Tin is the chemical element with the largest number of stable isotopes. Its complete proton shell, comparable with the closed electron shells in the chemically inert noble gases, is not a mere precursor to extended stability; since the protons carry the nuclear charge, their spatial arrangement also drives the nuclear electromagnetism. We report high-precision measurements of the electromagnetic moments and isomeric differences in charge radii between the lowest $1/2^+$, $3/2^+$, and $11/2^-$ states in $^{117-131}$Sn, obtained by collinear laser spectroscopy. Supported by state-of-the-art atomic-structure calculations, the data accurately show a considerable attenuation of the quadrupole moments in the closed-shell tin isotopes relative to those of cadmium, with two protons less. Linear and quadratic mass-dependent trends are observed. While microscopic density functional theory explains the global behaviour of the measured quantities, interpretation of the local patterns demands higher-fidelity modelling.
Nuclear science greatly relies on observations, not only in naturally-occurring, but also in laboratory-synthesized nuclides, which represent the majority of approximately 3000 species discovered to date. Either type can be studied by laser spectroscopy, a non-destructive experimental technique probing the hyperfine splitting of atomic energy levels induced by the nuclear electromagnetic. An electric quadrupole moment, for instance, reflects an anisotropic (deformed) charge distribution within the nucleus. Appreciable nuclear deformation is primarily found in species with open shells for both protons and neutrons. The tin isotopes, with their proton core complete (spherical), may still acquire quadrupole moments through the geometry of valence neutron orbitals. Those can be discussed in terms of schematic theoretical descriptions such as the seniority or generalized-seniority models, which explain the striking regularities previously observed, e.g., the nearly-constant energy of excited states and simple patterns exhibited by other quantities. When looking into details, however, deviations from regular behavior are revealed as fingerprints of the underlying nuclear shell structure and many-body correlations.

Here we study the odd-mass isotopes $^{117-131}$Sn. An 11/2− state with an unpaired neutron confined by the rules of quantum mechanics to the unique-parity $h_{1/2}$ orbital is present in each case. The remaining valence orbitals in the neutron shell have the opposite parity and considerably lower angular momenta, which results in isomerism (metastability of an excited nuclear state). Quadrupole moments in the closed-shell tin isotopes are found at variance with those in the cadmium isotopes having two protons less. Differences in radii between nuclear ground and isomeric states, on the other hand, are shown to remain surprisingly similar. Calculations in the framework of nuclear density functional theory with recently optimized input describe the global behavior of the experimental observables. Interpretation of the local patterns, however, calls for a dedicated microscopic modeling.

Results and discussion

Measurements. Short-lived nuclei, naturally occurring only in astrophysical phenomena such as supernovae explosions, are synthesized on Earth using particle accelerators. The tin isotopes for this study were produced at the CERN-ISOLDE laboratory by uranium fission using fast protons traveling with more than 90% of the speed of light. Prior conversion to neutrons increased the fission purity. Tin atoms were laser ionized, accelerated to an energy of 40 or 50 keV to form a continuous beam of fast-traveling ions, and mass separated. Typically, each 100-ms segment of the beam was compressed into an ion bunch with a temporal width of less than 10 μs using a linear Paul trap. Individual bunches were subsequently released, re-accelerated, and guided with a dedicated set of electrostatic optics into a volume of vaporized sodium for neutralization. Narrowbandwidth continuous-wave laser light was introduced along the axis of ion/atom propagation. The atomic-beam energy and the associated Doppler-shifted laser frequency were defined at the sodium charge-exchange cell, whose electrostatic potential was scanned in search of resonant atomic-beam fluorescence. The latter was collected by telescopes of aspheric lenses and imaged onto the photocathodes of photomultiplier tubes for single-photon counting. The measurements were correlated with the timing structure of the atomic beam, which allowed substantial background suppression and high sensitivity. A sketch of the experimental arrangement is shown in Fig. 1a.

Laser excitation of tin atoms was performed using the two complementary transitions in Fig. 1b to resolve the nuclear properties, as described in “Methods”. The laser system comprised a diode-pumped solid-state laser, a tunable laser using either dye or titanium–sapphire as the active medium, and a second-harmonic-generation cavity. Two nuclear states were detected for each odd-mass isotope in the range $^{117-131}$Sn, as shown in Fig. 2. The hyperfine structure is characterized by a sizeable quadrupole splitting in the $5p^6 1^2P_1^o$ state and a large magnetic splitting in the $5p^6 1^2P_1^o$ state. The two are correlated through the nuclear electromagnetic properties and are thus fitted simultaneously. All results are shown in Table 1. The magnetic moments therein incorporate the latest computation of the absolute shielding constant in tin. The accuracy of quadrupole moments is ensured by the theoretical work outlined in the following.

Atomic structure calculations. The fully relativistic multi-configuration Dirac–Hartree–Fock (MCDHF) method was employed to calculate the magnetic dipole hyperfine-structure constants and electric-field gradients in the $5p^6 1^2P_1^o$ and $5p^6 1^2P_1^o$ states of tin (see “Methods” for the definition of these quantities). Three independent series of large-scale calculations were performed, adopting different computational strategies and correlation models using the General Relativistic Atomic Structure Package computer codes GRASP2K and GRASP2018, based on the same relativistic MCDHF theory and methodology. Classes of electron excitations adopting different multireference spaces and active orbital sets were investigated in detail to clarify the role of electron correlation in the relevant matrix elements. A combined effort was put in assessing the reliability of the resulting ab initio electronic factors involved in M1 and E2 hyperfine interactions for both levels (Papoulia, A. & Schiffman, S. et al. manuscript in preparation). The quadrupole moments from this work are obtained with the electric-field gradient 706(50) MHz/b in the singlet state, which is the mean value resulting from the aforementioned calculations. With regard to the dipole hyperfine constants in the triplet state, cross-checking calculations were performed using the configuration interaction Dirac–Fock–Sturm (CI-DFS) method. The hyperfine anomaly (see “Methods”) was estimated in separate multireference calculations for each isotope using a Fermi charge distribution with adopted root mean square radius and a parametrized squared harmonic-oscillator wave function of the last unpaired neutron as magnetization distribution. It reaches a maximum at $^{119}$Sn of $0.05%$ due to the limited overlap between the 3s and 1h nuclear wave functions and partly due to the increase in the charge radius between the two isotopes. The anomaly between positive-parity states was found to be negligible with respect to the experimental precision.

Experimental trends. The data on quadrupole moments and differences in mean square charge radii between nuclear ground and isomeric states are compared in Fig. 3 with values measured in the cadmium isotones. A number of key observations are worth being pointed out: (i) There is a significant attenuation of the quadrupole moments of tin ($Z = 50$) with respect to cadmium ($Z = 48$). Note that the observed charge (proton) quadrupole moment originates from the nuclear response to an odd neutron in a $d_{3/2}$ or an $h_{1/2}$ single-particle state. (ii) The fitted trends in Fig. 3a, b cross each other close to zero, i.e., the $h_{1/2}$ orbital is half full for both tin and cadmium at $N = 73$, as is $d_{3/2}$ at $N = 75$. (iii) The quadrupole moments of tin in the 11/2− states are by a factor of about two larger in magnitude than those in the 3/2− states. This is consistent with a stronger quadrupole polarization exerted by unique-parity $h_{1/2}$ nucleons. (iv) All trends are remarkably smooth, often near linear, at most quadratic. (v) The quadrupole moments of the 11/2− states in tin exhibit a quadratic behavior with changing neutron number, strikingly different from the linear trend observed along the cadmium chain. (vi) The
pattern is unexpectedly reversed for the $3/2^+$ states whose quadrupole moments change linearly for tin and quadratically for cadmium. (vii) Re-evaluated values for $^{113,115,119}$Sn in Fig. 3a, b are consistent with the trends defined by the heavier isotopes. These are independently calibrated to experimental $\gamma$-decay rates, thus showing consistency between nuclear data and atomic theory. (viii) The measured mean square charge-radii changes in Fig. 3c are fairly similar for tin and cadmium. All these features are discussed in the following.

Nuclear structure calculations. The theoretical analysis at the level of nuclear density functional theory (DFT) employs the standard Skyrme functional SV-min and the recently optimized Fayans functional $Fy(\Delta r, \text{HFB})$, the latter containing gradient terms in surface and pairing energies. Both models are optimized to the same large set of basic ground-state nuclear data. In addition, $Fy(\Delta r, \text{HFB})$ accommodates the isotopic shifts of charge radii in the calcium chain, a feature which could only be achieved by invoking the Fayans gradient terms. The calculations for the charge radius, which is an isotropic observable, were done in spherical approximation with pairing handled at Hartree–Fock–Bogoliubov (HFB) level. The odd nucleons were treated within the blocking ansatz. In principle, the odd nucleon polarizes the nucleus and so perturbs the spherical shape. The impact of this polarization effect on charge radii and correlations beyond mean field are small for heavier spherical species as the tin isotopes. To check the uncertainty from the spherical mean-field approximation, we performed more elaborate blocked HFB calculations allowing axial deformations and spin polarization for the case of the SV-min model. In this variant, each magnetic sub-state produces a slightly different radius whose average is very close to the spherical result. This supports our spherical calculations and the variance of charge radii within a $jm$ shell delivers an estimate of their theoretical uncertainties.
Figure 3 Sn vs. Cd. a $^{11/2}^-$ quadrupole moments. b $^{3/2}^+$ quadrupole moments. Correlated uncertainties originating from the electric-field gradients are smaller than the dots. c Mean square charge-radii changes for the $^{11/2}^-$ states relative to the $^{1/2}^+$ ($N \geq 71$) and $^{3/2}^+$ ($N \geq 71$) states. Shaded bands represent systematic uncertainties originating from the field-shift coefficients. The literature values are taken from refs. 25,26,28.

Figure 4a shows the quadrupole moments of $^{11/2}^-$ states in tin and cadmium which were obtained by blocking the $m = 11/2$ magnetic subspace of the $h_{11/2}$ orbital in calculations that break spherical symmetry. It is satisfactory to see that the general experimental pattern in Fig. 3a is reproduced. Namely, the quadrupole moments exhibit a smooth increase as a function of the neutron number, with the quadrupole moments of tin being reduced in magnitude relative to cadmium. The enhanced quadrupole correlations in cadmium stem from the enhanced polarizability through the two $g_{9/2}$ proton holes. Indeed, in the nuclear shell model and in nuclear DFT, deformation is primarily driven by the isoscalar neutron–proton (quadrupole) interaction, acting against the sphericity-favoring monopole force, which includes the isovector pairing interaction. According to the seniority coupling scheme, the spectroscopic quadrupole moment should vanish at mid-shell. In SV-min, the neutron $h_{11/2}$ shell becomes half-filled at $N = 75$, as seen in Fig. 4a. Experimentally, the zero crossover point is at $N = 73$, which suggests that the single-particle energy of the $h_{11/2}$ shell is perhaps not optimal in our model. This nicely demonstrates that the present high-precision data on quadrupole moments deliver extremely sensitive criteria for probing the shell structure of a model.

Theoretical values for the isomeric charge-radii shifts of the odd-mass tin isotopes are displayed in Fig. 4b, c. The error bars on the SV-min results indicate the estimated uncertainty of the spherical approach as compared to calculations allowing shape deformation as well as spin polarization and subsequent angular momentum projection, as explained above. We expect similar uncertainty for the $^{11/2+}$, HFB model. One finds an acceptable agreement for the charge radii difference between the $^{11/2}^-$ and the $^{3/2}^+$ states, with a preference towards the $^{11/2+}$, HFB description, especially when considering the theoretical uncertainty. This is not the case for the radii changes between the $^{11/2}^-$ and the $^{1/2}^+$ states, since the experimental data approach the upper end of theoretical results in Fig. 4b. A word of caution is in order here: the $^{1/2}^+$ state is particularly prone to a dynamical coupling with low-energy quadrupole vibrations which is expected to enhance the charge radius.

The trends of quadrupole moments, linear vs. quadratic, are different for cadmium and tin owing to a significant configuration dependence. The latter does not cause a substantial deviation between the corresponding mean square charge-radii changes. The future theoretical analysis would need to address these features in greater detail together with variations of the magnetic moments shown in Fig. 5. Any connection with the quadrupole moments of the lowest $^{2+}$ states in the even–even isotopes should also be examined.

**Perspective.** Complex systems often display regular patterns. Atomic nuclei, composite structures consisting of hundreds of nucleons, are no exception; they often behave as ordered systems obeying elementary rules. The reason for such simplities is the presence of many-body symmetries resulting in a collective nucleonic motion. A challenge for the modern microscopic theory is to explain the origin of underlying symmetries.

In this work, we showed that electromagnetic properties of tin nuclei evolve from one isotope to another in a simple way: along a line or parabola. The microscopic mechanisms behind the observed behavior are rooted in many-body polarization effects. While the general trends are explained by theory, the regularities seen at high experimental resolution provide a strong motivation for further theoretical developments. Similar effects are expected to be common for nuclei whose valence nucleons move in a unique-parity shell. Dedicated studies would be required to refine the systematics in lead and mercury.
isotopes\textsuperscript{44}, which are the closest analogues of tin and cadmium in terms of nuclear structure. While initial assessments could be made by in-source measurements\textsuperscript{45,46}, the high-resolution spectroscopic techniques employed here, in combination with advanced atomic calculations, will be essential for developing further understanding of complex nuclear systems.

Methods

Hyperfine structure. The electromagnetic interaction of the nucleus with the electron environment in an atom causes splitting of the energy levels which is about a millionth of the electron environment in an atom causes splitting of the energy levels which is about an average magnetic-flux density at the origin \( B_0 \). \( B = eQV_J \) is proportional to the nuclear quadrupole moment and the average electric-field gradient at the origin \( V_J \). \( F = I + J \) is the total angular momentum of the atom, and \( k = R(F + 1) - I(I + 1) - J(J + 1) \). The hyperfine-structure splitting is determined by the \( A \) and \( B \) parameters whose values are obtained from the experiment. The decay rate per electron structure splitting, hence the term hyperfine structure. The \( fi \) component equals

\[
\Delta F \approx 4\frac{(2I + 1)(2J + 1)}{(2F + 1)(2F_1 + 1)} \left( \frac{F}{F_1} \right)^2
\]

where \( \tau \) is the lifetime of the excited atomic state and \( \gamma \) is the ratio between the induced and spontaneous emission coefficients, which incorporates the laser intensity and the spectral lineshape.

Hyperfine anomaly. The \( A \) hyperfine constant is influenced by the extended nuclear magnetization, known as Bohr–Weisskopf effect, and the extended nuclear charge distribution, known as Breit–Rosenthal–Crawford–Schawlow correction. Both contribute to the hyperfine anomaly:

\[
1\Delta F = \frac{A_1 I_1 \mu_B}{A_2 I_2 \mu_B} - 1.
\]

Following justifications by atomic calculations, the anomaly is neglected in our analysis. However, its estimated contribution to the 11/2\textsuperscript{-} magnetic moments is predicted to be on the level of the experimental precision and it is therefore incorporated into the final uncertainties quoted in Table 1, as further discussed.
Fig. 6 Fitted fluorescence spectra of $^{109,117-131}$Sn. The common frequency scales are relative to the fine-structure splittings in the transitions $5p^2$ $^3P_0 \rightarrow 5p6s$ $^3P_1$ and $5p^2$ $^1S_0 \rightarrow 5p6s$ $^1P_1$. Positive- and negative-parity states are represented by dashed and solid lines, respectively. Solid lines in the right column also show the sum fit function. $^{119}$Sn is studied from a mass marker to observe only the stable $1/2^+$ g.s., and after target irradiation to detect the radioactive $11/2^-$ state. Spectra of the stable g.s. in $^{115,117}$Sn (similar to $^{119}$Sn g.s.) are not shown. $^{133}$Sn, used together with $^{109}$Sn for calibration of the $B$-ratio, will be published elsewhere.
Isomer shifts. A change in the nuclear mean square charge radius between a nuclear ground state and an isomer results in a common energy displacement of all levels in a given hyperfine multiplet. The combined effect in a transition between two atomic levels is manifested in spectra from laser spectroscopy as an apparent isomer shift. A change in the nuclear mean square charge radius: 

\[ \delta \nu = F_2 \delta \langle r^2 \rangle. \]

Distinction should be made between \( F_2 \) and the total angular-momentum quantum number \( F \) introduced earlier. The effect from a change in the nuclear mass is negligible.

Fitting of multiple spectra. Routines for fitting multiple spectra were developed in the ROOT data analysis framework, making use of the WrappedMultiTFI class for enveloping individual fit functions under a common \( \chi^2 \). Spectra of the stable 1/2+ ground states in \(^{115,117,119,131}\)Sn, free of quadrupole splitting, were used to determine the proportionality of \( A \) factors between the singlet and the triplet state. With this condition applied to the spectra of \(^{109}\)Sn and \(^{133}\)Sn, which are unperturbed by the presence of an isomer, one obtained the ratio of \( B \) factors. Individual masses were used for ground and isomeric states. The three aforementioned ratios are presented in Table 1. These in combination with their corresponding isomeric shifts relative to the unique-parity state \( \delta \nu = \delta \langle r^2 \rangle \) with systematic uncertainties from the computed electric-field gradient and the experimental field-shift factor shown in the second sets of parentheses. In the SI system of units, 1\( \text{b} = \text{fm}^2 = 1 \times 10^{-28} \text{m}^2 \).

D.L.B. acknowledges support from the EU Development Fund and Competitiveness Operational Program for the EU-IP Project Phase II (1/07.07.2016, COP, ID1334) and the Swedish Research Council (IER) under Contract No. 2015-04842 and P.P. from the Magnus Ehrnrooth Foundation.

**Author contributions**

M.L.B., R.F.G.R., C.G., H.H., S.K., V.I., S.L., S.M.-E., L.V.R., S. Saaler, L.X., Y.Y., and D.T.Y. prepared the instrumentation and contributed to the on-line measurements along with D.L.B., K.B., R.C., G. Georgiev, W.G., A.K., B.M., R.N., G.N., W. Nörtershäuser, R.S., S. Schmidt, L.W., C.W., and Z.K. L.V.R. developed routines for the fitting of multiple spectra. Nuclear DFT analysis was carried out by W. Nazarewicz and P.-G.R. J.B., J.E., G. Gaigalas, M.R.G., Z.H., P.J., C.H.K., N.S.O., A.P., P.P., and S. Schifflmann contributed to the ab initio large-scale MCDHF and CI-DFS calculations of the relevant electronic parameters and to their reliability assessment. J.E. computed the hyperfine anomalies.
D.T.Y. proposed the measurements and prepared the manuscript with input from all authors. These results are part of the PhD theses of C.G. and L.V.R.

**Competing interests**
The authors declare no competing interests.

**Additional information**
Correspondence and requests for materials should be addressed to D.T.Y.
