Abstract
Background: Psoriasis is a systemic inflammatory disease capable of creating stigmatization in the form of social exclusion and decrement of psychological conditions. Aim: The aim of the study was to determine the level of stigmatization in patients with plaque psoriasis. Methods: The study included 166 patients with plaque psoriasis (55.6% women and 44.3% men) with Psoriasis Area and Severity Index scores ≤10. The age of the study patients ranged between 18 and 72 years (arithmetic mean = 37.4; median = 38; standard deviation [SD] = 11.0). The mean age at the diagnosis of psoriasis was 21.5 years (median = 20; SD = 9.1) and disease duration varied from 2 to 59 years (arithmetic mean = 15.8; median = 15; SD = 11.3). The study patients completed the Polish version of the 6-item Stigmatization Scale and the 33-item Feelings of Stigmatization Questionnaire and a survey developed by the authors of this study, containing questions about the participants’ sociodemographic characteristics (sex, age, place of residence, marital status, education, employment status) and information about their disease (location of psoriatic lesions, time elapsed since the diagnosis of psoriasis). Results: The mean score for the 6-item Stigmatization Scale for the whole study group was 7.6 out of 18 points (median = 7; SD = 3.8; minimum = 0; maximum = 17). The average score for the 33-item Stigma Feelings Questionnaire in our series was 84.5 out of 165 points (median = 88; SD = 20.9; minimum = 30; maximum = 136). A statistically significant sex-related difference was observed in the 6-item Stigmatization Scale scores, with higher stigmatization levels found in men than in women (p = 0.0082). Moreover, significantly higher levels of stigmatization were observed in countryside dwellers (p = 0.0311) and unmarried persons (p = 0.0321). Patients with a longer history of the disease (≥15 years) scored significantly higher on the 6-item Stigmatization Scale (p = 0.0217) than those in whom psoriasis lasted less long, and presented with higher, at the threshold of statistical significance, scores for the 33-item Feelings of Stigmatization Questionnaire. Conclusions: Stigmatization awareness should be promoted among physicians and psoriatic patients to improve psoriasis management.

Introduction
Psoriasis is one of the most common dermatologic conditions worldwide. The most frequently diagnosed form of this chronic inflammatory disease of the skin is plaque psoriasis. Research has shown that psoriasis is not limited to the skin, but can produce systemic effects and
be associated with many comorbidities. Psoriasis has been shown to coexist with psoriatic arthritis [1], cardiovascular disorders [1, 2], and diabetes mellitus [2, 3], and its systemic treatment is known to negatively affect alimentary function [4]. The link between psoriasis and other comorbidities, such as respiratory diseases [2], is not fully understood, and available results are conflicting. Due to its recurring clinical course, chronic character, and burdensome treatment, psoriasis may significantly deteriorate quality of life [5]. The disease is not infrequently an underlying cause of depression [1, 2] and other psychological problems, and since it is considered infectious by many, some patients with psoriasis may be stigmatized by people around them.

The term “stigmatization” refers to rejection as a result of having an attribute or physical feature which is deeply disapproved and discredited by society [6], as is the case in psoriasis patients. Stigmatization may not only lead to social exclusion of patients with psoriasis, but may also impair their psychological status, cause depression, or even trigger suicidal attempts [7, 8]. Patients with psoriasis avoid others, limit their social relations to their closest relatives, abandon their work, and eventually completely alienate from society. Furthermore, social stigmatization may eventually result in self-stigmatization, a condition in which the patient feels inferior after any interaction with others [6, 7]. It needs to be emphasized that not only psoriatic lesions visible to others, but also those that are usually covered, e.g., in the genital area, may be a cause of alienation. Stigmatization contributes to decrease in self-esteem, disruption of social roles, and impairment of normal functioning within the work and family environment.

The aim of this study was to determine the level of stigmatization in patients with plaque psoriasis and to ana-

analyze the relationships between stigmatization and sociodemographic and clinical variables.

Materials and Methods

For further details, see the online supplementary material (see www.karger.com/doi/10.1159/000510654 for all online suppl. material) (Fig. 1) (Table 1) [9].

Results

The mean score for the 6-item Stigmatization Scale for the whole study group was 7.6 out of 18 points (Table 2). The study group included 25% of respondents who scored 6–7 points and 34% of patients with scores of 10 points (Fig. 2).

The 33-item Feelings of Stigmatization Questionnaire measures the stigmatization level in six domains: anticipation of rejection, feeling of being flawed, sensitivity to the opinions of others, guilt and shame, positive attitudes, and secretiveness. The mean score for the 33-item Feelings of Stigmatization Questionnaire in our series was 84.5 out of 165 points (Table 3). The results are also presented graphically as the distribution of the overall scores within 10-point brackets (Fig. 3). The largest proportion of the respondents (22%) scored 90–99 points.

The levels of stigmatization were also analyzed according to the sociodemographic and clinical characteristics of patients with psoriasis (Table 4). A statistically significant sex-related difference was observed in the 6-item Stigmatization Scale scores, with higher stigmatization levels found in men than in women ($p = 0.0082$). Moreover, significantly higher levels of stigmatization were observed in countryside dwellers ($p = 0.0311$) and unmarried persons ($p = 0.0321$).

Both analyzed clinical variables, duration of psoriasis and location of skin lesions, turned out to be significant determinants of stigmatization in the study patients. Patients with a longer history of the disease ($\geq 15$ years) scored significantly higher on the 6-item Stigmatization Scale ($p = 0.0217$) than those in whom psoriasis lasted less long, and presented with higher, at the threshold of statistical significance, scores for the 33-item Feelings of Stigmatization Questionnaire.

Another significant clinical determinant of the stigmatization level was the location of psoriatic lesions, with patients with visible lesions scoring significantly higher on the 33-item Feelings of Stigmatization Questionnaire than those with the lesions invisible to others ($p = 0.0360$). The sense of stigmatization did not depend on patient age, education, or occupation.

Age and duration of psoriasis were also analyzed as potential correlates of stigmatization. While age did not turn out to be a significant determinant of stigmatization...

level, a correlation between the duration of psoriasis and stigmatization level determined with the 6-item Stigmatization Scale was at the threshold of statistical significance. The longer the disease, the higher the stigmatization levels found (Table 5).

Aside from completing the two standardized questionnaires, the study patients were also asked about their subjective feeling of stigmatization. According to 51.1% of the respondents, society does not show tolerance to patients with psoriasis, 57% of the study participants experienced uncomfortable questions about changes in their appearance caused by the disease, and 59.1% claimed that they felt discriminated due to the altered condition of their skin.

Discussion

Each disease, especially chronic, causes various emotional responses in the affected individual. Due to their location, the presence of dermatologic conditions is visible to others and can thus constitute the reason either for lack of acceptance of the disease or for lack of self-acceptance [10–13].

Erving Goffman, a sociologist from the 1960s, was a pioneer of stigmatization studies. He defined stigma as a sign, a symptom which separates the affected individual from others. Stigmatization may have a direct (voiced opinions and behavior of others) or indirect form (observing the stigmatization of individuals affected with similar condition) or refer to self-stigmatization of a patient (the patient and his/her close relatives feel aversion to his/her body due to the presence of dermatologic lesions). The stigmatization may lead to the so-called “Golem effect,” in which lower expectations of a patient stimulate a deterioration of his/her status [11].

A growing number of studies have recently addressed the effect of psoriasis on mental status and social functioning of patients affected with this disease [14–19]. The results of Young [12], Vardy et al. [13], and Wahl et al. [11] unequivocally indicate that psoriatic patients usually experience insecurity, isolation, and stigmatization, which affects the quality of their lives.

The aim of our present study was to estimate the frequency of stigmatization among patients with psoriasis and to identify its sociodemographic and clinical determinants. Previous studies showed that psoriasis is a strongly stigmatizing disease [20–23]. According to Zięciak et al. [24], approximately 78% of patients with psoriasis presented with moderate or high stigmatization levels, and in the study conducted by van Beugen et al. [21], up to 73% of patients stated that they experienced being stigmatized. Hrehorów et al. [23] also found moderate levels of stigmatization among patients with psoriasis examined with the 6-item Stigmatization Scale (5.0 ± 3.7 points). In our present study, 61% of the respondents presented with moderate stigmatization levels (7.6 points on the 6-item Stigmatization Scale and 84.5 points on the 33-item Feelings of Stigmatization Questionnaire), which is consistent with the results published by Dimitrov and Szepietowski [22].

According to the literature, the most substantial burdens experienced by patients with psoriasis include observation of their skin lesions by others (1.3 ± 0.9 points) and the misconception of psoriasis as a contagious disease (1.1 ± 0.9 points) [23]. The results of our previous study [25] were similar to those published by Hrehorów et al. [23]; moreover, we demonstrated that patients with psoriasis frequently considered their bodies impure.

Russo et al. [10] revealed that 58% of psoriatic patients experience anxiety due to their condition and that 42% of them suffer from uncertainty. However, it was the body image which proved to be the most harmful aspect of psoriasis; as many as 89% of the respondents declared being ashamed and embarrassed with their body image. Other authors also confirmed that unattractive appearance exerts a significant negative effect on one’s self-image, which is reflected by the feelings of being stigmatized and problems in social functioning [7, 26].

Our present study demonstrated that the location of psoriatic lesions might be a significant determinant of stigmatization level. Our study is consistent with previous ones, indicating that the lesions visible to others prove the most harmful for the patients. Similarly, Krueger et al. [27] reported that patients with lesions on the head, hands, and arms perceive their condition as impairing their normal functioning more strongly than those whose psoriatic lesions are limited to the trunk and lower limbs.

The lesions located on the buttocks and in the genital area, usually invisible to others, play a significant role in intimate relationships, and hence may also contribute to a stronger feeling of stigmatization. In a study conducted by Russo et al. [10], >40% of patients with psoriasis experienced sexual problems related to their disease, and another study demonstrated low levels of sexual satisfaction.

| Table 5. Correlations of stigmatizations level with patient age and duration of psoriasis |
|-----------------------------------------------|----------------|-------------------|
| Psychometric measures                          | Age            | Duration of psoriasis |
| 6-item Stigmatization Scale                    | –0.02 (p = 0.8221) | 0.19 (p = 0.0910) |
| 33-item Feelings of Stigmatization Questionnaire | –0.02 (p = 0.8458) | 0.10 (p = 0.3613) |

p values for Spearman coefficients of rank correlation (R).
in psoriasis patients [7]. However, in the study conducted by Hawro et al. [28], all patients with psoriasis, regardless of the location of their skin lesions, presented with similar stigmatization levels.

Duration of the disease and patient age were the other factors included in our analysis. In our present study, patients with a longer history of psoriasis presented with higher stigmatization levels than those in whom the disease had been diagnosed more recently (\( p = 0.0217 \)). This observation is consistent with the results published by van Beugen et al. [21]. Interestingly, we did not find a significant association between patient age and stigmatization level. Patients aged <40 years and those aged ≥40 years had similar mean stigmatization scores: 7.6 and 7.7 points, respectively, for the 6-item Stigmatization Scale, and 84.7 and 84.1 points, respectively, for the 33-item Feelings of Stigmatization Questionnaire. In contrast, both Lu et al. [29] and van Beugen et al. [21] found higher stigmatization levels in younger patients.

Objective changes of image or their subjective perception significantly affect the self-image of psoriatic patients, who perceive themselves as less attractive, worse, or even disgusting. Our study showed that men with psoriasis had higher stigmatization scores than female patients with psoriasis, which is consistent with the results published previously by Miniszewska et al. [30] and Kostyła et al. [31]. However, the results of previous studies analyzing the link between sex and stigmatization are inconclusive. According to Schmid-Ott et al. [19], women presented with higher stigmatization levels than men; similar findings were also reported by Hawro et al. [28] and Krueger et al. [27].

Family situation is an important determinant of psychological status and comfort of life. Understanding and help from family members is of vital importance, as every patient needs large amounts of support from his/her closest relatives. This is equally important for individuals with extensive, visible lesions and for those with small, hidden psoriatic foci. Most patients with psoriasis participating in our study were married (54.5%). Unmarried patients had higher stigmatization scores on both the 6-item Stigmatization Scale and the 33-item Feelings of Stigmatization Questionnaire. Also, according to other authors [21, 29, 32], persons living alone were more prone to stigmatization than married patients.

Stigma can be considered as one of the most powerful social instruments to marginalize or exclude persons with undesirable traits. Stigmatization is a social response to a threat, especially one that cannot be avoided or controlled [6]. In the case of patients with psoriasis, the stigma is represented by the skin lesions which make the patients “different” in the opinion of others.

## Conclusions

Stigmatization is an important problem in psoriasis, as it has profound effects on social functioning of the patients. The awareness of psoriasis among laymen should be improved, as better understanding of underlying mechanisms of the disease might be reflected by broader social acceptance and support offered to affected patients.

To improve the outcomes of psoriasis treatment, both physicians and patients should be aware that this disease can be stigmatizing. Holistic treatment is a modern therapeutic approach that should be undertaken by healthcare professionals. The mental condition of psoriatics should be assessed during each visit, and physicians should remember that for these patients, psychological and social problems often constitute a more significant burden than the biological consequences of the disease.

## Key Message

In psoriasis, the stigma is represented by skin lesions, and patients are referred to as “others.”
