In the past decade, several multi-resolution representation theories for graph signals have been proposed. Bipartite filter-banks stand out as the most natural extension of time domain filter-banks, in part because perfect reconstruction, orthogonality and bi-orthogonality conditions in the graph spectral domain resemble those for traditional filter-banks. Therefore, many of the well known orthogonal and bi-orthogonal designs can be easily adapted for graph signals. A major limitation is that this framework can only be applied to the normalized Laplacian of bipartite graphs. In this paper we extend this theory to arbitrary graphs and positive semi-definite variation operators. Our approach is based on a different definition of the graph Fourier transform (GFT), where orthogonality is defined with the respect to the $Q$ inner product. We construct GFTs satisfying a spectral folding property, which allows us to easily construct orthogonal and bi-orthogonal perfect reconstruction filter-banks. We illustrate signal representation and computational efficiency of our filter-banks on 3D point clouds with hundreds of thousands of points.

**Index Terms**— graph filterbank, graph Fourier transform, multi-resolution representation, two channel filterbank

**1. INTRODUCTION**

Graph signal processing (GSP) provides a toolbox for analysis and manipulation of signals living in irregular domains [1, 2]. Given the success of multi-resolution representation theories (MRR) to analyze and process traditional signals [3], significant efforts have been put into extending them for graph signals [4].

Applications often require these MRRs to: (i) be perfect reconstruction (invertible), (ii) be critically sampled (non-redundant), (iii) be orthogonal, and (iv) have compact support (polynomial filter implementation). In the graph setting, it has proven challenging to find theories that satisfy more than a few of these properties simultaneously. Current theories require strong assumptions on the graph topology (e.g., bipartite[5, 6], circulant [7]), and are valid for a single type of graph operator (e.g., normalized Laplacian or adjacency). Narang and Ortega [5, 6] proposed two channel filter-banks on bipartite graphs, composed of graph filters, vertex down-sampling, and vertex up-sampling operators (see Figure 1). These bipartite filter-banks (BFB) obey (i), (ii), and either (iii) or (iv), can be designed in the frequency domain, and can be implemented using low degree polynomials. In addition, regular domain filter-banks can be easily converted to the graph domain [5, 6, 8, 9, 10]. Given their strong theoretical properties and efficient implementations, BFB have found numerous applications [11, 12, 13, 14].

Despite all these remarkable properties, BFB theory [5, 6] only applies to normalized Laplacians and adjacency matrices of bipartite graphs. These are major limitations since the graph structure is rarely bipartite (which dictates the down-sampling operator), whereas the graph variation operator (or graph shift) is determined by the application. To overcome these issues, we propose a new theory that can be applied to: 1) arbitrary graphs, 2) any vertex partition for down-sampling, and 3) positive semi-definite variation operators (see [15, 16, 17, 18] for examples). The proposed filter-banks also satisfy (i), (ii), and either (iii) or (iv), as with BFB.

The BFB theory is built upon a spectral folding property satisfied by the eigenvectors and eigenvalues of the normalized Laplacian of bipartite graphs. Our theory follows a similar strategy, by proving a new spectral folding property for the $(M, Q)$ graph Fourier transform ($(M, Q)$-GFT). This result builds upon a generalization of the graph Fourier transform to arbitrary finite dimensional Hilbert spaces [15, 19] with inner product $\langle x, y \rangle_Q = y^\top Q x$ and variation operator $M$. In our framework, the down-sampling and variation operators $M$ completely determine the choice of inner product $Q$. Interestingly, our spectral domain conditions on the filters match those of [5, 6] for the normalized Laplacian of bipartite graphs, and therefore we can re-use any of their filter designs, or any of the more recent improvements [8, 9]. When the graph is bipartite, and $M$ is the normalized or combinatorial Laplacian, we recover the nonZeroDC and ZeroDC filter-banks, respectively [5, 6].

Early MRRs on arbitrary graphs were constructed by scaling and shifting spectral graph filters [20, 21, 22]. These methods are difficult to invert (e.g., requiring least squares), are not critically sampled, and lack orthogonality. More recent approaches are redundant [23, 24], lack perfect reconstruction [25, 26], or change the graph to a bipartite one [27, 28, 29, 5]. While some of these approaches [27, 28, 5] can exploit efficient filter-bank implementations, once a sparse bipartite graph is available, obtaining the bipartite graph itself, either by graph approximation or through graph learning may be computationally infeasible for large graphs. More recently, [30] proposed graph filter-banks with spectral domain down-sampling. This sampling operator induces spectral folding of the GFT which is...
exploited to obtain perfect reconstruction conditions. Although this approach can be used for arbitrary graphs and variation operators, it requires computing a full GFT, which does not scale well to large graphs. In contrast to previous approaches, we show that the proposed filter-banks can be implemented efficiently on large graphs (e.g., with hundreds of thousands of nodes), as long as these are sparse, and outperform BFB in energy compaction and run time.

The rest of the paper is organized as follows. In Sections 2 and 3 we review the fundamentals of GSP on arbitrary Hilbert spaces, and two channel filter-banks on bipartite graphs, respectively. Our theory is presented in Section 4. We end this paper with numerical results and conclusions in Sections 5 and 6, respectively.

2. GSP IN ARBITRARY HILBERT SPACES

Scalars, vectors and matrices are written in lower case regular, lower case bold and upper case bold respectively (e.g., a, b, C). Positive definite and semi-definite matrices are denoted by \( A \succ 0 \) and \( A \succeq 0 \) respectively. Consider a weighted undirected graph \( G = (V, E, M) \) with vertex set \( V = \{1, 2, \cdots, n\} \), edge set \( E \subseteq V \times V \), and variation operator \( M = (m_{ij}) \) satisfying \( m_{ij} = m_{ji} \neq 0 \) when \( i \neq j \) and \( m_{ij} = 0 \) otherwise. A graph signal is a function \( x = \{x_i\} \), that can be represented by a vector \( x = [x_1, \cdots, x_n]^\top \). The variation operator is assumed to be positive semi-definite, and the variation of a signal is \( \Delta(x) = \sqrt{M}x \). Intuitively, signals with increased variation are said to have higher frequency content. We will further assume that \( M \) is irregular, that is, the graph is connected. Typical examples of variation operators include the combinatorial and normalized Laplacian matrices. For a symmetric non-negative matrix \( W = (w_{ij}) \), degree of node \( i = d_i = \sum_{j \in V} w_{ij} \), and the degree matrix \( D = \text{diag}(d_1, \cdots, d_n) \). The combinatorial Laplacian is \( L = D - W \), while the normalized Laplacian is \( \mathcal{L} = D^{-1/2}LD^{-1/2} = I - D^{-1/2}WD^{-1/2} \) [15] introduced the idea of using an inner product \( \langle x, y \rangle_Q = x^\top Q y \), and induced norm given by \( ||x||_Q = \sqrt{\langle x, x \rangle_Q} \). The (M, Q)-GFT basis vectors are the columns of \( U = [u_1, \cdots, u_n] \), which solve the generalized eigenvalue problem

\[
M u_i = \lambda_i Q u_i, \quad (1)
\]

and \( 0 \leq \lambda_1 \leq \cdots \leq \lambda_n \). The set of eigenvalues (spectrum) of a graph is denoted by \( \sigma(M, Q) \). The generalized eigenvectors are \( Q \)-orthonormal, hence \( ||u_i||_Q = 1, \forall i \in V \), and \( \langle u_i, u_j \rangle_Q = 0, \forall i \neq j \), that is, \( U^\top Q U = I \) in matrix form. A graph signal \( x \) has the following representation in the \( (M, Q) \)-GFT basis

\[
x = \sum_{i=1}^{n} \langle x, u_i \rangle_Q u_i = U \hat{x}. \quad (2)
\]

The \((M, Q)\)-GFT of \( x \) is denoted by \( \hat{x} \), with coordinates \( \hat{x}_i = \langle x, u_i \rangle_Q \). In matrix form this corresponds to \( \hat{x} = U^\top Q x \), while the inverse transform is given by \( x = U \hat{x} \), since \( U U^\top Q = I \). A linear operator \( H \) is a spectral filter if there is a function \( h : \mathbb{R}_+ \rightarrow \mathbb{R} \) so that \( H = U h(A) U^\top Q = h(Z) \), where \( Z = Q^{-1}M = U A U^\top Q \) is the fundamental matrix, and \( A = \text{diag}(\lambda_1, \cdots, \lambda_n) \).

3. TWO CHANNEL FILTER-BANKS

In this section we define two channel filter-banks on arbitrary graphs, and review the BFB theory [5, 6]. A two channel filter-bank is depicted in Figure 1. The analysis filters are \( H_A \) and \( H_I \), while the synthesis filters correspond to \( G_0 \) and \( G_1 \). Consider the set \( A \) and \( B = A \setminus V \), which form a partition of the vertex set \( V \). Without loss of generality we assume that \( A = \{1, 2, \cdots, |A|\} \). Down-sampling a signal \( x \) on a set \( A \) corresponds to keeping the entries \( x_i \) if \( i \in A \), and discarding the rest. This can be represented by \( x_A = S_A x \), where \( S_A = [I_A, 0] \) is a \( |A| \times |V| \) selection matrix. The up-sampling operator is \( S_A^\top \). Down-sampling followed by up-sampling sets to zero the entries in \( B \), thus \( S_A x_A = S_A S_A^\top x_A = [x_A, 0]^\top \).

3.1. Vertex domain conditions for arbitrary graphs

The analysis operator (filtering and down-sampling) from Fig. 1 is

\[
T_A = S_A^\top S_A H_0 + S_A^\top S_B H_1 = \begin{bmatrix} S_A H_0 \\ S_B H_1 \end{bmatrix}. \quad (3)
\]

The outputs of the low pass and high pass channels, called approximation \( a \) and detail \( d \) coefficients, respectively, are given by:

\[
T_a x = \begin{bmatrix} a \\ d \end{bmatrix} = \begin{bmatrix} S_A H_0 x \\ S_B H_1 x \end{bmatrix}. \quad (4)
\]

The synthesis operator has a similar expression

\[
T_s = G_0 S_A^\top S_A G_1 + G_1 S_B^\top S_B = [G_0 S_A^\top G_1 S_B]. \quad (5)
\]

We say that a two channel filter-bank is perfect reconstruction (PR) if \( T_s x = T_a x, T_s = I \). A linear operator \( T \) is \( Q \)-orthogonal if for each \( x \), the norm of the transformed signal is preserved, that is, \( ||T x||_Q = ||x||_Q \). In matrix form this corresponds to \( T^\top Q T = Q \). For a PR two channel filter-bank, \( T_A \) is \( Q \)-orthogonal if and only if \( T_s \) is \( Q \)-orthogonal. Finding operators \( T_A, T_s \) that are orthogonal and PR is not that difficult, in fact, any non-singular orthogonal matrix can be used for \( T_A \), and the synthesis operator can be chosen as \( T_s = Q^{-1} T_a^\top Qu \). The challenge is finding operators that exploit the graph structure, and that can be efficiently implemented on large arbitrary graphs. In the next subsection we review the approach of \[5, 6\] to design BFB using spectral graph filters.

3.2. Spectral domain conditions for bipartite graphs

BFBs can be constructed on bipartite graphs:

**Definition 1.** A graph \( G = (V, E) \) is bipartite on \((A, B)\), if i) \((A, B)\) forms a partition, that is, \( A \cap B = \emptyset \), and \( A \cup B = V \), and ii) for all \((i, j) \in E \), \( i \in A \) and \( j \in B \), or \( i \in B \) and \( j \in A \).

In bipartite graphs, only edges between sets \( A \) and \( B \) are allowed, therefore the Laplacian matrices have the form

\[
L = \begin{bmatrix} D_A & -W_{AB} \\ -W_{BA} & D_B \end{bmatrix}, \quad \mathcal{L} = \begin{bmatrix} I_A & -W_{AB} \\ -W_{BA} & I_B \end{bmatrix}, \quad (6)
\]

where \( \mathcal{L} = D^{-1/2}LD^{-1/2} = I - \tilde{W} \), and \( \tilde{W} = D^{-1/2}WD^{-1/2} \). Spectral filters are defined using the \((\mathcal{L}, I)\)-GFT, thus \( Z = \mathcal{L} \), and \( H_i = h_i(\mathcal{L}), G_i = g_i(\mathcal{L}), \) for \( i \in \{0, 1\} \).

We define \( J = \text{diag}(f) \), where

\[
f_i = \begin{cases} 1 & \text{if } i \in A \\ -1 & \text{if } i \in B \end{cases}. \quad (8)
\]

Then we can write the operators as \( S_A J S_A = \frac{1}{2} (I + J) \), and \( S_B J S_B = \frac{1}{2} (I - J) \). The PR condition now becomes

\[
I = \frac{1}{2} (G_0 H_0 + G_1 H_1) + \frac{1}{2} (G_0 J H_0 - G_1 J H_1). \quad (9)
\]
The BFB framework attains PR by designing filters that obey

\[ G_0H_0 + G_1H_1 = 2I, \quad \text{and} \quad G_0H_0 - G_1H_1 = 0. \quad (10) \]

**Theorem 1.** [5] For a BFB with filters given by (7), a necessary and sufficient condition for PR is that \( \forall \lambda \in \sigma(L, I) \),

\[ h_0(\lambda)g_0(\lambda) + h_1(\lambda)g_1(\lambda) = 2 \] \hspace{1cm} (11)
\[ h_0(\lambda)g_0(2 - \lambda) - h_1(\lambda)g_1(2 - \lambda) = 0. \] \hspace{1cm} (12)

Theorem 1 is proven using the following property.

**Proposition 1.** [5] [Spectral folding] If \( L \mathbf{u} = \lambda \mathbf{u} \), then \( \mathbf{Ju} \) is also an eigenvector with eigenvalue \( 2 - \lambda \).

I-orthogonal filter-banks can be realized if and only if for all \( \lambda \in \sigma(L, I) \), the filters also satisfy

\[ h_0^0(\lambda) + h_1^0(\lambda) = 2, \] \hspace{1cm} (13)
\[ h_0(\lambda)h_0(2 - \lambda) - h_1(\lambda)h_1(2 - \lambda) = 0. \] \hspace{1cm} (14)

Orthogonal filter-banks are PR, while the converse is not true in general. In fact, filters \( h_0, h_1, g_0, g_1 \) obey (13) and (14), if and only if, they obey (11) and (12) and \( h_1 = g_1 \). Orthogonal filter-banks do not have polynomial implementations, thus requiring full eigendecomposition for implementation. A popular approach to overcome this is to approximate the filters with Chebyshev polynomials [22, 8]. An alternative is to use perfect reconstruction bi-orthogonal filters,

\[ h_0(\lambda) = g_1(2 - \lambda), \quad h_1(\lambda) = g_0(2 - \lambda), \] \hspace{1cm} (15)

which can be designed to be near orthogonal and polynomial [6]. The proofs of orthogonality and PR require Proposition 1, which holds only for the normalized Laplacian of bipartite graphs. To the best of our knowledge no other variation operators have this property for bipartite or arbitrary graphs.

**4. MAIN RESULTS**

In this section we extend Proposition 1 and the BFB theory to arbitrary graphs and positive semi-definite variation operators by using an alternative definition of GFT.

**Theorem 2 (Spectral folding).** Consider an arbitrary partition of the vertices, \( A \subset V \) and \( B = V \setminus A \). Without loss of generality we assume \( A = \{1, 2, \cdots, |A|\} \). Let \( M \succeq 0 \) be a variation operator, and

\[ M = \begin{bmatrix} M_{AA} & M_{AB} \\ M_{BA} & M_{BB} \end{bmatrix}, \quad Q = \begin{bmatrix} M_{AA} & 0 \\ 0 & M_{BB} \end{bmatrix} \] \hspace{1cm} (16)

where \( Q \) is the inner product matrix. If \( Q \succeq 0 \), then

\[ M \mathbf{u} = \lambda Q \mathbf{u} \iff M \mathbf{Ju} = (2 - \lambda)Q \mathbf{Ju}. \] \hspace{1cm} (17)

We sketch the proof of \( \implies \), since the other direction follows from the same argument. Let \( \mathbf{u} = [\mathbf{u}_A, \mathbf{u}_B] \) be a generalized eigenvector of \( M \) with eigenvalue \( \lambda \), then

\[ M_{AA} \mathbf{u}_A + M_{AB} \mathbf{u}_B = \lambda Q_{AA} \mathbf{u}_A, \quad M_{BA} \mathbf{u}_A + M_{BB} \mathbf{u}_B = \lambda Q_{BB} \mathbf{u}_B. \]

Set \( \mathbf{v} = \mathbf{Ju} = [\mathbf{u}_A, -\mathbf{u}_B] \), and compute \( M \mathbf{v} \). A simple calculation and using the fact that \( \mathbf{u} \) is a generalized eigenvector, and \( M_{AA} = Q_A \), and \( M_{BB} = Q_B \) produces the desired result. For this \( (M, Q) \)-GFT, the fundamental matrix is

\[ Z = Q^{-1}M = \begin{bmatrix} I_A & M_{AA}^{-1}M_{AB} \\ M_{BB} & I_B \end{bmatrix} = \mathbf{UAU}^\top Q, \]

and \( \mathbf{A} = \text{diag}(\lambda_1, \lambda_2, \cdots, \lambda_n) \). This \((M, Q)\)-GFT shares some properties with the \((L, I)\)-GFT of bipartite graphs. First, the generalized eigenvalues obey \( 0 \leq \lambda_i \leq 2 \), and inequalities become strict when \( M \) is non-singular. Second, the eigenvalue \( \lambda = 1 \) has multiplicity at least \( |A| - |B| \), thus the middle graph frequency is less selective when the down-sampling sets have uneven size.

Finally, when \( M = L + V \) and \( V \) is diagonal, i.e., \( L \) is a generalized Laplacian, the multiplicity of \( \lambda_1 \) (smallest eigenvalue) is equal to the number of connected components of the graph. Now we state conditions for PR filter-banks.

**Theorem 3 (Perfect reconstruction).** For any positive semi definite variation operator \( M \), and any vertex partition \( \mathcal{A} \cup \mathcal{B} \). Choose the inner product matrix \( Q \) according to Theorem 2, and spectral graph filters for \( i \in \{0, 1\} \)

\[ H_i = U_{h_i}(A)U_i^\top Q, \quad G_i = U_{g_i}(A)U_i^\top Q. \] \hspace{1cm} (18)

The functions \( h_i, g_i \) for \( i \in \{0, 1\} \) obey conditions (11) and (12) for all \( \lambda \in \sigma(M, Q) \), if and only if the filter-bank of Figure 1 is PR.

The proof follows from Theorem 2 and similar arguments as those used in [5] to prove that (10) is true. Theorem 3 implies that our framework can be implemented using filters designed for bipartite graphs (see [5, 6, 9, 8]). We can also construct \( Q \)-orthogonal filter-banks.

**Theorem 4 (Parseval).** Under the conditions of Theorem 3, the analysis filters obey (13) and (14) for all \( \lambda \in \sigma(M, Q) \), if and only if,

\[ \langle T_x, T_y \rangle_Q = \langle x, y \rangle_Q, \quad \langle T_x, T_y \rangle_Q = \langle x, y \rangle_Q, \forall x, y. \]

In particular, we have preservation of the \( Q \) norm, thus \( \|T_x\|_Q^2 = \|x\|_Q^2 \) and \( \|T_x\|_Q^2 = \|x\|_Q^2 \). When \( Q = I \), the synthesis operator is the transpose of \( T_a \), however, in general we have the relation

\[ T_x = Q^{-1}T_a^\top Q. \] \hspace{1cm} (19)

It was demonstrated in [6] that orthogonal filter-banks cannot be implemented with polynomials of \( L \). The same arguments can be used to show that the proposed orthogonal filter-banks cannot be implemented as polynomials of \( Z \). As an alternative, [6] proposed the bi-orthogonal filters (15), which have polynomials implementations. Although these filters are not orthogonal, we can use the reasoning from [Section III-B][6], to show the analysis and synthesis operators can be designed to be approximately \( Q \)-orthogonal, and satisfy

\[ \alpha \|x\|_Q \leq \|T_x\|_Q \leq \beta \|x\|_Q \quad \forall x, \] \hspace{1cm} (20)

where \( \alpha \) can be \( \alpha \) or \( \beta \), and

\[ \alpha^2 = \frac{1}{2} \inf_{\lambda \in [0,2]} (h_0^2(\lambda) + h_1^2(\lambda)), \quad \beta^2 = \frac{1}{2} \sup_{\lambda \in [0,2]} (h_0^2(\lambda) + h_1^2(\lambda)). \]

**Remark 1.** The zero-DC filter-bank was proposed in [6], so that the smoothest basis function is constant. This approach can be implemented by multiplying the input signal by \( D^{-1/2} \) before applying the analysis filter-bank, and multiplying by \( D^{-1/2} \) at the output of the synthesis filter-bank. This ensures that a constant input signal has zero response in the high pass channel. [6] showed that bi-orthogonal zero-DC filter-banks can be implemented with polynomials of the random walk Laplacian of a bipartite graph. The zero-DC filter-banks can be derived as a special case of our framework, by noticing that for bipartite graphs with Laplacian \( L \), the inner product matrix from Proposition 2 is \( Q = D \), and the fundamental matrix is the random walk Laplacian \( Z = D^{-1}L \).
implement the iterated filterbank on 3D point clouds we follow the steps: 1) construct a graph with $K$ nearest neighbor (KNN) algorithm and compute its combinatorial Laplacian matrix, 2) generate a random down-sampling set $A$, and $B = A^c$, and 3) if a bipartite graph is desired, keep edges between $A$ and $B$ and remove the rest.

Signal representation. We apply the iterated filter-bank described above with $L = 7$ levels to the color attributes of a single frame of the “longdress” sequence. For each $L$, we reconstruct the color signal using only the low frequency coefficients. We compare the proposed filter-banks with the BFBs as a function of $m/n$, where $m$ is the number of coefficients in the low pass channel, and $n$ is the total number of coefficients. Figure 2 shows that the proposed filter-bank has better energy compaction when the KNN graph has fewer edges ($K = 5$), and performance decreases as $K$ increases. The best performance of the BFBs is achieved with an intermediate value of $K = 10$. In Figure 3 we show the reconstructions of regions of the point cloud. When the bipartite graph is too sparse ($K = 5$), several artifacts can be observed, which can be attributed to points/nodes in the high pass channel that do not have connections in the low pass channel. When the bipartite graph is denser $K = 20$, the reconstruction has no artifacts, however details are smoothed more aggressively. The proposed filter-bank, with a sparser graph, better preserves textures and facial features (e.g., eyes, mouth and hair).

Complexity. We compare the run time of the iterated analysis filter-bank ($L = 7$) applied to 20 frames of the “longdress” sequence. We run the experiment using Matlab on a desktop computer. The bipartite filter-bank with $K = 20$ and $K = 10$ takes 14.3 and 8.23 seconds per frame respectively, while the proposed filter-bank with the best performance ($K = 5$), takes 6.72 seconds per frame. These point clouds have an average of 795,000 points per frame. The complexity of our implementation is dominated by two factors. Graph construction, which is implemented using approximate KNN, and complexity proportional to $K$. Complexity of filtering is dominated by the product $Zx$. When the graph is bipartite, $Zx$ is a sparse matrix-vector product. In the non-bipartite case, $Zx$ is computed in two steps, first we perform a sparse matrix-vector product $y = Lx$, and then solve the linear system $Qz = y$. Since $Q$ is sparse, a numerically accurate approximation of $z = Q^{-1}y$ can be found efficiently using the “\"” operator in Matlab.

6. CONCLUSION

This paper extended the graph filter-bank framework [5, 6], which uses the normalized Laplacian of bipartite graphs, to positive semi-definite variation operators, and arbitrary graphs. We achieve this by proving that the spectral folding property is not unique to the normalized Laplacian of bipartite graphs, and in fact, it is satisfied by certain generalized eigenvalues and eigenvectors of non-bipartite graphs. Based on this, we proposed a new graph Fourier transform that is orthogonal in a $Q$ inner product, and that leads to perfect reconstruction, orthogonal and biorthogonal conditions, equivalent to those already known for the bipartite graph case. We implemented a simple degree 1 polynomial filter-bank on 3D point clouds graphs hundreds of thousands of vertices. Our numerical results indicate that our framework outperform the same filter-bank, implemented with bipartite graphs at various sparsity levels. The proposed filter-bank outperforms bipartite filter-banks in run-time and energy compaction.
