ABSTRACT

The detection of radio pulsars within the central few parsecs of the Galaxy would provide a unique probe of the gravitational and magnetico-ionic environments in the Galactic center (GC) and, if close enough to Sgr A*, precise tests of general relativity in the strong-field regime. While it is difficult to find pulsars at radio wavelengths because of interstellar scattering, the payoff from detailed timing of pulsars in the GC warrants a concerted effort. To motivate pulsar surveys and help define search parameters for them, we constrain the pulsar number and spatial distribution using a wide range of multiwavelength measurements. These include the five known radio pulsars within 15′ of Sgr A*, non-detections in high-frequency pulsar surveys of the central parsec, radio and gamma-ray measurements of diffuse emission, a catalog of radio point sources from an imaging survey, infrared observations of massive star populations in the central few parsecs, candidate pulsar wind nebulae in the inner 20 pc, and estimates of the core-collapse supernova rate based on X-ray measurements. We find that under current observational constraints, the inner parsec of the Galaxy could harbor as many as ~10^3 active radio pulsars that are beamed toward Earth. Such a large population would distort the low-frequency measurements of both the intrinsic spectrum of Sgr A* and the free-free absorption along the line of sight of Sgr A*.

Key words: Galaxy: center – pulsars: general

1. INTRODUCTION

The discovery of one or more pulsars in the inner parsecs around Sgr A*, the massive black hole (MBH) at the center of our Galaxy, would provide an invaluable tool for studying the innermost regions of the Galactic center (GC). Most of the current understanding of the inner parsec comes from infrared observations of the nuclear star cluster (for a recent review, see Genzel et al. 2010). The nuclear star cluster is centered on Sgr A* and consists of young massive stars at a projected radius of r ≈ 0.5 pc and a dense collection of B-stars (the “S-stars”) within r < 0.04 pc with the closest orbit passing just 6 x 10^-4 pc (∼100 AU) from Sgr A* (Schödel et al. 2002; Ghez et al. 2003). Two decades of monitoring the orbits of these S-stars has yielded the mass of the central object to be $M = 4 \times 10^6 M_\odot$, unambiguously classifying it as an MBH (Ghez et al. 2008; Gillessen et al. 2009).

Despite the success of tracking stellar orbits in the infrared, the sensitivity of this method is ultimately limited by source confusion. The detection of a radio pulsar at a similar distance with an orbital period of $P_{\text{orb}} \lesssim 100$ yr would provide unparalleled tests of gravity in the strong-field regime. The timing of such a pulsar could allow the measurement of the spin or quadrupole moment of the MBH (Pfahl & Loeb 2004; Laguna & Wolszczan 1997; Wex & Kopeikin 1999; Liu et al. 2012). Additionally, a pulsar found anywhere in the inner few parsecs of the Galaxy would provide a useful probe of the GC environment. The mere detection of a pulsar would place constraints on the star formation history (SFH), and measurements of the dispersion measure and pulse broadening times would provide information on the electron density distribution of the region.

However, even with the detection of almost 2000 radio pulsars in the Galaxy (Manchester et al. 2005) and several directed searches of the GC, only five pulsars have been found within 15′ of Sgr A* and the closest of these is 11′ away (Deneva et al. 2009; Johnston et al. 2006; Bates et al. 2011). While these few objects indicate the existence of a GC pulsar population, the perceived dearth of pulsars near Sgr A* is the result of interstellar scattering from turbulent plasma, which temporally broadens pulses to approximately $2000\nu_{\text{GHz}}^{-4}$ s (where $\nu_{\text{GHz}}$ is the observing frequency in GHz) at the center of the Galaxy (Cordes & Lazio 2002). Pulse broadening makes it almost impossible to detect even long-period pulsars in periodicity searches at commonly used frequencies ($\nu \sim 1$ GHz). To mitigate the deleterious effects of interstellar scattering, periodicity searches of the GC have migrated to higher frequencies ($\nu \sim 10$ GHz). However, since pulsars have power-law spectra of the form $S(\nu) \propto \nu^{\alpha}$ (with $\alpha < 0$), increasing the observing frequency also decreases the observable flux density. To date, high-frequency searches have produced no new detections using existing 100 m class telescopes (Deneva 2010; Macquart et al. 2010).

Even though the absence of pulsar detections in the central parsecs of the GC is well explained by scattering effects, the existence of a GC pulsar population was established by Deneva et al. (2009) based on the five pulsars on the outskirts of the region that cannot be explained as foreground disk objects. Since future surveys can benefit from better knowledge of the region that cannot be explained as foreground disk objects, the detection of radio pulsars in the vicinity of Sgr A* on parsec scales is shown in Figure 1.

In this paper, we present observational constraints on the pulsar populations in the GC. A brief overview of the conventions and notations used in this paper are presented in Section 2. In Section 3, population limits are set from the detections of pulsars in the inner 15′ and from non-detections in the vicinity of Sgr A* on parsec scales. In Section 4, a catalog of steep-spectrum radio
sources in the inner 150 pc is considered. Interferometric measurements of the spectrum of Sgr A* are used in Section 5 to set upper limits on the pulsar population in the GC on arcsecond scales. In Section 6, *Fermi* observations of the diffuse gamma-ray flux of the inner degree of the GC are used to estimate the millisecond pulsar (MSP) population in the GC. In Section 7, infrared observations of young massive stars are used to estimate the number of neutron stars (NSs) produced in the inner parsec of the Galaxy. *Chandra* X-ray observations of pulsar wind nebulae (PWNe) are used to constrain the pulsar population in the inner 20 pc in Section 8. In Section 9, limits are set on the intrinsic NS population in the GC based on the estimated supernova (SN) rate. Finally, in Section 10, the estimates are summarized and discussed.

2. CONVENTIONS AND NOTATIONS

We note briefly a few conventions and notations that we adopt in this paper. The name “Sgr A*” is used to describe both the MBH and the compact radio source at the dynamical center of the Galaxy. In the event where a distinction must be made (for example, Section 5), “Sgr A*” is taken to mean the observed radio source. All distances from Sgr A* are given as a projected distance unless explicitly stated otherwise. The distance from Earth to Sgr A* is taken to be $d = 8.5$ kpc (Ghez et al. 2008; Gillessen et al. 2009).

Pulse broadening times are taken from the NE2001 electron density model of Cordes & Lazio (2002). The NE2001 model accounts for the geometry of the scattering region in the GC, and as such, it is preferable over empirical fits to pulsars in the Galactic disk (e.g., Bhat et al. 2004), which do not consider the particular scattering geometry of the GC. As discussed in Deneva et al. (2009), NE2001 tends to overestimate the scattering times for the five pulsars closest to Sgr A* by factors of $10^2$–$10^3$. However, these pulsars likely lie along the edges of the GC scattering region where slight ($\sim 0.1$ kpc) changes to the line of sight distance can cause dramatic (factors of $\sim 10^3$) changes in scattering times with only modest (factor of $\sim 2$) changes in dispersion measure. Additionally, we note that the scattering times of pulsars deeper in the GC will be highly constrained by the measured angular scattering of Sgr A* itself.

Pulse broadening times are found at arbitrary observing frequencies by scaling the 1 GHz values given by NE2001 as $\propto \nu^{-4}$ (Lambert & Rickett 1999). However, see Löhmer et al. (2001) for potentially significant deviations from this scaling in highly scattered pulsars.

All pulsar population estimates are given as the number of active radio pulsars beamed toward the Earth, where a beaming fraction of $f_b = 0.2$ is assumed for all pulsars. The fixed beaming fraction of $f_b = 0.2$ comes from a simple model in which the magnetic dipole moment is oriented randomly with respect to the rotation axis (Emmering & Chevalier 1989). A better empirical fit to the data is provided by the period-dependent model of Tauris & Manchester (1998), which typically finds $f_b \approx 0.1$ for isolated pulsars. However, since the Tauris & Manchester (1998) model does not include MSPs that may have beaming fractions as high as $f_b \approx 0.5$–$0.9$ (Kramer et al. 1998), we adopt the $f_b = 0.2$ value as a population-wide representative value. As this factor only shows up in our analysis as a multiplicative constant, it is trivial to scale our results to different beaming fractions.

In many of the limits presented below, it will be necessary to utilize a distribution for pulsar pseudoluminosities ($L = Sd^2$). We adopt the power-law distribution of Lorimer et al. (2006) with a minimum cutoff in preference to distributions that do not require cutoffs like the log-normal model of Faucher-Giguère & Kaspi (2006). Both are two-parameter models and the power-law distribution provides a much better empirical fit to the observations (see, e.g., Figure 6 of Lorimer et al. 2006). However, if the log-normal distribution were used instead of the power law in the calculations below, the total pulsar populations predicted would be larger by factors of 10–100 owing to the much larger fraction of low-luminosity objects. As a result, our adoption of the power-law pseudoluminosity distribution is a conservative one in the sense that using another distribution would predict a larger pulsar population.

Lastly, we note that in some cases our constraints will involve all types of pulsars, while others involve one of two
subsets of pulsars: the “canonical” pulsars (CPs) and recycled or MSPs. CPs have periods of $P \sim 1$ s, surface magnetic fields $B \sim 10^{12}$ G, and active radio lifetimes of $\tau \sim 10^3$ years, while MSPs have periods $P \lesssim 10$ ms, low surface magnetic fields $B \lesssim 10^9$ G, and active radio lifetimes of $\tau \sim 10^9$–$10^{10}$ years.

3. CONSTRAINTS FROM PULSAR SURVEYS OF THE GC

Several pulsar searches have been conducted in the inner degree of the Galaxy. To date, only five pulsars have been detected within 15' of Sgr A*, with none closer than 11' (Manchester et al. 2005). To have any chance of making detections in the inner few arcminutes of the Galaxy, higher observing frequencies must be used to overcome the roughly 2000$\nu$4 GHz broadening times caused by scattering. Deep searches have been attempted at frequencies from 4 to 15 GHz, but have made no detections in the inner few parsecs around Sgr A* (Johnston et al. 2006; Deneva et al. 2010; Macquart et al. 2010). Both the pulsar detections in low-frequency (2–3 GHz) surveys and the absence of detections in high-frequency (4–15 GHz) directed searches can be used to constrain the GC pulsar population.

3.1. GC Pulsar Detections in Low-frequency Surveys

The five known pulsars within 15' of Sgr A* currently provide the best direct evidence for an intrinsic GC pulsar population. Of these five pulsars, two were detected at 3.1 GHz with the Parkes radio telescope (Johnston et al. 2006) and three4 were detected at 2 GHz with the Green Bank Telescope (GBT; Deneva et al. 2009). In each of these surveys, the expected number of detectable disk pulsars in the field of view is $\ll 1$. Thus, the detections strongly suggest a pulsar population in the GC that is distinct from that of the disk.

In an attempt to constrain the number and spatial distribution of the GC pulsars, Deneva et al. (2009) simulated the pulsar population to determine what would be consistent with the survey detections. A simple two-component density model of the form

$$n_{GC} \propto \exp \left( -\frac{h^2}{H_{GC}^2} \right) \exp \left( -\frac{r^2}{R_{GC}^2} \right)$$

was adopted with $H_{GC} = 26$ pc fixed to coincide with the scale height of the scattering screen in the NE2001 electron density model of Cordes & Lazio (2002). The density distribution was normalized so that, for a given $R_{GC}$, there were a total of $N_{GC}$ pulsars (not necessarily beamed toward Earth) associated with the population.

Using Monte Carlo methods, Deneva et al. (2009) then generated 1000 pulsar populations consistent with Equation (1) for each ($R_{GC}$, $N_{GC}$) pair and determined how many of these pulsars would have been detected in their 2.1 GHz survey. Searching over a grid of values and performing a maximum likelihood (ML) analysis, Deneva et al. (2009) found lower bounds of $N_{GC} \gtrsim 2000$ and $R_{GC} \gtrsim 0.3$ kpc for the parameters. Thus, this analysis provides additional evidence for an intrinsic pulsar population in the GC.

Although Deneva et al. (2009) have set a lower bound on $N_{GC}$, this parameter applies to the entire GC population and does not necessarily translate into a lower bound on the number of pulsars within a particular distance from Sgr A*. For example, a distribution with $N_{GC} = 2000$ and $R_{GC} = 0.3$ kpc will produce a very different number of pulsars within 100 pc of Sgr A* than will a distribution with $N_{GC} = 2000$ and $R_{GC} = 0.6$ kpc. Regardless, the existence of a pulsar population in the GC is firmly established.

We note briefly that the primary reason the Deneva et al. (2009) analysis does not find upper bounds on the parameters $N_{GC}$ and $R_{GC}$ even after extending the grid to $N_{GC} = 10^4$ and $R_{GC} = 5$ kpc is that the only constraints come from the detections in the survey region ($r \lesssim 50$ pc). Incorporating survey results from the inner few degrees of the Galaxy would certainly introduce upper bounds to the parameters.

With this in mind, it is instructive to consider the results at a fixed $R_{GC}$. From Figure 4 of Deneva et al. (2009), we see that a wide range of $N_{GC}$ values with $N_{GC} \gtrsim 500$ are equally likely for $R_{GC} = 0.1$ kpc. Thus, a very conservative lower bound on the number of pulsars in the inner 100 pc of the Galaxy that are beamed toward Earth is $N_{tot} \gtrsim 100$ (where we have assumed a beaming fraction of 0.2).

3.2. High-frequency Pulsar Searches of the Central Parsec

Recently, searches of the central few parsecs around Sgr A* have been conducted with the GBT at 5 GHz and 9 GHz (Deneva et al. 2010) and at 15 GHz (Macquart et al. 2010). No pulsars were detected in any of these searches. We follow a similar analysis to that of Macquart et al. (2010) to estimate an upper limit to the pulsar population based on the absence of detections.

3.2.1. Observations

The 5 and 9 GHz observations were carried out by Deneva (2010) in 2006. Since no pulsar candidates were detected, limits on the flux density of periodic signals may be set using the radiometer equation

$$S_{min,v} = \frac{mT_{sys}}{\eta G\sqrt{\nu h N_{pol} \Delta v T_{obs}}} = \frac{mT_{sys}}{\zeta_{pol} \Delta v T_{obs}} = \frac{mT_{sys}}{\zeta_{pol} \Delta v T_{obs}},$$

where $T_{sys}$ is the system temperature, $G$ is the telescope gain, $\eta \approx 0.8$ is a correction factor that accounts for system imperfections and the digitization of the signal, $N_{pol} = 16$ is the maximum number of harmonics summed in a periodicity search, $\Delta v = 800$ MHz is the receiver bandwidth, and $T_{obs} = 6.5$ hr is the observation time. The telescope gain is given by $G = 1.85$ K Jy$^{-1}$ and $\Delta v = 1.8$ K Jy$^{-1}$ for observing frequencies of 5 and 9 GHz, respectively. The value of $m$ is determined by the detection significance threshold set at $m\sigma$. In this fast Fourier transform search the threshold was set to 6$\sigma$, so $m = 6$.

The system temperature of the telescope is given by $T_{sys} = T_{rec} + T_{bg}$. The receiver temperature of the GBT is 18 K at 5 GHz and 27 K at 9 GHz. The dominant contribution to the background temperature is the bright extended Sgr A Complex (comprised of Sgr A East and Sgr A West), which surrounds Sgr A*. We may set lower bounds on this background using data from a multiwavelength survey by Law et al. (2008), which imaged the GC at 1.4, 5, and 9 GHz. Only lower bounds may be set since a non-trivial iterative scheme was used to subtract out the noise contributions from the atmosphere. Law et al. (2008) found the flux density of the Sgr A Complex to be 85 Jy beam$^{-1}$

---

4 One of these pulsars, J1746–2850, was independently discovered by Bates et al. (2011) in a Parkes 6.5 GHz multibeam survey.

5 We take $T_{rec}$ to include all non-astronomical contributions to the system temperature from the receiver, spillover effects, and the atmosphere.

6 As provided in the GBT Proposer’s Guide: http://www.gb.nrao.edu/gbtprops/man/GBTpg.pdf.
at 5 GHz and 39 Jy beam$^{-1}$ at 9 GHz, which translate to background temperatures of $T_{\text{bg}} = 157$ K and $T_{\text{bg}} = 70$ K, respectively. Thus, the system temperature is $T_{\text{sys}} = 175$ K at 5 GHz and $T_{\text{sys}} = 97$ K at 9 GHz. From Equation (2), we find that $S_{\text{min},v} = 29\mu$Jy at 5 GHz and $S_{\text{min},v} = 17\mu$Jy at 9 GHz.

Likewise, Macquart et al. (2010) conducted a search for pulsars at 14.8 and 14.4 GHz using the GBT in 2006 and 2008. The Macquart et al. (2010) search used a 10$\sigma$ detection threshold and combined observations to get an effective observation time of $T_\text{obs} \approx 9.75$ hr. The system temperature was determined to be $T_{\text{sys}} \approx 35$ K by firing a noise diode on a calibrator source. No pulsars were detected and a 10$\sigma$ detection threshold flux density of $S_{\text{min},v} \approx 10\mu$Jy is set from the 14.4 GHz measurements.

### 3.2.2. Upper Limits on Observable Pulsar Population

Assuming that a given pulsar in the GC will be detected with some probability $p_d$, binomial statistics can be used to find the maximum number of pulsars consistent with zero detections. The simplest way to determine $p_d$ is to set it equal to the fraction of pulsars bright enough to be seen in each survey when placed at Sgr A*. This fraction can be estimated from the 1.4 GHz pseudoluminosity function, which is given by $dN/d\log L \propto L^{-\beta}$ taken over a range of pseudoluminosities from $L_{\text{min}} = 0.1$ mJy kpc$^2$ to $L_{\text{max}} = 10^4$ mJy kpc$^2$. We adopt a value of $\beta = -0.7$ as an average of the two fits found by Lorimer et al. (2006) of over 1000 pulsars observed in the Parkes Multibeam Survey. The detection probability is then given by $p_d = f_d(L > L_{\text{det}})$, where

$$L_{\text{det}} = S_{\text{min},v} \left(\frac{1.4\,\text{GHz}}{v}\right)^{-1.7} d^2_{gc}$$

and $S_{\text{min},v}$ is the minimum detectable flux density of the search. Using the $S_{\text{min},v}$ values found by each search (see Table 1), we find that $p_d = (0.027, 0.020, 0.015)$ at $v = (5, 9, 15)$ GHz.

Given the above detection probabilities and the lack of any detections in the surveys, the upper limits to the number of pulsars (at 99% confidence level) are found to be $N = (170, 230, 299)$ for the 5, 9, and 15 GHz observations, respectively. However, since a pulsar with a spin period less than the pulse-broadening time would have a greatly reduced chance of being detected, the calculated upper limits are for pulsars with $P > \tau_{\text{sc}}$. Using the 1 GHz scattering time from the NE2001 model of Cordes & Lazio (2002) and scaling $(\propto v^{-2})$ to the appropriate frequency, the scatter-broadening times are found to be $\tau_{\text{sc}} = (4.2, 0.44, 0.05)$ s at observing frequencies of $v = (5, 9, 15)$ GHz.

### 3.2.3. Implications for Total GC Pulsar Population

The upper limits of Section 3.2.2 are only valid for pulsars within certain period ranges. To make an estimate of the total number of pulsars, knowledge of the underlying pulsar period distribution is needed. Though the period distribution of pulsars in the inner parsecs of the GC is entirely unknown, a reasonable approximation would be to assume the same distribution as the local pulsar population (to reduce observational biases). From the ATNF pulsar catalog$^7$ (Manchester et al., 2005), we see that there are 88 pulsars within 1 kpc of Earth. Of these, 5 have $P > 4.2$ s, 38 have $P > 0.44$ s, and 55 have $P > 50$ ms. This gives $p_P(P > 4.2$ s) = 0.06, $p_P(P > 0.44$ s) = 0.43, and $p_P(P > 50$ ms) = 0.63 for the fractions of pulsars with periods greater than the scatter-broadening times.

Assuming these values are representative of the GC population, we can estimate upper bounds on the total number of pulsars (regardless of period) to be $N_{\text{max}} = N/f_P$. Applying these corrections to the estimates of Section 3.2.2 gives $N_{\text{max}} = (2830, 535, 475)$ for observing frequencies of $v = (5, 9, 15)$ GHz.

The half-power beam width of the GBT is $\theta(v) \approx 150''(v/5\,\text{GHz})^{-1}$. At Sgr A*, the projected radii of these beams are $r \approx (3.0, 1.5, 1.0)$ pc at 5, 9, and 15 GHz, respectively. Thus, we estimate that there are as many as $N_{\text{max}} < 2830$ pulsars beamed toward Earth within $r \approx 3.0$ pc of Sgr A*, $N_{\text{max}} < 535$ within $r \approx 1.5$, and $N_{\text{max}} < 475$ within $r \approx 1$ pc.

The results of this section are summarized in Table 1. In addition to the surveys of Deneva (2010) and Macquart et al. (2010), we also include for reference the less sensitive GC pointings from surveys by Johnston et al. (2006) and Bates et al. (2011).

### Table 1

Pulsar Upper Limits of High-frequency Surveys

| $v$ (GHz) | $S_{\text{min}}$ (μJy) | $\tau_{\text{sc}}$ (s) | $f_d(L > L_{\text{det}})$ | $N(P > \tau_{\text{sc}})$ | $p_P(P > \tau_{\text{sc}})$ | $N/f_P$ | $r$ (pc) | Ref. |
|-----------|------------------------|-------------------------|---------------------------|--------------------------|---------------------------|--------|------|-----|
| 4.85      | 29                     | 4.2                     | 0.027                     | <170                     | 0.06                      | <2830  | 3.0  | (1) |
| 6.6       | 550                    | 1.28                    | 0.002                     | <2220                    | 0.17                      | <13000 | 4.0  | (2) |
| 8.4       | 200                    | 0.46                    | 0.003                     | <1380                    | 0.43                      | <3200  | 3.0  | (3) |
| 8.50      | 17                     | 0.44                    | 0.020                     | <220                     | 0.43                      | <535   | 1.5  | (1) |
| 14.4      | 10                     | 0.05                    | 0.015                     | <290                     | 0.63                      | <475   | 1.0  | (4) |

Notes. Columns 1 and 2 give the center frequency and minimum detection threshold, respectively, of a given survey. Column 3 gives the scattering time at the survey center frequency of a pulse originating from the GC as calculated with the NE2001 model (Cordes & Lazio, 2002). Column 4 gives the fraction of pulsars bright enough to be detected at the GC with the survey sensitivity (see Equation (3)). Column 5 gives 99% upper limit values to the number of pulsars that could potentially have been seen by the survey (that is, have $P > \tau_{\text{sc}}$). Column 6 gives the fraction of pulsars in the ATNF catalog (Manchester et al., 2005) that have periods longer than the scattering time and Column 7 gives an estimated upper bound for the total number of pulsars in the GC. Column 8 gives the projected radial distance of the beam size at the distance of Sgr A* and Column 9 gives the reference from which the survey was taken.

A number of assumptions are made in the upper limit estimates of the previous sections, so it is important to consider what happens if the assumptions fail. The first assumption is that the probability of detecting a pulsar (with period large enough not to be smeared out by interstellar scattering) is equal to the fraction of pulsars with 1.4 GHz pseudoluminiosities large enough to be detected at the GC. Since the detection probability only considers the best-case sensitivity of the telescope and ignores any effects of radio-frequency interference at the telescope end or intermittency at the pulsar end, it is likely to be an overestimate. An underestimate of the detection probability would result in an underestimation of the upper bound on the number of pulsars.

Another assumption is that the 1.4 GHz pseudoluminosity distribution of pulsars in the GC is the same as those in the Galactic field. However, if the GC region contains a larger number of low-luminosity MSPs, then the detection probability will again be overestimated and the upper limit underestimated. One could also imagine the case where enough bright young pulsars exist in the GC as a result of recent star formation to skew the pseudoluminosity distribution to higher luminosities. In that case, the detection probability would be an underestimate and the upper limits an overestimate.

We have also assumed that the upper limits are for pulsars with $P > \tau_{sc}$. However, as the scattering time gets to be a significant fraction of the pulsar period, it will start to smear out the signal and reduce the number of detectable harmonics. Since this is a gradual process, it will likely make some pulsars undetectable even with $P > \tau_{sc}$. As a result, we would be overestimating the minimal detectable period, which would cause the upper bound to be an underestimate.

Finally, we have assumed that the period distribution of the pulsars within 1 kpc of Earth is representative of the GC population. This certainly does not have to be the case, as the star formation histories of the Galactic field and GC are likely to be different. For example, the GC could potentially have a much higher concentration of young pulsars and old MSPs as compared to the Galactic disk. The increased stellar encounter rate in the GC could favor MSP production and any recent starburst would favor young pulsars. In both cases, the periods would be biased low. Thus, the period distribution would be skewed lower than the assumed and the fraction of pulsars with periods greater than a certain value will be overestimated. This will result in the upper bound being underestimated.

Since most of the assumptions made tend to decrease the upper limits, our estimates are best interpreted as the most restrictive upper bounds to the pulsar population in the inner few parsecs of the GC.

4. RADIO POINT SOURCES

Motivated by the study of GC pulsar search methods by Cordes & Lazio (1997), Lazio & Cordes (2008) performed a Very Large Array (VLA) survey of compact radio sources in the inner degree of the Galaxy. Though pulsars cannot be identified by their pulsed emission in an imaging survey, promising pulsar candidates may be found by looking for steep-spectrum sources with angular diameters consistent with the angular broadening of point sources caused by scattering at locations near Sgr A* ($\approx 1''$ at 1 GHz). Of the 170 compact radio sources cataloged, Lazio & Cordes (2008) estimate that the number of pulsars included is of the order of $\sim 10$. Based on this survey, upper limits to the pulsar population within $1^\circ$ (150 pc) of Sgr A* may be estimated.

4.1. Observations

The survey was conducted at observing frequencies of 1.4 and 5 GHz with the VLA in the A-configuration. A total of 13 fields arranged in a hexagonal grid covered the region of the GC out to roughly $1^\circ$ (150 pc) from Sgr A* (the half-power radius of the VLA primary beam is 15' at 1.4 GHz). The typical resolution for the survey was a synthesized beam size of $2.4' \times 1.3'$.

Sources were identified using a method similar to that of Lazio & Cordes (1998). Essentially, a histogram of intensities was constructed from the image of the primary beam for each field. If the field just contained noise, the intensity histogram would be a Gaussian with a mean of zero and a standard deviation equal to the thermal noise of 0.05 mJy per synthesized beam. Sources could then be determined by looking for deviations from this noise-only histogram. In practice, the histogram was found to have larger tails than a Gaussian, with zero mean and a standard deviation of $\approx 0.5$ mJy beam$^{-1}$. Since the resolution is comparable to the scattering size of a point source at the distance of Sgr A*, a 10σ detection threshold of $S_{\text{det}} \approx 5$ mJy was adopted for the survey.

4.2. Pulsar Population Estimate

Given that $N_{\text{obs}} \sim 10$ pulsars were likely observed, the total pulsar population in the survey region can be estimated as $N_{\text{psr}} \sim N_{\text{obs}}/f_{L}$, where $f_{L}$ is the fraction of pulsars luminous enough to be detected at the distance of Sgr A*. Taking the survey detection threshold to be $S_{\text{det}} = 5$ mJy at 1.4 GHz, a pulsar must have a 1.4 GHz pseudoluminosity of at least $L_{\text{det}} = 360$ mJy kpc$^2$ to be detected at the distance of Sgr A*.

The fraction of pulsars with $L > L_{\text{det}}$ can be determined from the 1.4 GHz pulsar luminosity function, which has the form $dN/d\log L \propto L^{-\beta}$. The range of pulsar pseudoluminosities is taken from $L_{\text{min}} = 0.1$ mJy kpc$^2$ to $L_{\text{max}} = 10^4$ mJy kpc$^2$ and the exponent in the distribution function is taken to be $\beta = 0.7$ (Lorimer et al. 2006). From this distribution, the fraction of pulsars luminous enough to be detected is $f_{L} = 3 \times 10^{-3}$. For $N_{\text{obs}} \sim 10$ pulsars detected in the survey, we expect a total population of $N_{\text{psr}} \sim 3000$ pulsars within $1^\circ$ (150 pc) of Sgr A*.

Though $N_{\text{psr}} \sim 3000$ is the nominal population estimate from the survey, a broader range results if the assumptions do not exactly hold. For instance, Lazio & Cordes (2008) estimate that $N_{\text{obs}} \sim 10$ of the unidentified steep-spectrum point sources will ultimately turn out to be radio pulsars. However, this number could range from zero to about 30. If one takes $N_{\text{obs}} = 30$, repeating the above analysis gives a pulsar population of $N_{\text{psr}} \sim 10^4$. Additionally, one may consider the case in which no pulsars were detected. Despite a follow-up observation of 15 of the pulsar candidates in this survey by Deneva (2010) with the GBT, none of the candidates have to date been confirmed. Assuming zero detections, an analysis similar to that in Section 3.2 gives an upper limit to the pulsar population of $N_{\text{psr}} \lesssim 1500$ at a 99% confidence level. These two extremes illustrate that although the survey allows for an estimate of the pulsar population in the inner degree of about 3000, the actual number could be below 1500 or as high as $10^4$.

As a result, we take $N_{\text{psr}} \lesssim 10^3$ as a conservative upper bound.

Finally, we note that although the survey covers the region within $1^\circ$ (150 pc) of Sgr A*, there will be reduced sensitivity in the field centered on Sgr A*. The reduced sensitivity is the result
of increased background temperatures and greater side lobes from the extended structure of the inner GC. In addition, since the scatter broadening of point sources in the vicinity of Sgr A* (≈1″) is comparable to the resolution of the survey, source confusion may become important in the innermost regions of the GC. Therefore, this survey would be largely insensitive to a fairly compact population of pulsars in the inner tens of arcseconds around Sgr A*.

5. RADIO SPECTRUM OF SGR A*

In this section, limits are placed on the maximum allowable number of pulsars in the inner parsecs of the GC based on radio interferometer observations of Sgr A* on arcsecond scales (1″ ≈ 0.04 pc at 8.5 kpc). Due to the finite resolution of interferometers and the broadening of angular diameters as a result of the interstellar scattering of radio waves, the Sgr A* radio source is actually extended (≈1″ at 1 GHz). Flux measurements of Sgr A* will therefore include a contribution from a collection of pulsars, if such a population exists. Although these pulsars will be unresolved, upper limits on the total population may be set based on the total flux density of Sgr A* in a manner analogous to similar constraints placed on pulsars in globular clusters (Fruchter & Goss 1990).

We consider a model in which the observed flux density of Sgr A* is actually the combination of two components. The first component is that due to radio emission from the immediate environment of the MBH itself, which we assume is described accurately by high-frequency observations where the pulsar component is negligible. The second component is that due to the population of pulsars near the MBH. This pulsar component becomes important at lower frequencies both because radio pulsars typically have steep spectra and the angular resolution of radio telescopes scales with frequency such that a larger region around the MBH is sampled at lower frequencies. By requiring that this model flux be consistent with existing observations, constraints may be set on the maximum number of pulsars allowed in the inner parsec of the Galaxy.

5.1. Observations

Two different measurements of the spectrum of Sgr A* over a wide range of frequencies are considered (An et al. 2005; Falcke et al. 1998). An et al. (2005) conducted simultaneous measurements of Sgr A* from 300 MHz to 43 GHz using the VLA (A-configuration) and the Giant Metrewave Radio Telescope (GMRT). Falcke et al. (1998) made simultaneous measurements of Sgr A* using the VLA (A-configuration), the Berkeley-Illinois-Maryland Array, the Nobeyama 45 m telescope, and the Institut de Radioastronomie Millimetrique (IRAM) 30 m telescope from 1.4 GHz to 235 GHz. Both groups observed a broken power-law spectrum with a break around 10 GHz. Since the power-law spectrum of pulsars decreases with increasing frequency, a population of pulsars contributes significantly only at lower frequencies. As a result, we consider the spectrum of Sgr A* only below the break frequency at 10 GHz.

5.2. Spectral Model

We model the measured flux density of the compact radio source Sgr A* as the sum of contributions from a collection of pulsars and a point source associated with the MBH attenuated by free–free absorption according to

\[
S_{\text{Sgr}}(\nu) = \left[ S_{\text{MBH},0} \left( \frac{\nu}{\nu_0} \right)^{\alpha_{\text{bh}}} + N(\nu) S_{\text{psr},0} \left( \frac{\nu}{\nu_0} \right)^{\alpha_{\text{psr}}} \right] \times \exp\left(-\frac{\nu^2}{\nu_0^2}\right).
\]

The emission from the immediate vicinity of the MBH, \(S_{\text{MBH},0}\), is taken to be a point source with a power-law spectrum with spectral index \(\alpha_{\text{bh}}\). \(N(\nu)\) is the number of pulsars contained in the solid angle of the effective point-spread function or beam size, which depends strongly on frequency (see Section 5.3). We use a simplified scaling for the free–free absorption that ignores the frequency dependence of the Gaunt factor. The free–free absorption factor has a turnover frequency \(\nu_f\) (An et al. 2005). The flux density per pulsar, \(S_{\text{psr},0}\), is taken to be the mean of the 1.4 GHz pulsar pseudoluminosity distribution given by \(dN/d\log L \propto L^{-0.7}\) (Lorimer et al. 2006) with a lower cutoff of \(L_{\text{min}} = 0.1\) mJy kpc\(^2\) and an upper cutoff of \(L_{\text{max}} = 10^4\) mJy kpc\(^2\). The mean observed flux density at 1.4 GHz is \(S_{\text{psr},1.4} = 99\) mJy. Since pulsar radio flux scales with frequency as a simple power law, we can scale our flux density as \(S_\nu \propto \nu^{\alpha_{\text{psr}}}\). We fix \(\alpha_{\text{psr}} = -1.7\) as a nominal value for the pulsar spectral index (Maron et al. 2000; Lorimer et al. 1995), but also consider values of \(-1.0\) and \(-2.5\) to test any major spectral index dependence.

5.3. Effective Angular Resolution

The number of pulsars included in a flux measurement of Sgr A* can be written as an integral of the number of pulsars per unit solid angle,

\[
N(\nu) = \int d\Omega \frac{dN_p}{d\Omega}.
\]

The integral is over the effective solid angle \(\Omega_{\text{eff}}(\nu) = (\pi/4)\theta_{\text{eff}}^2(\nu)\), where

\[
\theta_{\text{eff}}(\nu) = \left[ \theta_b^2(\nu) + \theta_s^2(\nu) \right]^{1/2} = \left( \theta_b^2 \nu^{-2} + \theta_s^2 \nu^{-4} \right)^{1/2}
\]

is the effective resolution with the subscript “0” representing values at 1 GHz and the frequencies are in GHz units. The effective resolution is the quadrature sum of the resolution of the interferometer and the angular extent of Sgr A* caused by scattering. The scaling for the synthesized array beam \(\theta_b(\nu)\) assumes a fixed array configuration and the scattering diameter \(\theta_s(\nu)\) scales in conformance to measurements of Sgr A* and OH/IR masers (e.g., Frail et al. 1994). Our treatment assumes that scattered images are circular whereas in fact some are elliptical, but given that we are making order of magnitude estimates of pulsar numbers, the differences are not important.

The angular diameter of Sgr A* is dominated by interstellar scattering at low frequencies, with an observed major axis of \(\theta_{\text{sc}} = 1″/2\) (Bower et al. 2006). For the VLA in the A-configuration and ignoring any effects of foreshortening, the half-power beam width is \(\theta_{\text{hp}} = 1″/95\) (Britle 1989).

The effective resolution of the VLA observations is then

\[
\theta_{\text{eff}}(\nu) = \theta_{\text{hp}}^2 \nu^{-2} (1 + 2.6v^2)^{1/2}.
\]

The two contributions are equal at \(v = 0.6\) GHz, so at frequencies lower than this the resolution is completely scattering dominated and the resolution solid angle scales steeply with frequency as \(v^{-4}\).
Additionally, a single data point measured with the GMRT will be considered in our analysis, so a similar effective resolution must be constructed for this telescope. Roy & Rao (2004) measure the resolution to be 11\'\'\' at 620 MHz. Converting this ellipse to a circle of equal area and scaling to 1 GHz gives $\theta_{bh} = 5.77$" for the GMRT. Combining this with scattering as above gives

$$\theta_{\text{eff}}(v) = 1.2 \, v^{-2} \left(1 + 23.1 v^2\right)^{1/2}. \quad (8)$$

For the GMRT, the two components of the effective resolution are equal at $v = 0.2\,\text{GHz}$.

### 5.4. Candidate Pulsar Distributions

We choose three physically motivated distributions as model pulsar populations. The distributions are illustrated in Figure 2. The first (Model A) assumes a constant number of pulsars per unit solid angle, $dn_p/d\Omega = \text{const}$, so the number of pulsars scales as

$$N_A(v) = N_1 \left[ \frac{\Omega_{\text{eff}}(v)}{\Omega_1} \right]. \quad (9)$$

where $\Omega_1$ is the solid angle enclosing $N_1$ pulsars. In the fitting below, $\Omega_1$ is set so that $N_1$ gives the number of pulsars in the inner parsec. Referring to Equation (4), it may be seen that when scattering dominates the effective resolution, the contribution to the unabsorbed spectrum from pulsars increases very rapidly as $N_A(v) \propto v^{-5.7}$. Free–free absorption attenuates much of the flux, thus allowing a significant pulsar population to remain hidden in spectral measurements.

In Model B, we assume that $dn_p/d\Omega \propto \Omega^{-0.7}$, corresponding to the surface density scaling observed for Wolf-Rayet and O-star populations in the inner parsec (Genzel et al. 2010). This yields

$$N_B(v) = N_1 \left[ \frac{\Omega_{\text{eff}}(v)}{\Omega_1^{0.3}} \right]. \quad (10)$$

However, the observed populations of Wolf-Rayet and O-stars have an inner cutoff at $\theta \approx 1''$ (Bartko et al. 2010). This core may affect the pulsar population in many ways, but we shall just consider two here. In both distributions, the pulsar surface density goes as $dn_p/d\Omega \propto \Omega^{-0.7}$ outside the inner cutoff, as before. Inside the cutoff, one of the distributions (Model B-1) has $dn_p/d\Omega = \text{const}$ and the other (Model B-2) has $dn_p/d\Omega = 0$. These models give

$$N_{B1}(v) = \begin{cases} N_1 \left[ \frac{\Omega_{\text{eff}}(v)}{\Omega_1^{0.3}} \right], & \Omega_{\text{eff}} \geq \Omega_0 \\ N_1 \left[ \frac{0.3 \Omega_{\text{eff}}^{0.7} \Omega_1^{0.3}}{\Omega_1^{0.3} - \Omega_0^{0.3}} \right], & \Omega_{\text{eff}} < \Omega_0 \end{cases} \quad (11)$$

and

$$N_{B2}(v) = \begin{cases} N_1 \left[ \frac{\Omega_{\text{eff}}(v)}{\Omega_1^{0.3} - \Omega_0^{0.3}} \right], & \Omega_{\text{eff}} \geq \Omega_0 \\ 0, & \Omega_{\text{eff}} < \Omega_0 \end{cases} \quad (12)$$

pulsars enclosed within $\Omega_{\text{eff}}$.

In Model C, we consider a compact population of pulsars contained in a solid angle much smaller than any resolution solid angle so that $dn_p/d\Omega$ is effectively a delta function. A compact distribution close to Sgr A* could conceivably arise as a product of dynamical friction (Morris 1993; Miralda-Escudé & Gould 2000). Here we simply have

$$N_C(v) = N_1. \quad (13)$$

In addition to the above three, one may consider other models for the pulsar distribution. For example, the pulsars could be arranged in a central core with a diffuse halo. However, most of these other distributions can be made as combinations of those we consider. As a result, we do not expect the final answers to change by more than an order of magnitude.

### 5.5. Model Fitting

To test our distributions, we calculated the $\chi^2$ values of the model given by Equation (4) with each of the three distributions against the VLA and GMRT data from An et al. (2005) and Falcke et al. (1998). We fix the pulsar spectral index at $\alpha_{psr} = -1.7$ and the flux density per pulsar at $S_{psr,\nu} = 99\,\mu\text{Jy}$ at 1.4 GHz, as described in Section 5.2. The flux from the point source associated with the MBH is normalized such that the total measured flux of Sgr A* exactly matches the data at 8.45 GHz. The spectral index of the MBH point source ($\alpha_{bh}$), the number of pulsars ($N_1$), and the free–free cutoff frequency ($\nu_f$) are allowed to vary. The number of pulsars, $N_1$, is taken within an angular distance of $\theta = 25''$, which corresponds to a projected radial distance of $r \approx 1\,\text{pc}$ from Sgr A*. The allowed ranges for each parameter were chosen to be consistent with current measurements and are presented below in Table 2. For reference, the best-fit values for the model with no pulsars present are $\alpha_{bh} = 0.15$ and $\nu_f = 0.26\,\text{GHz}$.

For each grid point in the three-dimensional parameter space, we calculate $\chi^2$ between the measured flux and our model and evaluate the likelihood function assuming independent Gaussian statistics for measurement errors,

$$L(N_1, \alpha_{bh}, \nu_f) = \prod_{i=1}^{N_p} \left(2\pi \sigma_i^2\right)^{-1/2} \exp \left\{ -\frac{\left[S_{\text{obs}}(\nu_i) - S_{\text{psr}}(\nu_i)\right]^2}{2\sigma_i^2} \right\} \propto \exp \left( -\frac{1}{2} \chi^2 \right). \quad (14)$$
The likelihood functions for three pulsar distribution models (see Section 5.4 for a description of each model). The likelihoods have been marginalized over the parameters $\alpha_{bh}$ and $\nu_f$ and normalized so that $\int \mathcal{L}(N) = 1$. In each case, the pulsar spectral index was taken to be $\alpha_{psr} = -1.7$.

![Figure 3](image_url)

**Figure 3.** Likelihood functions for three pulsar distribution models (see Section 5.4 for a description of each model). The likelihoods have been marginalized over the parameters $\alpha_{bh}$ and $\nu_f$ and normalized so that $\int \mathcal{L}(N) = 1$. In each case, the pulsar spectral index was taken to be $\alpha_{psr} = -1.7$.

### Table 2

Searched Parameters for Each Pulsar Distribution Model

| Model | Parameter Ranges$^a$ | $\nu_f$ (GHz) |
|-------|----------------------|---------------|
| A     | $[0, 50000, 10]$    | $0.05, 1.00, 0.01$ |
| B     | $[0, 50000, 10]$    | $0.05, 1.00, 0.01$ |
| C     | $[0, 5000, 10]$     | $0.05, 1.00, 0.01$ |

Note: $^a$ Data given as [min, max, step size].

The likelihood function is then marginalized over $\alpha_{bh}$ and $\nu_f$ to get a distribution for $N_1$. The marginalized likelihood functions for the number of pulsars within 1 pc of Sgr A* are plotted in Figure 3.

### 5.6. Results

The best-fit parameters for the ML number of pulsars within the inner parsec of the GC for each model is provided in Table 3 and the resulting spectra are plotted in Figure 4. The number quoted in Table 3 is the ML number of pulsars as determined from the likelihood function and the uncertainties denote the most compact 68% confidence interval around the ML value. If the ML value for a distribution is zero, then the upper limits are given at the 68% confidence level. In addition to the fiducial pulsar spectral index of $\alpha_{psr} = -1.7$, we include spectral indices of $-1.0$ and $-2.5$. For comparison, the best-fit parameters for the model with the number of pulsars fixed at zero is also included in Table 3 and odds ratios are calculated against this “null” model.

It is interesting to note that although Models A and B give only upper limits to the pulsar population (of $\lesssim 10^3$–$10^4$), Model C provides a non-zero ML value of $\sim 10^5$. Additionally, Model C provides a better fit than the model with no pulsars at all (the “null” model in Table 3).

In all of the models considered, an increase in the maximum number of pulsars is accompanied by an increase in the free–free turnover frequency. The increased free–free absorption is required to mask the bright low-frequency tail of a large pulsar population. Current estimates of free–free absorption in the region near Sgr A* give turnover frequencies around 330 MHz (Pedlar et al. 1989). Estimates of the free–free absorption of the flux from Sgr A*, however, assume a power-law flux density for Sgr A* and would likely underestimate the absorption if a pulsar population were present. As a result, any independent measurement of the free–free absorption along the line of sight of Sgr A* that does not assume a spectrum of the Sgr A* source could place an important constraint on the pulsar population in the inner parsecs of the Galaxy.

From current radio measurements of the inner parsec of the GC, total pulsar populations (that is, both CPs and MSPs) of up to $\sim 10^3$ are consistent with observations, regardless of the underlying spatial distribution.

### 6. DIFFUSE GAMMA-RAY EMISSION AND MSPS

MSPs are known gamma-ray sources (Abdo et al. 2009a). As a result, we may set constraints on the MSP population in the GC by measuring the diffuse gamma-ray emission from the GC. In a recent analysis of the first two years of data from the Fermi Gamma-ray Space Telescope, Hooper & Goodenough (2011, hereafter HG) observed an excess of gamma-ray flux toward the inner 1° (150 pc) of the GC, with a significant excess within 0.25° ($\approx 40$ pc). HG argued that the signal is consistent with the annihilation of 7–10 GeV dark matter particles with a cusped halo distribution around Sgr A* and difficult to explain using known astrophysical sources. Abazajian (2011), however, claimed that while the spectrum may be inconsistent with the average pulsar spectrum, it is consistent with some pulsar spectra and therefore could be explained by astrophysical sources. HG provide a spectrum for the gamma-ray excess in the GC of the form

$$\frac{dN_\gamma}{dE} \propto E^{-\Gamma} \exp(-E/E_{cut}),$$

where $\Gamma = 0.99^{+0.10}_{-0.09}$ and $E_{cut} = 1.92^{+0.21}_{-0.17}$ GeV. These parameter values are consistent (to current uncertainties) with the spectra of 16 out of 46 pulsars in the first Fermi Large Area Telescope (LAT) catalog of gamma-ray pulsars (Abdo et al. 2010b). We proceed assuming that the observed excess seen
The correction factor, $f_{\Omega}$, is similar to the beaming fraction in radio pulsars and is generally taken to be unity in most modern models (Watters et al. 2009).

Following calculations made to estimate the number of MSPs in globular clusters (Abdo et al. 2010a), we can estimate the MSP population of the GC as

$$N_{\text{MSP}} = \frac{L_{\gamma}}{\langle E \rangle \langle \eta_{\gamma} \rangle},$$

(18)

where $\langle E \rangle$ is the total spin-down luminosity of an MSP, $\eta_{\gamma} = L_{\gamma}/E$ is the “efficiency” of converting spin-down power into gamma rays, and angled brackets denote an average over the population. The values of $\langle E \rangle$ and $\langle \eta_{\gamma} \rangle$ are taken from the local ($d < 1$ kpc) MSP population to avoid selection effects. The mean spin-down luminosity is taken to be $\langle E \rangle = 1.1 \times 10^{34}$ erg s$^{-1}$ from the 27 MSPs within 1 kpc of Earth listed in the ATNF catalog (Manchester et al. 2005). Since $\langle \eta_{\gamma} \rangle \propto L_{\gamma} \propto d^2$, the uncertainties in $\langle \eta_{\gamma} \rangle$ are dominated by distance uncertainties and values range from $\langle \eta_{\gamma} \rangle = 10^{-3} - 1$ in the first Fermi gamma-ray pulsar catalog (Abdo et al. 2010b). To mitigate this distance problem, we take only those seven nearby pulsars in the catalog for which distances could be measured accurately with parallax. For these pulsars, we find $\langle \eta_{\gamma} \rangle = 0.08 \pm 0.04$. Using Equation (18), we get an estimate of $N_{\text{MSP}} \approx 5000$. In order to contribute the observed excess, these pulsars would be located within 1° (150 pc) of Sgr A$^*$, with the highest concentration within 0:25 (40 pc).

Our estimate for the number of MSPs in the GC is essentially an upper bound for the population. However, modeling the background component of the diffuse gamma-ray emission in the GC is still somewhat uncertain (Abdo et al. 2009b) and, as a result of this uncertainty, our estimate can only be taken as an approximate upper limit. Additionally, as this is a measure of the excess gamma-ray flux in the region (with the Galactic plane and a central point source coincident with Sgr A$^*$ subtracted), there exists the possibility that a significant number of MSPs are unaccounted for in this estimate. Assuming the HG gamma-ray excess in the GC is real and does not suffer from systematic errors in background subtraction, we see that it is not inconsistent with a centrally concentrated population of $\approx 10^3$ MSPs in the inner tens of parsecs from Sgr A$^*$.

Finally, we note that similar estimates for the MSP population in the GC have been made in the past. Wang et al. (2005) used a model proposed by Zhang & Cheng (1997) to predict the emission of gamma rays from MSPs as a function of global pulsar parameters like spin period and polar magnetic field. They used Monte Carlo methods to simulate a population of pulsars and measured the total gamma-ray luminosity. Comparing this luminosity to measured values from EGRET, Wang et al. (2005) estimated a GC MSP population of $N_{\text{MSP}} \approx 6000$ in the EGRET field ($r \approx 1:5$, 220 pc).

7. MASSIVE STARS IN THE GALACTIC CENTER

The central parsec of the GC is one of the most active massive star formation regions in the Milky Way and is currently known to contain about 200 young massive stars (Genzel et al. 2010). As massive stars are the progenitors of NSs, we may use current stellar populations to estimate the number of pulsars in this region.

The inner parsec stellar population is divided into three fairly distinct regions. The innermost region ($R \leq 1''$) is the so-called...
S-star Cluster of main-sequence B-stars. These stars can be fitted with a standard Salpeter initial mass function (IMF) for a single star formation event or for a continuous star-forming population with ages of a few Myr to 60 Myr (Bartko et al. 2010). Outside this region (1″ ≤ R ≤ 12″), the stars are largely arranged in at least one disk (possibly two) of mass M ∼ 10^4 M_⊙ with a top-heavy IMF of dN/dm ∝ m^{-0.45} (Bartko et al. 2010). The early-type stars in this region appear to have been formed in a starburst ~6 Myr ago. Outside the disk region (R > 12″) the stellar population is again consistent with a Salpeter IMF.

Following similar calculations by Lazio & Cordes (2008) and Faucher-Giguère & Loeb (2011), the current stellar populations can be used to estimate the number of radio pulsars harbored in the central parsec. The number of active CPs and MSPs beams toward Earth are estimated to be

\[ N_{\text{CP}} = f_{\text{psr}} f_b f_r f_c N_{\text{NS}} \]  \hspace{1cm} (19)

and

\[ N_{\text{MSP}} = f_{\text{psr}} f_b f_r f_c f_t N_{\text{NS}}. \]  \hspace{1cm} (20)

respectively, where N_{\text{NS}} is the number of NSs in the inner parsec, f_{\text{psr}} is the fraction of NSs that form pulsars, f_b = 0.2 is the beaming fraction, f_r is the fraction of pulsars with ages less than the typical pulsar radio lifetime, f_c is the fraction of pulsars with birth velocities small enough to be retained in the inner parsec, and f_t is the fraction of NSs that are recycled into MSPs. The fraction of NSs that form pulsars is taken to be f_{\text{psr}} ∼ 1, although this factor is still fairly uncertain (Lazio & Cordes 2008). The terms N_{\text{NS}}, f_r, f_c, and f_t are discussed below.

### 7.1. Neutron Star Population in the Inner Parsec (N_{\text{NS}})

The total number of NSs residing in the inner parsec may be estimated from current observations of the massive star population. Velocity measurements of stars allow for the total dynamical mass enclosed within a few parsecs of Sgr A* to be determined. Subtracting the mass of the MBH gives an extended mass of ~10^6 M_⊙ in stars within a parsec of Sgr A* (Genzel et al. 1996; Schödel et al. 2009). With the total mass of stars established, the number of NSs can be calculated for a given IMF and mass range of stars that end their lives as NSs.

A typical NS progenitor mass range is 9 M_⊙ < M < 25 M_⊙ (Heger et al. 2003). However, such ranges are theoretically determined for only isolated non-rotating stars and rely on mass-loss and stellar wind models that are poorly constrained by observations (Heger et al. 2003). If very massive stars have higher mass-loss rates than modeled, then NSs could form from stars with initial masses above ~25 M_⊙. That this may be the case is supported by the limited observational constraints. For example, Munu et al. (2006) detected an X-ray pulsar in the young Galactic cluster Westerlund 1 that requires a progenitor mass of M > 40 M_⊙ to have formed in the age of the cluster.

To calculate the number of NSs produced by the GC massive star population, we consider IMFs of the form dN/dm ∝ m^{-α} over a range of masses from 0.1 M_⊙ to 100 M_⊙. For the case of the standard Salpeter IMF (α = 2.35) observed in most of the inner parsec and a progenitor mass range of 9 M_⊙ < M < 25 M_⊙, a total of N_{\text{NS}} ≈ 4900 NSs are produced. If the top-heavy IMF (α = 0.45) observed in the young disks is taken to hold for the whole central parsec, a total of N_{\text{NS}} ≈ 5700 are produced. If a wider range of progenitor masses is taken, say 9 M_⊙ < M < 40 M_⊙ to allow the Munu et al. (2006) observation, the total NS populations increase to N_{\text{NS}} ≈ 5700 and N_{\text{NS}} ≈ 9500 for the Salpeter and top-heavy IMFs, respectively. Even given a wide range in IMF and progenitor mass, the above results are consistent to an order of magnitude with an NS population of N_{\text{NS}} ∼ 10^4. In terms of NSs formed per stellar mass, we find a value of β_{\text{IMF}} ∼ 10^{-2} M_⊙^{-1} for the ~10^6 M_⊙ worth of stars within a parsec of Sgr A*.

### 7.2. Fraction of Still active Pulsars (f_{psr})

The typical lifetimes over which pulsars maintain active radio emission are τ ∼ 10^3 yr for CPs and τ ∼ 10^9–10^10 yr for MSPs. As a result, the fraction of pulsars formed recently enough to still be active must be considered in estimates of the observable population. This factor will depend on the SFH of the region. In the case of continuous star formation, the active fraction of pulsars can be estimated to be f_r ∼ τ/τ_{df}, where τ_{df} is the amount of time elapsed since the star formation began.

### 7.3. Fraction of Pulsars Retained (f_{r})

The typical observed velocities (~10^2–10^3 km s^{-1}) of some pulsars, it has been inferred that NSs are given a large “kick” velocity at birth as a result of binary dissociation or an asymmetric SN explosion (or both). A pulsar created in the inner parsec will be retained in the inner parsec only if its birth velocity does not exceed the local escape velocity of its orbit around Sgr A*. Assuming only the influence of an MBH of mass M ∼ 4 × 10^6 M_⊙, the escape velocity at a distance r from Sgr A* is given by

\[ v_e(r) = 185 \text{ km s}^{-1} \left( \frac{M}{4 \times 10^6 \text{ M}_\odot} \right)^{1/2} \left( \frac{r}{1 \text{ pc}} \right)^{-1/2}. \] \hspace{1cm} (21)

Assuming a Maxwellian distribution of birth velocities with a mean of (v_{\text{birth}}) = 380 km s^{-1} (Faucher-Giguère & Kaspi 2006), we find retention fractions of f_r ≈ 0.1 and f_r ≈ 0.25 for radial distances of r = 1 pc and r = 0.5 pc, respectively. However, the actual shape of the pulsar birth velocity distribution is not well constrained and one may worry that the Maxwellian distribution is arbitrary. In an analysis of pulsar velocities, Faucher-Giguère & Kaspi (2006) consider six different pulsar velocity distributions. Repeating our calculation for each distribution, we find retention fractions in the ranges of f_r ≈ 0.05–0.4 and f_r ≈ 0.1–0.5 for distances of r = 1 pc and r = 0.5 pc, respectively.

If no other effects are important, we would expect a retention fraction of f_r ≥ 0.1. However, a similar analysis to the one performed above would underestimate the retained NS populations in globular clusters by orders of magnitude. Observations of pulsars and low-mass X-ray binaries (LMXBs) suggest that up to ~10% of all NSs formed in some globular clusters may be retained (Pfahl et al. 2002). However, current models for isolated pulsars predict that ≤ 1% of NSs will have birth velocities below ~50 km s^{-1} globular cluster escape velocities. This “retention problem” is currently an unsolved problem, but likely has to do with the high stellar densities and binary fractions found in the cores of globular clusters (see Pfahl et al. 2002 and references within). Since the GC has even higher stellar densities than cores of globular clusters, we expect a similar heightening of the retention fraction and thus adopt as a nominal value f_r ∼ 1.

### 7.4. Fraction of Pulsars Recycled to MSPs (f_{psr})

MSPs are thought to be formed when an NS in a binary gains angular momentum through accretion of matter in a process...
known as “recycling” (Alpar et al. 1982; Bhattacharya & van den Heuvel 1991). Thus, the fraction of NSs recycled into MSPs must be determined to estimate the MSP population. Within 3 kpc of the Sun, the birthrate of pulsars with 400 MHz pseudoluminosities above 1 mJy kpc$^{-2}$ is observed to be $\sim-10^{-3}$ yr$^{-1}$ and $\gtrsim10^{-6}$ yr$^{-1}$ for CPs and MSPs, respectively (Lyne et al. 1998). Using these birthrates, we may infer that the recycling fraction is at least $f_r \gtrsim 10^{-3}$ in the Galactic disk. The increased stellar density and stellar encounter rate in the GC will very likely increase this fraction. LMXBs, the assumed progenitors of MSPs, have been found to be $\sim100$ times more abundant in globular clusters than the general Galactic field (Clark 1975; Katz 1975). As the central parsec of the GC has a higher stellar density than globular clusters, we would expect at least a similar overabundance of LMXBs and their resultant MSPs as is seen in globular clusters. As a result, we adopt a recycling fraction of $f_r \sim 0.1$.

7.5. Pulsar Estimates for Various Star Formation Histories

As the SFH of the central parsec of the GC is still somewhat uncertain, we will consider two general SFHs suggested by current observations. In the first case, we take the massive star disk(s) to have formed in a well-defined starburst $\sim6$ Myr ago (Paumard et al. 2006; Bartko et al. 2010) and assume that the rest of the central parsec has experienced continuous star formation over the age of the Galaxy. In the second case, we consider SFHs based on spectrophotometry of cool giant stars which indicate that most of the stars in the inner parsec were formed $\gtrsim5$ Gyr ago but also show an increased star formation rate in the last $\sim100$ Myr. In their best-fit models, Blum et al. (2003) found an average star formation rate of $\sim3 \times 10^{-3} M_\odot$ yr$^{-1}$ within 2 pc of Sgr A* from 10 to 100 Myr ago and Pfuhl et al. (2011) found an average star formation rate of $\sim10^{-3} M_\odot$ yr$^{-1}$ within 1 pc of Sgr A* from 50 to 200 Myr ago. Both cases are consistent with $\sim10^7 M_\odot$ worth of stars being formed in the inner parsec of the GC in the last $\sim100$ Myr.

7.5.1. Continuous Star Formation + Disk Starburst

In the first SFH, pulsars can come from both the general population of stars in the central parsec and the young disk population. For the general population, we take the total mass of stars to be $M \sim 10^6 M_\odot$ and assume continuous star formation over the last $\sim10^8$ yr. From the parameters discussed above, the number of NSs is found to be $N_{\text{ns}} \sim 10^4 (\beta_{\text{ns}}/10^{-2} M_\odot)$. Taking a CP active radio lifetime of $\tau \sim 10^5$ yr, continuous star formation over $\sim10^8$ yr will give the fraction of CPs still active to be $f_r \sim 10^{-3}$. From Equation (19), the CP contribution from the continuous star-forming region of the inner parsec is

$$N_{\text{CP}}^{\text{gen}} \sim 2 \left( \frac{f_r}{1.0} \right) \left( \frac{\beta_{\text{ns}}}{0.01 M_\odot^{-1}} \right) \left( \frac{M}{10^6 M_\odot} \right).$$

For MSPs with a radio lifetime of $\sim10^9$ yr, the fraction still active is $f_r \sim 1$. Adopting the recycling fraction of $f_r \sim 0.1$ discussed above, the contribution of MSPs from the general population of the inner parsec is given by Equation (20) as

$$N_{\text{MSP}}^{\text{gen}} \sim 200 \left( \frac{f_r}{1.0} \right) \left( \frac{f_r}{0.1} \right) \left( \frac{\beta_{\text{ns}}}{0.01 M_\odot^{-1}} \right) \left( \frac{M}{10^6 M_\odot} \right).$$

Additionally, the contribution of pulsars from the massive star disk(s) must be considered. The disk is assumed to have a population of stars formed in a starburst event $\sim6 \times 10^8$ yr ago with a total stellar mass of $\sim10^5 M_\odot$ (Paumard et al. 2006; Bartko et al. 2010). Since the age of the disk is comparable to the active radio lifetime of a CP, the fraction of CPs still active is taken to be $f_i \sim 1$. From Equation (19), the CP contribution from the disk is found to be

$$N_{\text{CP}}^{\text{disk}} \sim 20 \left( \frac{f_i}{1.0} \right) \left( \frac{\beta_{\text{ns}}}{0.01 M_\odot^{-1}} \right) \left( \frac{M_{\text{disk}}}{10^3 M_\odot} \right).$$

The disk population is not expected to produce any currently observable MSPs as the short timescale of $\sim6 \times 10^8$ yr provides insufficient time to create and evolve an NS population into MSPs. As a result, this first SFH produces roughly $N_{\text{CP}} \sim 20$ CPs and $N_{\text{MSP}} \sim 200$ MSPs.

7.5.2. SFH from Observations of Cool Giant Stars

The SFH has also been estimated by comparing simulated populations with the observed cool giant stars in the central parsec. Such simulations allow the average star formation rate to be calculated as a function of look-back time for a few coarse time bins. In two separate analyses, both Blum et al. (2003) and Pfuhl et al. (2011) found that $\gtrsim80\%$ of the stellar mass in the central parsec was formed $\gtrsim5$ Gyr ago and that there has been increased star formation in the last $\sim100$ Myr. In their best-fit models, Blum et al. (2003) found an average star formation rate of $\sim3 \times 10^{-3} M_\odot$ yr$^{-1}$ within 2 pc of Sgr A* from 10 to 100 Myr ago and Pfuhl et al. (2011) found an average star formation rate of $\sim10^{-3} M_\odot$ yr$^{-1}$ within 1 pc of Sgr A* from 50 to 200 Myr ago. Both cases are consistent with $\sim10^7 M_\odot$ worth of stars being formed in the inner parsec of the GC in the last $\sim100$ Myr.

If there has been continuous star formation in the last $\sim100$ Myr, then the fraction of still active CPs would be $f_r \sim 0.1$. Taking all other parameters as before, the continuous formation of $\sim10^5 M_\odot$ worth of stars over the last $\sim10^5$ yr would produce

$$N_{\text{CP}}^{\text{con}} \sim 20 \left( \frac{f_i}{1.0} \right) \left( \frac{\beta_{\text{ns}}}{0.01 M_\odot^{-1}} \right) \left( \frac{M (t < 10^8 \text{yr})}{10^5 M_\odot} \right).$$

If the recent star formation all took place in the last $\sim10^7$ yr, then the fraction of CPs still active would be $f_i \sim 1$. In this case, the number of active CPs would be

$$N_{\text{CP}}^{\text{burst}} \sim 200 \left( \frac{f_i}{1.0} \right) \left( \frac{\beta_{\text{ns}}}{0.01 M_\odot^{-1}} \right) \left( \frac{M (t < 10^8 \text{yr})}{10^5 M_\odot} \right).$$

In either of the above cases, the majority ($\gtrsim90\%$) of the star formation took place at look-back times $\gtrsim10^8$ yr ago. As a result, the number of MSPs produced will be approximately the same as the first SFH considered, namely, $N_{\text{MSP}} \sim 200$.

7.5.3. Upper Limits to the Pulsar Population

Using the above estimates of CP and MSP populations for a range of observationally supported SFHs, upper limits may be set on the total allowable number of pulsars in the inner parsec. For CPs, the most favorable formation scenarios produce $N_{\text{CP}} \sim 200$. For MSPs, a variety of SFHs consistently produce $N_{\text{MSP}} \sim 200 (f_r/0.1)$. Since the recycling fraction is unknown for the extreme conditions of the inner GC, an upper limit of $N_{\text{MSP}} \sim 2000$ may be set by adopting $f_r \sim 1$. Thus, observations of current stellar populations place an upper limit of a few $\times 10^5$ on the number of active radio pulsars beamed toward Earth in the inner parsec of the GC.
8. PULSAR WIND NEBULAE IN INNER 20 pc

Using a total of 1 Ms of Chandra ACIS–I observations of the inner parsecs of the GC, Muno et al. (2008) compiled a catalog of 34 diffuse X-ray-emitting features. Based on the X-ray luminosities and sizes of the sources in their catalog, Muno et al. (2008) expect ∼20 PWNe to be present within 20 pc of Sgr A*. Since PWNe are powered by pulsars, we may use this inferred population of PWNe to estimate the pulsar population in the inner 20 pc of the GC.

Pulsars can lose their rotational kinetic energy by the release of relativistic winds of charged particles. The winds exert a pressure upon and deposit energy into the surrounding interstellar medium, producing luminous PWNe that radiate across the electromagnetic spectrum (see, e.g., Gaensler & Slane 2006). As a result, the luminosity of the PWN will be directly related to the spin-down luminosity of the pulsar given by

\[ \dot{E} = -dE_{\text{rot}}/dt = 4\pi^2 I P / P^3, \]  

(27)

where \( I \) and \( P \) are the moment of inertia and period, respectively, of the pulsar.

Since the spin-down luminosity of a pulsar decreases with increasing age, one would expect the most luminous PWNe to contain young pulsars (however, older pulsars may be "recycled" sufficiently to power PWNe as described by Cheng et al. 2006). Of the 30 confirmed pulsars associated with PWNe, 25 have characteristic ages \( (\tau_c = P/2P) \) of \( \tau_c \lesssim 10^6 \) yr and 23 have characteristic ages \( \tau_c \lesssim 10^5 \) yr (Roberts 2004). Thus, we adopt a lifetime for a typical PWN of \( \tau_{\text{pwn}} \sim 10^5 \) yr.

Given the observed number of PWNe in the GC \( (N_{\text{obs}} \sim 20) \) and a typical lifetime of \( \tau_{\text{pwn}} \sim 10^5 \) yr, we find a mean rate of formation of PWNe over the last \( 10^7 \) yr to be

\[ \beta_{\text{pwn}} \sim 2 \times 10^{-4} \text{ yr}^{-1} \left( \frac{N_{\text{pwn}}}{20} \right) \left( \frac{\tau_{\text{pwn}}}{10^5 \text{ yr}} \right)^{-1}. \]  

(28)

Assuming that the PWN formation rate has remained constant over the last \( 10^7 \) yr, we may estimate the number of CPs in the inner 20 pc to be

\[ N_{\text{CP}} \sim \beta_{\text{pwn}} \tau_{\text{psr}} f_{\text{psr}} f_{\nu} f_{\nu}^{-1}. \]  

(29)

where \( \tau_{\text{psr}} \sim 10^7 \) yr is the typical radio lifetime of a CP, \( f_{\text{psr}} = 0.2 \) is the beaming fraction, \( f_{\nu} \) is the fraction of pulsars with birth velocities low enough to be retained in the inner 20 pc, and \( f_{\text{pwn}} \sim 1 \) is the fraction of pulsars that form PWNe.

Taking the mass of the central 20 pc to be \( M = 3 \times 10^7 M_\odot \) (Lindqvist et al. 1992), we find that pulsars must have velocities \( v_{\text{birth}} < 115 \text{ km s}^{-1} \) to remain gravitationally bound to the inner 20 pc. From the birth velocity distributions considered by Faucher-Giguère & Kaspi (2006), we find \( f_{\nu} \approx 0.05–0.30 \). However, the distance traveled by a pulsar is given by

\[ d \approx 10 \text{ pc} \left( \frac{v}{100 \text{ km s}^{-1}} \right) \left( \frac{t}{10^5 \text{ yr}} \right). \]  

(30)

Thus, pulsars with velocities high enough to become gravitationally bound will also have velocities high enough to escape the inner 20 pc on timescales comparable to the PWN lifetime. As a result, the PWNe observed within the inner 20 pc are very likely to remain there and we can take \( f_{\nu} \sim 1 \).

From Equation (29), we see that if the PWN birthrate has been constant over the last \( 10^7 \) yr, we would expect

\[ N_{\text{CP}} \sim 400 \left( \frac{N_{\text{pwn}}}{20} \right) \left( \frac{\tau_{\text{pwn}}}{10^5 \text{ yr}} \right)^{-1} \left( \frac{f_{\text{pwn}}}{1.0} \right)^{-1}. \]  

(31)

CPs within 20 pc of Sgr A*.

Finally, we note that of the ∼20 PWN candidates identified by Muno et al. (2008), 4 fall within a projected radial distance of 1 pc from Sgr A*. Assuming the number of pulsars scales accordingly, then Equation (31) predicts \( N_{\text{CP}} \sim 80 \) CPs within the inner parsec of the GC.

9. SUPERNOVA RATE IN THE GALACTIC CENTER

NSs are formed as the end products of core-collapse supernovae (CCSN). An estimate of the rate of CCSN in the GC would therefore offer a constraint on the pulsar population. The CCSN rate is estimated below for both \( r < 150 \) pc and \( r < 20 \) pc.

9.1. CCSN Rate Within \( r < 150 \) pc of Sgr A*

By measuring the total mass of \( ^{26}\text{Al} \) in the Galaxy, Diehl et al. (2006) estimate the Galactic CCSN rate to be \( \beta_{\text{CCSN}} = 1.9 \pm 1.1 \) century \(^{-1} \). One may, in principle, scale this estimate to smaller regions of the Galaxy using massive star populations. Taking the inner 500 pc to contain 10% of the Galaxy’s massive star formation (Figer 2008), we can estimate that the inner ∼150 pc contains ∼2% of the massive star formation and therefore should have a CCSN rate of \( \beta_{\text{CCSN}} \approx 0.04 \) century \(^{-1} \). Crocker et al. (2011) estimate a similar rate and show that it is consistent with SN rate estimates from infrared observations, stellar composition, X-ray emission, gas turbulence, and high-velocity compact clouds (see Crocker et al. 2011 and references within). We may now estimate the CP population in the GC to be

\[ N_{\text{CP}} = f_{\text{psr}} f_{\text{psr}} f_{\nu} f_{\nu} \beta_{\text{CCSN}}, \]  

(32)

where \( \beta_{\text{CCSN}} \approx 4 \times 10^{-4} \) yr\(^{-1} \) is the CCSN rate, \( \tau_{\text{psr}} \sim 10^7 \) yr is the mean CP lifetime, \( f_{\nu} = 0.2 \) is the fraction of pulsars beamed toward Earth, \( f_{\nu} \) is the fraction of pulsars with birth velocities small enough to be retained by the GC, and \( f_{\text{pwn}} \sim 1 \) is the fraction of CCSN that results in active pulsars. Using the distributions from Faucher-Giguère & Kaspi (2006), the fraction of pulsars with birth velocities smaller than the escape velocity \( v_e \approx 200 \text{ km s}^{-1} \) at 150 pc ranges from \( f_{\nu} \approx 0.1–0.4 \). These values give an estimate of \( N_{\text{CP}} \sim 100 \). Likewise, accounting for the longer ages for MSPs (\( \tau_{\text{psr}} \sim 10^{10} \) yr), we can estimate the MSP population to be \( N_{\text{MSP}} \sim 10^5 f_e \), where \( f_e \) is the fraction of NSs that get recycled to MSPs (see Section 7.4).

9.2. CCSN Rate in Inner 20 pc from X-Ray Observations

Studies of diffuse X-ray emission can also provide insight into the SN rate in the GC. Using over 600 ks of Chandra ACIS–I observations, Muno et al. (2004) found that the diffuse X-ray emissions in the GC could be explained by a two-temperature plasma composed of a "soft" component \( (kT \approx 0.8 \text{ keV}) \) and a "hard" component \( (kT \approx 8 \text{ keV}) \). Assuming the soft component of the plasma is primarily heated by SNe, an estimate for the SN rate can be made by observing the loss of energy from the inner 20 pc.

Let us first consider the case in which the soft component of the plasma just cools radiatively. The X-ray luminosity of the soft component of the plasma in the inner 20 pc is...
\[ L_X \approx 3 \times 10^{36} \text{ erg s}^{-1} \] (Muno et al. 2004). If each SN transfers \(~1\%\) of its total kinetic energy of \(\sim 10^{51} \text{ erg}\) to the plasma, then an SN rate of \(\beta_{\text{SN}} \approx 10^{-5} \text{ yr}^{-1}\) is required to maintain the currently observed temperature. Taking this rate to be constant and \(f_r \approx 0.1\) (see Section 8) gives an estimate for the CP population of \(N_{\text{CP}} \sim 2 \left( f_r / 0.1 \right)\).

The above estimates assume that the SN rate is constant over the radio lifetime of a CP (\(\sim 10^7 \text{ yr}\)). However, the SN rate estimates are only required to hold over a characteristic cooling time of \(t_c \approx E / L\), where \(E \approx 5 \times 10^{50} \text{ erg s}^{-1}\) is the total thermal energy stored in the plasma and \(L\) is the appropriate cooling luminosity (Muno et al. 2004). The cooling timescales for radiative cooling and adiabatic expansion are \(5 \times 10^6 \text{ yr}\) and \(2 \times 10^4 \text{ yr}\), respectively.

Keeping this caveat in mind, the assumption of a constant SN rate does allow useful bounds to be put on the pulsar populations in the GC. Taking a constant SN rate from radiative cooling to be a lower bound and a constant SN rate from adiabatic expansion to be an upper bound, we find the CP population in the inner 20 pc to be \(1 \lesssim N_{\text{CP}} \lesssim 10^3\). Likewise, for MSPs with \(\tau \approx 10^{11} \text{ yr}\), we estimate a population of \(10^3 f_r \lesssim N_{\text{MSP}} \lesssim 10^6 f_r\), where \(f_r\) is the fraction of NSs recycled into MSPs (see Section 7.4).

### 10. DISCUSSION

#### 10.1. Summary of Estimates

We have used observations over a wide range of wavelengths to make order of magnitude estimates of the number of pulsars allowed within \(r \leq 1 \text{ pc}\) and \(r \leq 150 \text{ pc}\) of Sgr A*. The estimates are summarized in Table 4.

#### 10.1.1. Pulsar Population Within \(r \leq 150 \text{ pc}\)

Limits on the pulsar population within 150 pc of Sgr A* may be set using the five known pulsars in the inner 15′, the catalog of compact radio sources by Lazio & Cordes (2008), measurements of an excess gamma-ray flux by Hooper & Goodenough (2011), and estimates of the Galactic CCSN rate.

The five known pulsars in the inner 15′ provide the strongest current evidence for an intrinsic pulsar population in the GC region. A Monte Carlo population analysis by Deneva et al. (2009) showed that the pulsar detections in the survey by Deneva et al. (2009) indicate a population of at least \(N \gtrsim 100\) pulsars within 100 pc of Sgr A*.

The catalog of compact radio sources compiled by Lazio & Cordes (2008) allows for upper limits to be placed on the pulsar population in the inner 150 pc. The VLA survey produced a total of 170 compact steep-spectrum sources. Although pulsars cannot be unequivocally classified in an imaging survey, Lazio & Cordes (2008) estimate that \(N \approx 10\) of the sources were likely pulsars. Using this estimate and the survey sensitivities, a conservative upper bound of \(N \lesssim 10^4\) may be set on the pulsar population in this region. Even if it turns out that there are no pulsars in the catalog, an upper limit of \(N \lesssim 10^3\) may be set to 99% confidence level. We note that although these upper limits should hold for the entire survey region, the increasing background temperature and side lobes caused by extended emission toward the inner GC mean that the inner field of the survey (half-power radius of 15′) likely experienced decreased sensitivity and could potentially hide a significant pulsar population in the immediate vicinity of Sgr A*.

Using the first two years of *Fermi* data, Hooper & Goodenough (2011) claim to have detected an excess diffuse gamma-ray flux in the inner 150 pc of the Galaxy, which they attribute to annihilating dark matter particles. If we assume the gamma rays come instead from a collection of MSPs, an upper limit to the number of MSPs in the GC may be set. Following similar calculations for globular clusters by Abdo et al. (2010a), we find that the excess is consistent with a population of \(\sim 5 \times 10^7\) MSPs. This estimate is nominally an upper limit, but considering the systematic uncertainties in current GC gamma-ray background models and difficulties subtracting the point source associated with Sgr A*, we adopt this value as only a lower limit on the upper bound of MSPs in the inner 150 pc.

As radio pulsars are formed in CCSNe, the SN rate also provides a constraint on the pulsar population in the GC. By scaling down the Galactic SN rate based on massive star populations in a manner similar to that of Crocker et al. (2011), we estimate an SN of \(\beta_{\text{CCSN}} \approx 0.04 \text{ century}^{-1}\). Such an SN rate indicates a CP population of \(N_{\text{CP}} \approx 100\) and an MSP.
population of \( N_{\text{MSP}} \sim 10^5 f_r \), where \( f_r \) is the recycling fraction discussed in Section 7.2. Since the recycling fraction of field pulsars is \( f_r \gtrsim 10^{-3} \) and potentially as high as \( f_r \sim 0.1 \) in globular clusters, we adopt a nominal value of \( f_r \sim 10^{-2} \), so \( N_{\text{MSP}} \sim 10^4 (f_r/10^{-2}) \).

Finally, we note that all of the upper limits considered for pulsar populations on the large scale of 150 pc may not include contributions from the few inner parsecs as a result of decreased sensitivity or failure to incorporate recent starburst activity. As a result, we consider these limits mainly applicable in the region 1 pc \( \lesssim r \lesssim 150 \) pc. The above estimates are consistent with a total pulsar population that is, both CPs and MSPs of \( 10^2 \lesssim N_{\text{PWN}} \lesssim 10^4 \), a CP population of \( N_{\text{CP}} \lesssim 10^3 \), and an MSP population of \( N_{\text{MSP}} \lesssim 10^4 \).

### 10.1.2. Pulsar Population Within \( r \lesssim 1 \) pc

Limits on the pulsar population in the inner parsec of the GC have been set using the non-detections of high-frequency directed pulsar searches, the spectrum of Sgr A* on arcsecond scales, the population and SFH of the massive star progenitors of NSs, the observations of \( \sim 20 \) PWN candidates in the inner 20 pc, and the limits on the SN rate based on X-ray observations in the inner 20 pc.

Directed pulsar searches of the inner parsec of the Galaxy have been conducted with theGBT at frequencies of 5, 9, and 15 GHz (Deneva et al. 2009; Macquart et al. 2010). Since none of these searches made any detections, an upper limit may be set on the total pulsar population that is still consistent with a null result. Using the survey parameters provided in the Deneva et al. (2009) and Macquart et al. (2010) surveys, we find that up to \( N_{\text{PWN}} \lesssim 10^3 \) pulsars (both CPs and MSPs) may be present in the inner parsec.

Since the compact radio source Sgr A* is broadened by interstellar scattering (\( \sim 1'' \) at 1 GHz), the observed flux density may actually be a combination of the emission near the MBH and a diffuse component from a population of unresolved pulsars. By requiring that this two-component system reproduces the observed spectrum of Sgr A*, constraints may be placed on the pulsar population on arcsecond scales. We consider a variety of spatial distributions and find that a total population of \( \sim 10^3 \) pulsars is consistent with flux density measurements, regardless of spatial distribution. The existence of such a large pulsar population would distort the low-frequency measurements of the intrinsic spectrum of Sgr A* and the free–free absorption along the line of sight of Sgr A*.

Upper limits to the total pulsar population can also be set by studying the populations of massive stars that end their lives as NSs. Infrared observations of the present day population of massive stars allows for estimates of the SFH. We consider the case of two general SFHs and find that the CP population can get as high as \( N_{\text{CP}} \lesssim 200 \) only under the most favorable conditions. More typical estimates for the CP population are \( N_{\text{CP}} \sim 20 \), with most of these being formed in the young disk of massive stars located \( \approx 0.5 \) pc from Sgr A*. The MSPs are less sensitive to the exact SFH and produce populations of \( N_{\text{MSP}} \sim 200 \) with an upper limit of \( N_{\text{MSP}} \lesssim 2000 \) for a range of reasonable SFHs.

Upper limits on the number of CPs in the inner parsecs of the GC may be set using the detection of \( \sim 20 \) PWNe within 20 pc of Sgr A*. Using the \( \sim 20 \) PWN candidates compiled by Munoz et al. (2008) in a catalog of diffuse X-ray sources and assuming PWNe are produced at a constant rate, we find that as many as 400 CPs may reside in the inner 20 pc. If the CP distribution follows that of the PWN candidates, then as many as 80 CPs could reside in the inner parsec.

Finally, we consider measurements of the soft \( (kT \approx 0.8 \text{ keV}) \) component of the diffuse X-ray plasma in the inner 20 pc. Assuming that the plasma was heated by the transfer of kinetic energy from SNe, we may set an upper limit on the number of pulsars in this region (Muno et al. 2004). By considering two different cooling regimes, we find that the most extreme cooling scenario will produce a population of up to \( \lesssim 10^3 \) CPs and \( \sim 10^6 f_r \) MSPs. Thus, we can set upper bounds of \( N_{\text{CP}} \lesssim 10^3 \) and \( N_{\text{MSP}} \lesssim 10^4 (f_r/10^{-2}) \) for CPs and MSPs in the inner 20 pc.

Overall, we find that the above estimates are consistent with a CP population of \( N_{\text{CP}} \lesssim 100 \) and an MSP population of \( N_{\text{MSP}} \lesssim 10^3 \) in the inner parsec of the GC.

### 10.2. Conclusions

Current observations of the GC are consistent with a population of up to \( \sim 10^3 \) active pulsars beamed toward Earth within the central parsec around Sgr A*. This total population may consist of up to \( N_{\text{CP}} \lesssim 100 \) CPs and as many as \( N_{\text{MSP}} \lesssim 10^3 \) MSPs. Such a population could distort the low-frequency measurements of both the spectrum of Sgr A* and free–free absorption along the line of sight of Sgr A*. However, even with a potentially sizeable collection of pulsars, the difficult observing conditions of the inner regions of the GC will make individual detections a challenge. The strong interstellar scattering and large pulse broadening times mean that typical pulsar periodicity searches at radio wavelengths will be sensitive to pulsars only at high observing frequencies and large bandwidths (Cordes & Lazio 1997). Even if most of the pulsars lie below the detection threshold, “giant” pulses intrinsic to the pulsar or as the result of an enhancement through multipath scattering may make a pulsar visible a search for single pulses. Since there may be many more MSPs than CPs, one may search for pulsars using interferometer imaging surveys of compact radio objects similar to that of Lazio & Cordes (2008). Finally, search methods should be considered at wavelengths less affected by the scattering effects of the ISM. Since many MSPs produce gamma-ray emission, a directed search of the GC region with the Fermi LAT could potentially detect a pulsar in a blind periodicity search.

Despite the difficulties in finding pulsars in the GC, the detection of a pulsar orbiting Sgr A* with an orbital period of \( P_{\text{orb}} \lesssim 10^4 \) yr would provide an unparalleled test of gravity in the strong-field regime and could potentially allow the measurement of the spin and quadrupole moment of the MBH (Pfahl & Loeb 2004; Laguna & Wolszczan 1997; Wex & Kopeikin 1999; Liu et al. 2012). Additionally, the detection of even one pulsar in the inner few parsecs would provide an excellent probe of the magnetio-ionic material, the gravitational potential, and the SFH in the vicinity of Sgr A*. In light of the significant scientific rewards and a potentially sizeable target population, we strongly recommend continued pulsar searches in the GC across a wide range of wavelengths.
