co at 4.2 K.
¹⁰Neutron scattering measurement at 4.2 K [30].
¹¹Magnetization measurement at 4.2 K.
¹²Neutron scattering measurement extrapolated to 0 K [38].
TABLE III. Calculated Curie temperatures of ferromagnetic metals in the mean-field approximation for non-relativistic (\(nr\)) and scalar-relativistic (\(sr\)) cases.

| Metal   | \(T_{\text{nr}}^C\) [K] | \(T_{\text{sr}}^C\) [K] |
|---------|--------------------------|--------------------------|
| Fe (bcc) | 1414                     | 1335                     |
| Co (fcc) | 1645                     | 1651                     |
| Co (hcp) | 1679                     | 1673                     |
| Ni (fcc) | 397                      | 428                      |
FIGURES

FIG. 1. Magnon dispersion relations along high-symmetry lines in the Brillouin zone: (a) bcc-Fe (experiment: Ref. [33], 10 K, filled circles and Ref. [35], Fe(12 % Si), room temperature, empty squares); (b) fcc-Co; and (c) fcc-Ni (experiment: Ref. [34], room temperature, empty circles). Lines are calculated results.

FIG. 2. Spin-wave stiffness constants calculated from Eq. (16) as a function of $R_{max}$ (in units of lattice constants) for fcc-Ni (full line), fcc-Co (short dashes), and bcc-Fe (long dashes).

FIG. 3. Spin-wave stiffness of fcc-Ni calculated from Eq. (6) as a function of $R_{max}$ (in units of lattice constant) for various values of the damping factor $\eta$.

FIG. 4. Spin-wave stiffness coefficients $D(\eta)$ for bcc-Fe (empty squares), fcc-Co (empty triangles), and fcc-Ni (empty circles) as a function of the parameter $\eta$ and extrapolated values for $\eta = 0$ (filled symbols). The solid line indicates the quadratic fit function used for extrapolation.
(b)
Ni fcc

The graph shows the dependence of $D$ [meV Å$^2$] on $R_{max}/a$ for different values of $\eta$. The lines represent $\eta = 0.0$, $\eta = 0.2$, $\eta = 0.4$, $\eta = 0.6$, and $\eta = 0.8$.
