Orbital migration induced by anisotropic evaporation

Can hot Jupiters form hot Neptunes?

ABSTRACT

Short period planets are subject to intense energetic irradiations from their stars. It has been shown that this can lead to significant atmospheric mass-loss and create smaller mass planets. Here, we analyse whether the evaporation mechanism can affect the orbit of planets. The orbital evolution of a planet undergoing evaporation is derived analytically in a very general way. Analytical results are then compared with the period distribution of two classes of inner exoplanets: Jupiter-mass planets and Neptune-mass planets. These two populations have a very distinct period distribution, with a probability lower than $10^{-4}$ that they were derived from the same parent distribution. We show that mass ejection can generate significant migration with an increase of orbital period that matches very well the difference of distribution of the two populations. This would happen if the evaporation emanates from above the hottest region of planet surface. Thus, migration induced by evaporation is an important mechanism that cannot be neglected.

Key words. Planets and satellites: formation – Planets and satellites: dynamical evolution and stability – Planet-star interactions

1. Introduction

Different scenarios have been proposed to explain the formation of hot Neptunes and Super-Earths: migration in a protoplanetary disk (Mordasini et al. 2009), in situ formation by accretion of planetesimals (Brunini & Cionco 2005), embryo formation in a compact multiplanetary system and subsequent migration through scattering (Ida & Lin 2010), tidal downsizing of giant planet embryo (Nayakshin 2010, 2011), or partial evaporation of more massive planets (Baraffe et al. 2004, Lecavelier Des Etangs et al. 2007, Valencia et al. 2010). Here, we focus on the evaporation hypothesis with a particular attention to semi-major axis evolution. Indeed, among the shortest period exoplanets, those closer to their star tend to be more massive than the outer ones (Mazeh et al. 2005, Southworth et al. 2007, Davis & Wheatley 2009, Benítez-Llambay et al. 2011). This has been attributed either to a combined effect of tidal interactions and migration in the protoplanetary disk (Benítez-Llambay et al. 2011), or to the fact that low-mass close-in planets cannot survive catastrophic evaporation (Davis & Wheatley 2009).

While isotropic planetary evaporation generates almost negligible migration, anisotropic ejection of matter can lead to substantial increase of semi-major axis. This effect is similar to anisotrophic thermal radiation (Fabrycky 2008). In the case of hot gaseous planets, two different mechanisms have been proposed to explain atmospheric escapes, i.e. how particles reach the Roche lobe (Hill) radius of their planet. On the one hand, this may be due to a thermal inflation of the planet. Particles of the upper atmosphere are assumed to follow a Maxwellian velocity distribution, and those with the highest speed escape (Gu et al. 2003, Lecavelier des Etangs et al. 2004). In that case, the evaporation is preferentially directed towards the L1 Lagrangian point located between the star and the planet (Gu et al. 2003). On the other hand, the escape may be driven by vertical winds on the planet's dayside (Yelle 2004, García Muñoz 2007, Murray-Clay et al. 2009). This situation is more complex and 3D hydrodynamical simulations are required to get the geometry of ejection. Nevertheless, winds are likely anisotropic.

Atmospheric circulation models predict the existence of a jet that displaces the hottest region of hot Jupiters from the substellar point, along the equator (Showman & Guillot 2002). More recent models agree that the jet is a common feature of circulation models, and that it is confined to latitudes between $-30^\circ$ and $30^\circ$ with a displacement from the substellar point usually eastward, by $10-60^\circ$ of longitude. Its value depends on the strength of the imposed stellar heating and other factors such as the radiative timescale and drag time constant (Showman & Polvani 2011). These predictions are corroborated by the observed surface temperature distribution of HD 189733b (Knutson et al. 2007).

Although there are evidences of a displacement of the hottest region with respect to the substellar point on planet surface, the dynamics of exobase is poorly known. Strictly speaking, it is thus not possible to assert in which direction and how mass is ejected by evaporation. Hereafter, in order to get estimates of the migration induced by evaporation, we will take the results mentioned above concerning planetary surface as representative of the exobase structure.

This letter is organized as follows. In Section 2 we derive analytically the orbital evolution of a planet undergoing evaporation in a very general way. In Section 3 we compare the dis-
distribution of two classes of close-in planets: Jupiter-like planets and Neptune-like planets. The statistical analysis is then used, in Section 4, to constrain the geometry of evaporation assuming that hot Neptunes are partially evaporation hot Jupiters. This geometry is also confronted with the predictions of atmospheric models. The conclusion is presented in Section 5.

2. Orbital evolution with evaporation

Two-body problems in which one component of the component loses mass should be solved with caution. Several misinterpretations have already been found in the literature ([Plastino & Muzzio 1992]), since the equations of motion are not the same whether the ejection is isotropic or not. Here, we consider a simple model of evaporation that is well suited for both isotropic and anisotropic mass-loss.

Let a planet of mass $m(t)$ orbiting a star with mass $m_\star$. The orbit is characterized by a radius vector $r$, an orbital velocity $\mathbf{v} = \dot{\mathbf{r}}$, a semi-major axis $a$, an eccentricity $e$, an orbital angular momentum $\ell = \mathbf{r} \times \mathbf{v}$, and a period $P = 2\pi / n$, where $n$ is the mean motion defined by $G(m + m_\star) = n^2 a^3$. $G$ is the gravitational constant. Let $v_p$ and $v_\star$ be respectively the velocity of the planet and of the star in a fixed reference frame. The orbital velocity is then $\mathbf{v} = v_p - v_\star$. For any vector $\mathbf{w}$, we note $w = \|\mathbf{w}\|$ its norm, and $\hat{w} = \mathbf{w}/w$ its unit vector. The frame $(\hat{r}, \hat{\theta}, \hat{k})$, where $\hat{k} = \ell / \ell$ and $\hat{\theta} = \hat{k} \times \hat{r}$, is used to define the geometry of the mass ejection, which is given by two parameters: the angle $\theta$ between the star and the direction of mass ejection, and the aperture $\varphi$ of the stream (see Fig. 1). In particular, the evaporation is completely focused in one direction when $\varphi = 0^\circ$, and becomes isotropic when $\varphi = 180^\circ$. We note $\mathbf{u} = -\cos \theta \hat{r} - \sin \theta \hat{\theta}$ the average direction of the stream. Let $V_{es}$ be the ejection speed of atmospheric particles with respect to the planet barycenter. Note that $V_{es}$ can vary between 10 and 20 km.s$^{-1}$ for a planet orbiting a Main-Sequence star, and a T Tauri star, respectively ([Murray-Clay et al. 2009]). The mean velocity $V$ of the stream is $\eta(\varphi) V_{e_\varphi} \mathbf{u}$, where

$$\eta(\varphi) = \frac{\int_0^\varphi \cos \varphi' \sin \varphi' d\varphi'}{\int_0^\varphi \sin \varphi' d\varphi'} = \cos^2 \frac{\varphi}{2},$$

(1)

and the equations of motion are

$$\frac{dv_p}{dt} = -Gm_\star m r \ell r^{-3} + \dot{m} V,$$

$$\frac{dv_\star}{dt} = +Gm_\star m r \ell r^{-3}.$$

(2)

We then assume that the mass-loss rate, $\dot{m}(t)$, scales linearly with the energy received by the planet from the stellar XEUV emission. It should be stressed that this has no effect on semi-major axis. Another scaling would modify only slightly the eccentricity evolution. The mass loss-rate is thus inversely proportional to the square of the distance

$$\dot{m}(t) = -B(t)/r^2,$$

(3)

where $B(t)$ is any slowly varying function accounting for the time evolution of the stellar luminosity. From (2), (3), and the expression of $V$, one gets

$$\frac{dv}{dt} = -\mu(t) \dot{\mathbf{r}} / r^2 + \kappa(t) \sin \theta \mathbf{\hat{\theta}},$$

(4)

where $\kappa(t) = \eta(\varphi) B(t) V_{es}/m(t)$ and $\mu(t) = G(m(t) + m_\star) - \kappa(t) \cos \theta$. Notice that even in the extreme case with a mass-loss rate $\dot{m} = 10^{-5}$ g.s$^{-1}$, and an ejection speed $V_{es} = 100$ km.s$^{-1}$, for a hot Jupiter at 0.05 AU, $\kappa/(Gm)$ remains lower than $2 \times 10^{-8}$. In the following, we thus use simply $\mu(t) = G(m(t) + m_\star)$.

From the definition of the semi-major axis

$$\frac{1}{2} v^2 - \frac{\mu}{r} = -\frac{\mu}{2a},$$

(5)

and the expression of the Laplace-Runge-Lenz vector $e$

$$e = v \times \ell / \mu - \dot{r},$$

(6)

the equation of motion (4) leads to

$$\frac{da}{dt} = \alpha \left(1 - \frac{2 \alpha}{\mu} \right) + 2 \alpha \kappa \sin \theta / \mu^3,$$

$$\frac{de}{dt} = -\left(\dot{r} + e\right) \mu + \kappa \sin \theta (\ell r + r^2 v \times \hat{k})/\mu^3.$$

(7)

The first terms of the right hands of Eq. (7) are only due to the mass decrease. They do not depend on the geometry and remain unchanged even for isotropic evaporation. On the other hand, the last terms of Eq. (7) vanish for isotropic ($\kappa = 0$) or radial ($\sin \theta = 0$) mass ejection. The long term evolution of the orbital parameters is obtained by averaging (7) over the mean anomaly $M$ keeping $\mu(t), \kappa(t)$ and $\ell = na^2 \sqrt{1 - e^2}$ constant (e.g. [Boué & Laskar 2009]). The results are

$$\frac{d\alpha}{dt} = \frac{-\alpha - 2 \kappa n \sin \theta}{\mu (1 - \frac{1}{e^2})},$$

$$\frac{d\kappa}{dt} = \frac{\frac{n \kappa}{\mu} \sin \theta}{\mu (1 + \sqrt{1 - e^2})} e.$$

(8)

In the following, we consider the simplest case where the orbit is circular. Eq. (8) shows that such orbits remain circular over the whole evolution. Replacing $B(t)$ (see Eq. (3)) by $-\alpha^2 m(t)$ in the expression of $\kappa(t)$, and using $v = na$ and $\mu(t) = G(m(t) + m_\star)$, the secular evolution of the semi-major axis becomes

$$\frac{d\alpha}{dt}_{M = 0} = -\frac{m}{m_\star + m} - \frac{2 v_0}{v} m,$$

(9)

where $v_0 = v(t = 0)$ is the initial orbital velocity. $\tau$ is a dimensionless parameter that controls the efficiency of the migration. We will thus refer to this parameter as the ‘migration efficiency’. Its expression is

$$\tau = \cos^2 \frac{\varphi}{2} \sin \theta \frac{V_{es}}{v_0}.$$

(10)
For isotropic evaporation ($\varphi = 180^\circ$) or radial ejection ($\theta = 0^\circ$), the migration efficiency vanishes. In that case, the product $a(m_\ast + m)$ of the semi-major axis with the total mass of the system remains constant [Hadjidemetriou1963]. Thus, even if a Jupiter-mass planet orbiting a Sun-like star loses all its mass, the semi-major axis increases only by a factor $M_{\text{Jup}}/M_\odot = 0.1\%$. The term $a/t_\ast/(m_\ast + m)$ in Eq. (12) will thus be neglected in the following.

For arbitrary migration efficiency, the solution of Eq. (12) is $a(t) = a_0[(1 + \ln(m(t)/m_0)]^{-\frac{1}{3}}$. For convenience, we provide an equivalent relation, with orbital period instead of semi-major axis, deduced from Kepler’s third law

$$\frac{P}{P_0} = (1 + \tau \ln q)^{-\frac{1}{3}},$$

where $q = m/m_0$ is the fraction of remaining mass in the planet. The expression (11) is independent of time, and holds for any mass-loss rate evolutions. The only requirement concerns the efficiency of evaporation. Here, we assume that the evaporation process is sufficiently strong to decrease the mass of a planet from $m_0$ to $m$.

Using a typical ejection speed $V_{\text{es}} = 15 \text{ km.s}^{-1}$ and an initial orbital velocity $V_0 = 145 \text{ km.s}^{-1}$ corresponding to a 3 days orbit, the order of magnitude of the migration efficiency given by (10) is $\tau \sim V_{\text{es}}/V_0 = 0.1$. With this value, if a Jupiter mass planet is transformed into a Neptune mass planet by evaporation ($q = 0.05$), the increase of its orbital period deduced from (11) is $P/P_0 = 1.5$. For comparison, the ratio of the median periods of Jupiter-like planets and Neptune-like planets (see section 3) is $4.9/3.4 = 1.4$.

### 3. Observed period distributions

From the more than 700 exoplanets discovered up to date, 204 have orbital periods smaller than 10 days and mass smaller than $5 M_{\text{Jup}}$ [1]. One can group these planets in two classes: Neptune-mass planets and smaller ($m < 2 M_{\text{Neptune}}$ or $2 \times 0.054 M_\odot$), and Jupiter-mass planets ($m > M_{\text{Jup}}$ or $0.3 M_\odot$). The first group contains 37 planets, from which we removed two couples belonging to the same system [2] while the second 151. Both correspond to 92% of short-period planets considered. The two populations are characterized by very distinct period distributions: the Neptunes have a median period of 4.9 days, an average period of 5.3 days and a standard deviation of 2.6 days, while for the Jupiters the same quantities are of 3.4, 3.5 and 1.6 days, respectively. A Kolmogorov-Smirnov test shows that the cumulative distribution functions (CDF) of the two distributions are significantly different, with the probability that they were derived from the same parent distribution being of $3.8 \times 10^{-5}$ (see Fig. 2).

It is important to keep in mind that the interpretation of these results is conditioned by different factors, which warrant a discussion. Firstly, the fitted parameters depend on the limits defined for the planetary classes. However, the general properties of the distributions are kept for a wide range of parameters, and the results are expected to be resistant to changes of these parameters. More important is that the observational bias imprint on the sample by radial-velocity detections, which depends on mass and period, is different for the two classes of planets. Since the amplitude of a signal and thus its detectability is proportional to $mP^{-1/3}$, heavier and closer planets are detected more easily than lighter far away planets. For this reason, the difference in median or average period values is expected to increase for the real unbiased population, showing that the difference in values we found here is not a detection effect but rather an underestimation of the real one. In any case, the reflex motion induced by a Neptune on a 10-day orbit on a 1 Solar-mass star is of 5 m.s$^{-1}$, significantly larger than the precision of state-of-the-art spectrographs (e.g. HARPS) [Mayor & Udry2008]. As a consequence, we expect the detections reported up to date to be representative of the true population.

### 4. Constraints and comparison with atmospheric models

Here, we derive the distribution of the migration efficiency $\tau$ assuming that the hot Neptune and the hot Jupiter populations correspond to the same planets at different degrees of evaporation. This provides constraints on the geometry of evaporation which are then compared with results of atmospheric models. That analysis relies on the possibility that hot Jupiters can lose 95% of their mass by evaporation. Although additional works are required, we expect this to happen at the early age of planet’s history, when stellar emission is strong [Ribas et al.2005], and planet density is low (e.g. Mordasini et al.2010). Indeed, these two conditions lead to important mass-loss [Erkaev et al.2007].
In order to simplify the study, and to derive analytical expressions, we approximate the CDFs of the two populations by log-normal distributions

$$\text{PDF}(\ln P_i) = N_{\mu_i, \sigma_i} \left( \ln P_i \right) = \frac{1}{\sqrt{2\pi}\sigma_i} \exp \left( \frac{\left( \ln P_i - \mu_i \right)^2}{2\sigma_i^2} \right). \quad (12)$$

where $i \in \{\text{Jup}, \text{Nep}\}$, and $P_i$ is expressed in days. $N_{\mu_i, \sigma_i}$ is the normal distribution. The best fits give ($\mu_{\text{Jup}} = 1.19$, $\sigma_{\text{Jup}} = 0.39$) for Jupiter-like planets, and ($\mu_{\text{Nep}} = 1.62$, $\sigma_{\text{Nep}} = 0.57$) for Neptune-like planets. Assuming that the migration represented by $\Delta_{\text{Jup}} = \ln P_{\text{Nep}} - \ln P_{\text{Jup}}$ is independent of $P_{\text{Jup}}$ and $P_{\text{Nep}}$, the law of total probability implies that $\Delta_{\text{Jup}}$ follows a normal distribution with mean $\mu_\Delta = \mu_{\text{Nep}} - \mu_{\text{Jup}}$ and standard deviation $\sigma_\Delta = \sigma_{\text{Nep}}^2 - \sigma_{\text{Jup}}^2$. Then, a change of variable from $\Delta_{\text{Jup}}$ to $\tau$ Eq. (11) gives

$$\text{PDF}(\tau) = -\frac{3}{1 + \tau \ln q} N_{\mu_\Delta, \sigma_\Delta} [-3 \ln (1 + \tau \ln q)]. \quad (13)$$

The PDF (13) is plotted in figure 3(a) for $q = 0.03$, which is the ratio of the geometric mean of the masses of the two planet populations. Using a typical ejection speed $V_{\text{es}} = 15 \text{ km.s}^{-1}$ and the typical initial orbital velocity $V_0 = 145 \text{ km.s}^{-1}$, the PDF of $\tau$ expressed as a function of $(\theta, \varphi)$ constrains the geometry of mass ejection (see Fig. 3(b)).

In particular, if one considers an aperture $\varphi$ lower than $30^\circ$, one obtains the highest probable displacement in the eastward direction at about $25^\circ$ of longitude (solid line in Fig. 3(b)). This value matches very well the one predicted by atmospheric models (Showman & Guillot 2002; Koskinen et al. 2007; Showman & Polvani 2011) or reported on HD 189733b (Knutson et al. 2007) (filled circle in Fig. 3(b)).

Nevertheless, it should be stressed again that the dynamical models and the observation of the temperature map of HD 189733b do not extend up to exobase. It is thus not possible to prove the connection between the direction of mass ejection and the position of the hottest region.

5. Conclusion

In this study, we provide a simple and very general analytical expression of orbital migration induced by anisotropic evaporation. The amplitude of this effect is not negligible. Indeed, the order of magnitude of the migration deduced from the expected ejection speed $V_{\text{es}}$ and the typical orbital velocity $V_0$ of a 3-day orbit is the same as the difference between the observed median period of hot Jupiters and hot Neptunes. Moreover, the agreement is greatly enhanced if one assumes that the evaporation emanates from above the hottest region of the planet surface as measured on HD 189733b (Knutson et al. 2007), or predicted by atmospheric circulation models (Showman & Guillot 2002; Koskinen et al. 2007; Showman & Polvani 2011). Further studies on the dynamics of the exobase may provide stronger constraints on the geometry of evaporation. The analysis presented here would then be easily applied to get precise evolution of evaporating planets.
