We show two experimental realizations of Hardy ladder test of quantum nonlocality using energy-time correlated photons, following the scheme proposed by A. Cabello et al. [Phys. Rev. Lett. 102, 040401 (2009)]. Unlike, previous energy-time Bell experiments, these tests require precise tailored nonmaximally entangled states. One of them is equivalent to the two-setting two-outcome Bell test requiring a minimum detection efficiency. The reported experiments are still affected by the locality and detection loopholes, but are free of the post-selection loophole of previous energy-time and time-bin Bell tests.

I. INTRODUCTION

A loophole-free violation of a Bell inequality would prove the impossibility of describing nature in terms of local hidden variable theories [1], and the possibility of eternally secure communications [2]. Among all versions of Bell’s proof, Hardy’s [3, 4] is probably the simplest. In addition to simplicity, Hardy’s has one interesting feature: it only works for nonmaximally entangled states, which are precisely the best candidates for a photonic loophole-free experiment with inefficient detectors [5, 6]. To be more specific, the experimental realization of the two-party, two-setting, two-outcome Bell test with minimum required detection efficiency, assuming that all detectors have the same efficiency [5, 6], is equivalent to a test of Hardy proof.

Standard energy-time and time-bin Bell tests (e.g., [7]) suffer from a specific loophole called the post-selection loophole [8, 9], which can be avoided using a scheme introduced in [9]. Energy-time Bell experiments without the detection loophole and maximally entangled states have been recently performed using this scheme [10]. Moreover, the scheme can be applied to nonphotonic systems [11] and can be extended to multipartite scenarios [12].

The aim of this work is to show that energy-time entanglement can also be used to produce Hardy-type violations of Bell inequalities free of the post-selection loophole, as a preliminary step towards a loophole-free Bell test with photonic random destination sources [13]. The two experiments reported in this paper will also show the feasibility of energy-time entanglement for producing nonmaximally entangled states which are essential for some quantum key distribution protocols [14].

II. HARDY PROOF

Hardy proof of nonlocality [3, 4] can be summarized as follows. Let us consider two observers, Alice and Bob, measuring dichotomic (with outputs −1 and 1) observables. Alice measures $a_0$ and $a_1$, while Bob measures $b_0$ and $b_1$. Let us define $P(a_i, b_j)$ as the joint probability of obtaining $a_i = b_j = 1$, and $P(\bar{a_i}, b_j)$ as the joint probability of obtaining $a_i = -1$ and $b_j = 1$. For any local hidden variable theory with (i) $P(a_0, b_0) = 0$, (ii) $P(\bar{a_0}, b_1) = 0$, and (iii) $P(a_1, b_0) = 0$, the probability $P(a_1, b_1)$ must be equal to zero. However, for any nonsymmetric pure entangled state, it is always possible to find observables $a_0$, $a_1$, $b_0$, and $b_1$ such that (i), (ii), and (iii) are satisfied, while (iv) $P(a_1, b_1) \neq 0$ [15]. $P(a_1, b_1)$ is known as “Hardy fraction”. This provides a proof of impossibility of describing quantum mechanics with local hidden variable theories.

As it was showed by Garuccio and Mermin [16, 17], Hardy proof can be put in a more generalized framework writing it in terms of the following inequality:

$$S_1 \equiv P(a_1, b_1) - P(a_0, b_0) - P(\bar{a_0}, b_1) - P(a_1, \bar{b_0}) \leq 0$$

which holds for any local hidden variable theory, for any choice of observables. In this generalized version, there is no need for vanishing terms in the experimental test, it is only required that the left hand side of Eq. (1) overcomes the sum of terms on the right hand side. Nevertheless, the interesting feature of Hardy’s argumentation lies in the fact that once one has proven that the probabilities on the right hand side of the Garuccio-Mermin-inequality are null, the detection of just one pair of photon, at the output $a_1 = 1$ and $b_1 = 1$ is enough to refute the local behavior of nature. However, in realistic conditions,
measuring a null probability is not trivial as it is discussed in Ref. [16], and the generalization of Hardy test to the Bell-type test based on the Clauser-Horne (CH) inequality [18] is unavoidable.

The inequality given in Eq. (1), is the CH inequality for an experiment where the following conditions hold: (a) The quantum efficiency of the detectors is $\eta = 1$, and (b) photons pairs impinge into the detection apparatuses. Therefore, Hardy proof can be seen as a special case of a Bell test based on the CH inequality. This can be easily demonstrated. Taking into account the above detection conditions, it comes out that the probabilities of single photon detections are given by

$$P_A(a_i) = P(a_i, b_j) + P(a_i, \bar{b}_j)$$
$$P_B(b_j) = P(a_i, b_j) + P(\bar{a}_i, b_j),$$

with $i, j = 0, 1$. For the experimental setup being considered, the CH inequality can be written as

$$P(a_1, b_1) + P(a_0, b_1) + P(a_1, b_0) - P(a_0, b_0) - P_A(a_1) - P_B(b_1) \leq 0,$$

which turns to be Eq. (1), when one replaces the marginal probabilities (2b) into Eq. (3). It is also worth to mention that, under these conditions, the CH inequality is equivalent to the Clauser-Horne-Shimony-Holt (CHSH) inequality [19]. Therefore, Hardy proof can also be seen as a particular case of the nonlocality tests based on the CHSH inequality. Indeed, any experimental setup prepared for testing the CHSH inequality, can also be used to test Hardy proof if the degree of entanglement of the state being generated can be manipulated.

Hardy proof can be generalized by considering a system in which, having defined $K+1$ dichotomic observables $a_k$ and $b_k$ ($k = 0, \ldots, K$), the following probabilities hold:

$$P(a_K, b_K) \neq 0,$$
$$P(\bar{a}_{k-1}, b_k) = 0,$$
$$P(\bar{a}_k, b_{k-1}) = 0.$$  

When $K$ is larger than 1, the test can be interpreted as a chained violation, and can be represented as a ladder [20, 21] on which each step implies the one below (see Fig. 1).

![FIG. 1: Ladder proof schemes for $K = 1$ and $K = 2$.](image)

Let us consider, for example, $K = 2$. If the first equation in (4) holds, then there exists a nonzero probability that both $a_2 = 1$ and $b_2 = 1$ occur. The second and third equations in (4) state that the probabilities of $a_2 = 1$ and $b_1 = -1$, or $a_1 = -1$ and $b_2 = 1$ are zero. In this case, $a_1 = 1$ and $b_1 = 1$ should have been observed. The same applies to the lower step, reaching in this way the bottom of the ladder. At this point, we obtain that both $a_0 = 1$ and $b_0 = 1$ should have been measured, and thus the probability $P(a_0, b_0)$ should be different from zero. In local theories $P(a_0, b_0)$ should be at least equal to $P(a_K = 1, b_K = 1)$. If there exist a system in which this probability is vanishing, a classical theory would not be able to describe the system, and the Hardy inequality would be violated. A system like that can be implemented by the setup shown in the next Section. It can be tested by generalizing Eq. (1) for the ladder proof case:

$$S_K \equiv P(a_K, b_K) - P(a_0, b_0) - \sum_{k=1}^{K} [P(a_k, \bar{b}_{k-1}) + P(\bar{a}_{k-1}, b_k)] \leq 0.$$  

### III. EXPERIMENT

#### A. Energy-time Hardy test

A Hardy test can be, in principle, implemented by using any entangled state, except the one which is maximally entangled. Our capacity to generate two photons correlated in the energy-time degree of freedom in partially entangled states, and the ability to detect them with controllable interferometric techniques allows for implementing a Hardy test with the experimental setup of Fig. 3. Let us consider the energy-time state of two down-converted photons $|\Phi\rangle \equiv \alpha|S_A S_B\rangle + \beta|L_A L_B\rangle$ and define the following $K + 1$ spatial measurement basis, in each direction $A_k, B_k$, where $k = 0, \ldots, K$:

$$|A_k\rangle = \cos \theta_k |S\rangle + \sin \theta_k |L\rangle,$$
$$|A_k^\perp\rangle = \sin \theta_k |S\rangle - \cos \theta_k |L\rangle,$$
$$|B_k\rangle = \cos \theta_k |S\rangle + \sin \theta_k |L\rangle,$$
$$|B_k^\perp\rangle = \sin \theta_k |S\rangle - \cos \theta_k |L\rangle.$$

Let us define the operators $a_k$ ($b_k$ is defined similarly) having outcome 1 or $-1$ when the state $|A_k\rangle$ or $|A_k^\perp\rangle$ is respectively detected. In order to prove nonlocality we need to satisfy the conditions written in (4). That is,

$$P(a_K, b_K) = |\langle A_K | \langle B_K | \Phi \rangle|^2 \neq 0,$$
$$P(\bar{a}_{k-1}, b_k) = |\langle A_{k-1}^\perp | B_k | \Phi \rangle|^2 = 0,$$
$$P(a_k, \bar{b}_{k-1}) = |\langle A_k | B_{k-1}^\perp | \Phi \rangle|^2 = 0.$$  

Moreover, we need that the following condition holds:

$$P(a_0, b_0) = |\langle A_0^\perp | B_0^\perp | \Phi \rangle|^2 = 0.$$  

The values of $\theta_k$ solving the previous equations are given by the relations:

$$\sin \theta_k = (-1)^k \frac{T^{k+1} + 1}{\sqrt{T^{2k+1} + 1}}$$  \hspace{1cm} (9)

with $t = \alpha/\beta$ related to the degree of entanglement. The Hardy fraction $P(a_K, b_K)$ is then given by

$$P(a_K, b_K) = \frac{t^2 (t^{2K} - 1)^2}{(t^{2K+1} + 1)^2 (1 + t^2)}$$  \hspace{1cm} (10)

When $K = 1$ ($K = 2$), this function is maximized at $t = t_1 \approx 0.46$ ($t = t_2 \approx 0.57$) with value $P(a_1, b_1)_{\text{max}} \approx 0.09$ ($P(a_2, b_2)_{\text{max}} \approx 0.17$). When $K = 1$, only 9% of particles violates locality, but this fraction can be amplified using a higher value of $K$. It has been shown in fact that when $K \to \infty$, $P(a_K, b_K)_{\text{max}} \to 50\%$ [20].

In order to perform a Hardy test, nonmaximally entangled states are needed, and it is also possible to use just two detectors instead of the four used in the previous experiment [10]. The new scheme is shown in Fig. 2: variable beam splitters ($VBS_{1A, B}$) are used on both modes in order to prepare the non maximally entangled state and project on the desired basis, as described in the text.

B. Experimental setup

We generated energy-time correlated photons by spontaneous parametric down-conversion (SPDC) [22, 23]. A 1 mm $\beta$-barium borate crystal (BBO) shined by an UV laser beam generated pairs of photons at wavelength 532 nm. The emission time of each pair is unpredictable due to the long coherence length ($\geq 1$ m) of the pump laser beam. The two photons generated with horizontal polarization are sent through two unbalanced interferometers as shown in Fig. 3. As it will be discussed shortly this is a modified version of the interferometric scheme previously used by us [10]. As for the setup previously used, the geometry of these interferometers has been showed to allow for more genuine tests of quantum nonlocality with energy-time correlated photons [9]. In this case, even though the experiment is still constrained by the locality and detection loopholes [24], it is not necessary to assume any other auxiliary assumption for validating it as a conclusively Bell test [1]. These interferometers are unbalanced and so one can refer to their arms as short ($S$) and long ($L$). The optical paths followed by the down-converted photons are such that coincidences between detectors $D_A$ and $D_B$ are measured only when they both propagate through the short or long photon paths.

In order to perform a Hardy test, nonmaximally entangled states are needed, and it is also possible to use just two detectors instead of the four used in the previous experiment [10]. The new scheme is shown in Fig. 2: variable beam splitters ($VBS_{1A, B}$) are used on both modes in order to prepare the non maximally entangled state:

$$|\psi\rangle = \alpha|S_A S_B\rangle + \beta|L_A L_B\rangle.$$  \hspace{1cm} (11)

In this way, the ratio $t = \alpha/\beta$ can be controlled by using the following relation between the transmittivities ($T_A$...
TABLE I: Experimental probabilities needed to violate the inequality $S_K \leq 0$ for $K = 1$ and $K = 2$. The reported data are obtained with the value of $t$ that maximize the violation, namely $t = t_1^* \simeq 0.46$ for $K = 1$ and $t = t_2^* \simeq 0.57$ for $K = 2$.

| $K = 1$, $t = t_1^*$ | $K = 2$, $t = t_2^*$ |
|-----------------------|-----------------------|

| 0.111 ± 0.002         | 0.124 ± 0.009         |

and $T_B$) and reflectivities ($R_A$ and $R_B$) of $VBS_{A,B}$ and $t$:

$$\sqrt{\frac{T_AT_B}{R_AR_B}} = \frac{\alpha}{\beta} = t. \quad (12)$$

The two $VBS_{A,B}$ can be used to project into the states of Eq. (6a)-(6d), providing that their transmittivities and reflectivities are linked to $\theta_k$ being $\sqrt{R} = \sin \theta_k$ and $\sqrt{T} = \cos \theta_k$.

In Fig. 3 we show the setup we actually used for the experiment. It is equivalent to the one shown in Fig. 2 but it doesn’t use variable beam splitters.

The VBSs used to prepare the state, namely $VBS_{A,B}$, are implemented in the way shown by the scheme of Fig. 4a): the polarization of both photons $A$ and $B$ is changed by a half wave plate (HWP1) and then by a polarizing beam splitter (PBS1) each photon is splitted in the long and short paths. After the PBS1 we will have on each mode, in transmission, the state: $|S\rangle|H\rangle$, while on reflection, the state: $|L\rangle|V\rangle$. By rotating HWP1, one can change the amount of light being reflected and transmitted, allowing to create a nonmaximally entangled state.

To implement the two VBS2, we used the scheme reported in Fig. 4b): since the $|S\rangle$ ($|L\rangle$) mode is horizontally (vertically) polarized, any state encoded into the energy-time degree of freedom is converted into polarization encoding by the PBS2. Then the projection on the desired state can be implemented by standard polarization analyzer (HWP2 rotated at $\theta_k/2$ and PBS3).

C. Experimental results

Our experiment aimed at the violation of the Hardy inequality (5) for $K = 1$ and $K = 2$. For this purpose, we measured the probabilities described by equations (7) and (8) as:

$$P = \frac{C(a_i = \alpha, b_j = \beta)}{C_{TOT}}, \quad (13)$$

where $i, j$ are the directions required, and $\alpha, \beta = -1, 1$ as previously specified. $C(a_i = \alpha, b_j = \beta)$ is the number of coincidences obtained measuring on the projected state needed for both modes, while $C_{TOT} = C(H, H) + C(V, V) + C(H, V) + C(V, H)$ is the sum of the number of coincidences over all the possible outcomes in the base $\{|H\rangle, |V\rangle\}$.

In table I we show the experimental probabilities obtained for $K = 1$ and $K = 2$ when $t = t_1^*$ and $t = t_2^*$ respectively. In Figs. 5 and 6 we show the probabilities obtained for $K = 1$ and $K = 2$ for different values of $t = \alpha/\beta$. Each figure shows the graph of the experimental $P(a_k, b_K)$ compared to the theoretical values described by equation (10) and the graph of the inequality violation $S_K$ defined in (1) and (5). The obtained values of $P(a_k, b_K)$ are in good agreement with the theoretical predictions for both $K$ values. The inequality is not violated for large values of $t$, $t \geq 0.8$ (see Fig. 5 and 6). This can be due to the imperfect experimental visibility. In fact, we measured $V \sim 96\%$ when the state is maximally entangled ($t = 1$). However, this value is not enough to allow the probabilities $P(a_{k-1}, b_{K})$, $P(\bar{a}_{k-1}, b_{K})$ and $P(a_0, b_0)$ to vanish completely. This feature is more evi.
FIG. 6: Experimental results for K=2. The results obtained for a two-steps ladder proof are shown. As in the previous figure, in the first one is reported the probability $P(a_2,b_2)$ along with the theoretical function, while in the second there is the inequality violation. When $S_2$ is greater than 0 the inequality (5) is violated.

IV. CONCLUSIONS

Recently introduced schemes for energy-time and time-bin entanglement can be improved for a Bell test with nonmaximally entangled states free of the postselection loophole. The important point is that these tests are less demanding in terms of detection efficiency than those based on maximally entangled states (which were the states used in previous Bell tests with energy-time and time-bin entanglement), even when the postselection is taken into account [13]. The experiments reported in this paper still suffer the detection and nonlocality loopholes, but show the feasibility of energy-time Bell tests with nonmaximally entangled states and free of the postselection loophole.

In addition, the ability for projecting energy-time correlated photons in this more general set of projections may also have other important applications. It could be useful for entanglement witnesses, quantum tomography, and for some cryptographic protocols requiring nonmaximally entangled states.
