Objective: In recent years, the incidence of Bordetella pertussis infection in infants and young children has been increasing. Multiple studies have suggested that B. pertussis may be one of the pathogens of bronchiolitis in infants and young children. However, the prevalence and clinical characteristic of B. pertussis in bronchiolitis is controversial. This prospective descriptive study evaluated the prevalence and clinical manifestations of infants and young children hospitalized for bronchiolitis with B. pertussis.

Methods: Children hospitalized with bronchiolitis were eligible for a prospective study for 36 months from January 1, 2017, to December 31, 2019. Besides B. pertussis, 10 common respiratory viruses and Mycoplasma pneumoniae (MP) were confirmed by laboratory tests. Medical records of patients were reviewed for demographic, clinical characteristics, and laboratory examination.

Results: A total of 1,092 patients with bronchiolitis were admitted. B. pertussis was detected in 78/1,092 (7.1%) patients. Of the 78 patients with B. pertussis bronchiolitis, coinfections occurred in 45 (57.7%) patients, most frequently with human rhinovirus (28/78, 35.9%), followed by MP (9/78, 11.4%), and human bocavirus (6/78, 7.7%). The peak incidence of B. pertussis infection was in May. A high leukocyte count could help distinguish B. pertussis–associated acute bronchiolitis from other acute bronchiolitis etiologies. After excluding coinfections, children with B. pertussis–only bronchiolitis exhibited a milder clinical presentation than those with RSV-only infection; also, children with MP-only and other pathogen infections revealed similar severity. The morbidity of B. pertussis was common (31/78, 39.7%) in infants with bronchiolitis under 3 months.

Conclusion: In summary, B. pertussis is one of the pathogens in children with bronchiolitis, and coinfection of B. pertussis with other viruses is common in bronchiolitis. B. pertussis should be considered when patients hospitalized with bronchiolitis present a longer course and have an elevated leukocyte count. Patients with B. pertussis–associated bronchiolitis present a milder clinical presentation.

Keywords: Bordetella pertussis, bronchiolitis, coinfection, immunization, disease progression, high leukocyte count
INTRODUCTION

Pertussis, caused by the bacterium Bordetella pertussis, is a highly contagious respiratory disease and one of the leading causes of death from infectious diseases in children. B. pertussis, a Gram-negative bacterium that was first described by Bordet and Gengou in 1906 (1), has recently reemerged as a major public health threat. The World Health Organization reported 141,074 confirmed pertussis cases worldwide in 2018 (2). Approximately 160,700 deaths were reported worldwide in 2014 from pertussis in children <5 years of age (3).

Bronchiolitis is the most common acute respiratory disease in infants and young children, and one of the most common causes of hospital admission (4, 5). A total of 40–80% of infection is caused by respiratory syncytial virus (RSV), followed by human rhinovirus (HRV), adenovirus (ADV), parainfluenza virus, human bocavirus (hBoV), and human metapneumovirus (hMPV) (6, 7).

In recent years, studies suggested that B. pertussis is a possible pathogen causing bronchiolitis in infants and young children hospitalized for lower respiratory tract infections (8–10). However, studies reporting the prevalence and clinical characteristics of B. pertussis bronchiolitis are rare. This study aimed to assess the epidemiological features and clinical characteristics of B. pertussis infection and evaluate its impact on infants and young children hospitalized with acute bronchiolitis.

MATERIALS AND METHODS

Patients and Definitions

This prospective descriptive study was conducted on children presenting with acute bronchiolitis who were admitted to the Department of Respiratory Medicine in the Children’s Hospital of Soochow University between January 1, 2017, and December 31, 2019. Acute bronchiolitis was characterized by age ≤2, cough, tachypnea, retractions, and expiratory wheezes, often accompanied by rales (11). B. pertussis was confirmed by polymerase chain reaction (PCR) assays (12). Patients requiring oxygen supply were considered with severe conditions. The exclusion criteria were as follows: (1) patients with incomplete clinical data; (2) patients with bronchopulmonary dysplasia, heredity metabolic diseases, neurological disorders, congenital heart disease, and immunodeficiency; and (3) patients with evidence suggesting that wheezing was caused by tuberculosis and non-infectious factors such as bronchial foreign bodies.

The study was approved by the ethics committees of Children’s Hospital Soochow University (Approval No. 2016026). Informed consent was obtained from the parents of all children enrolled in this study.

Determination of Vaccination Status

Vaccination history was obtained by querying the “Suzhou Children’s Vaccination Inquiry and Evaluation Platform.” A diptheria, tetanus, and acellular pertussis combination vaccine was administered as a primary series at 3, 4, and 5 months, followed by a booster dose at 24 months in China. The vaccination status was regarded as ever-vaccinated if one to three doses were received.

Data Collection

Data regarding demographic, clinical, and laboratory characteristics were documented. Demographic and clinical characteristics included age, gender, length of hospital stay, and requirement of supplemental oxygen. Laboratory specimens were obtained including blood and nasopharyngeal aspirates (NPAs). NPAs were obtained during the first 24 h of hospitalization, using a sterile plastic catheter briefly inserted into the lower pharynx via the nasal cavity. The blood samples were taken immediately after hospitalization. The laboratory data of leukocyte count, percentages of lymphocytes and neutrophils, and detection of common viruses were collected.

PCR Detection of B. pertussis

B. pertussis DNA was detected in NPAs by real-time PCR assays. The primer sequence was synthesized by Shanghai Sangon Biotech Company. The pertussis PtxA-pr and IS481 gene sequences were used as specific primers (Table 1). The RT-PCR assay result was considered negative if the cycle threshold (CT) was ≥40. Specimens that tested positive by PCR for both insertion sequence IS481 (CT < 40) and ptxS1 (CT < 40) were considered positive for B. pertussis. If a specimen was PtxA-pr target negative with an IS481 assay CT <35, it was also considered positive for B. pertussis.

Respiratory Pathogens

Direct immunofluorescence was used to detect RSV; ADV; influenza virus A (IV-A) and B (IV-B); and parainfluenza virus 1 (PIV I), 2 (PIV II), and 3 (PIV III) using a D3 Ultra Respiratory Virus Screening and LD Kit (Diagnostic Hybrids, Athens, OH, USA). A positive result was defined as over five inclusion bodies analyzed under a fluorescence microscope. Mycoplasma pneumoniae (MP), HRV, HMPV, and HBoV were detected by a PCR (nucleic acid amplification fluorescent reagent kit, Ann Gene Co., Guangdong, China) according to the manufacturer’s instructions.

Statistical Analyses

Statistical analyses were conducted using SPSS 26.0 (IBM, SPSS, Chicago, IL, USA).

Data were shown as mean ± standard deviation and median and interquartile range. Quantitative variables among the three age groups were compared using one-way analysis of variance or the Kruskal–Wallis test when appropriate. Frequency

### Table 1 | Gene primer sequence and product length detected by real-time PCR.

| Gene name  | Primer sequence products | Length |
|------------|--------------------------|--------|
| IS481      | 5’GATTCAATAGGATTGATAGCTGTTT3’   | 145    |
|            | 5’TGGACCATTTCGAGTCGGG3’       |        |
| PtxA-pr    | 5’CCAATGCGGTGCTGATGTTG3’      | 191    |
|            | 5’CCTCTGCGTTGATGCGCTATTG3’    |        |
distribution was compared by the chi-square test. A p value < 0.05 was considered as a significant difference.

RESULTS

Demographic Characteristics

Of the total 1,092 patients admitted for bronchiolitis, one or more respiratory pathogens including virus and MP were detected in 1,057 of 1,092 patients (a positive rate of 96.8%) and B. pertussis was identified in 78 patients (7.1%, based on positive results by PCR). Of the 78 cases of bronchiolitis with B. pertussis infection, 47 (60.3%) were male and 31 (39.7%) were female. The male-to-female ratio was 1.52:1. The median age was 6.45 ± 4.94 months. The age distribution of patients is shown in Figure 1; 31 (39.7%) patients were aged ≤ 3 months, 20 (25.6%) patients were aged 4–6 months, 16 (20.5%) patients were aged 7–11 months, and 11 (14.1%) patients were aged ≥ 12 months.

Seasonality of B. pertussis Infection

The monthly distribution of B. pertussis infection is shown in Figures 2A,B. Bronchiolitis could occur throughout the year, and the peak incidence was in December. MP was detected in 1,057 of 1,092 patients (a positive rate of 96.8%) and B. pertussis infection was in 78 patients (7.1%, based on positive results by PCR). Of the 78 cases of bronchiolitis with B. pertussis infection, 47 (60.3%) were male and 31 (39.7%) were female. The male-to-female ratio was 1.52:1. The median age was 6.45 ± 4.94 months. The age distribution of patients is shown in Figure 1; 31 (39.7%) patients were aged ≤ 3 months, 20 (25.6%) patients were aged 4–6 months, 16 (20.5%) patients were aged 7–11 months, and 11 (14.1%) patients were aged ≥ 12 months.

Coinfection Status

Overall, one or more respiratory pathogens including virus and MP were detected in 1,057 of 1,092 patients. The most commonly detected pathogens in patients with bronchiolitis were as follows: RSV (48.9%), HRV (25.9%), HMPV (13.0%), MP (14.6%), HBoV (12.1%), B. pertussis (7.1%), PIV III (7.0%), ADV (1.1%), and PIV I (1.1%).

Of the 78 B. pertussis–infected patients, B. pertussis was the sole pathogen detected in 33 (42.3%) patients. The remaining 45 patients (57.7%) were coinfected with other respiratory pathogens, most frequently with HRV (n = 28, 35.9%), followed by MP (n = 9, 11.4%), HBoV (n = 6, 7.7%), PIV III (n = 4, 5.1%), RSV (n = 3, 3.9%), IV-A (n = 3, 3.9%), and HMPV (n = 2, 2.6%) (Figure 3).

Clinical Features of B. pertussis–Only Infection Compared With Infections With Other Pathogens

In the present study, 33 patients with B. pertussis–only infection, 438 patients with RSV–only infection, 87 patients with MP-only infection, and 534 patients infected with other pathogens were analyzed. In unadjusted comparisons, children with B. pertussis–only infection were similar to children with RSV–only infection in age, but the number of children with age ≤ 3 months who were only infected with pertussis was less than that of children with RSV–only infection (Table 2). Children with B. pertussis–only infection were significantly more likely to have vomiting (36.4%), cyanosis (12.1%), leukocyte count > 15 x 10^9 (57.6%), longer duration of symptoms before admission (median day, 14.0), and longer hospital stay (median day, 9.0) compared with those with RSV–only infection (17.8%, 2.7%, 7.5%, media 5.0, and 8.0 days, respectively; p < 0.05 for all comparisons). Patients with B. pertussis–only infection requiring supplemental oxygen were fewer than patients with RSV–only infection (6.1 vs. 34.9%; p < 0.05).

In unadjusted comparisons, among 120 patients with B. pertussis and MP infections excluding co-detection with other pathogen types, children with B. pertussis–only infection were younger than children with MP-only infection (median 3.9 vs. 5.8 months, respectively) (Table 2). Children with B. pertussis–only infection were significantly more likely to have dyspnea (6.1%), rhinorrhea (15%), vomiting (15%), cyanosis (4%), and leukocyte count > 15 x 10^9/L (57.6%) compared with those with MP-only infection (0.0, 24.1, 10.3, 0.0, and 6.9%, respectively; p < 0.05 for all comparisons). Children with B. pertussis–only infection had a higher number of leukocyte and higher percentage of lymphocyte compared with children with MP-only infection. Children with B. pertussis–only infection had a longer duration of hospital stay (median 9.0 days) than those with MP-only infection (median 8.0 days); however, no significant difference was observed in the duration of symptoms before admission.

B. pertussis Infection and Results of Laboratory Examination in Different Age Groups

B. pertussis–positive patients were divided into three age groups to assess the difference among different age groups (Table 3). A total of 31 patients aged ≤ 3 months, 36 patients aged 4–11 months, and 11 patients aged ≥ 12 months were analyzed. Patients aged ≤ 3 months had a longer duration of hospital stay than others (p < 0.05). The common clinical characteristics among the 78 confirmed patients were paroxysmal cough 92.3% (72/78), whoops 15.5% (12/78), post-tussive vomiting 38.5% (30/78), and cyanosis 12.8% (10/78). Patients with cyanosis aged ≤ 3 months were more compared with older ones (p < 0.05); the others exhibited no difference among three age groups (p > 0.05). Patients aged ≤ 3 months requiring supplemental oxygen were more compared...
with older ones ($p < 0.05$). The gender ratio exhibited no significant difference among the three groups ($p < 0.05$). Coinfection among the three age groups was also compared, which showed no difference ($p > 0.05$). Although, patients aged $\geq 12$ months had a higher number of leukocytes, and higher percentages of neutrophils and lymphocytes, no
significant difference was observed among the three groups (p > 0.05).

**Clinical Features of B. pertussis–Only Infection Compared With Coinfection**

Patients with B. pertussis–only infection were younger and had a high incidence of paroxysmal cough compared with patients with coinfection (p < 0.05). However, patients with coinfection had an increased demand for oxygen and showed more crackles in lungs (p < 0.05) (Table 4).

**DISCUSSION**

In recent years, an increasing incidence of pertussis has been reported in infants and young children (13). Several studies suggested that B. pertussis is a possible pathogen causing bronchiolitis in infants (8–10). Several investigators demonstrated that B. pertussis is a common pathogen of bronchiolitis (14, 15). A study conducted in Turkey identified 44 (25.6%) of the 172 infants with B. pertussis hospitalized for acute bronchiolitis (15). Another study showed B. pertussis involvement in 12 of 142 (8.5%) infants hospitalized for bronchiolitis in Finland (9). Yet other studies identified that B. pertussis was an uncommon pathogen in bronchiolitis (16). Pedro A. Piedra and his colleges found only four of 2,027 children admitted to the hospital as B. pertussis positive using PCR in the USA (10). Similarly, Walsh et al. found B. Pertussis infection in three of 488 patients (0.6%) in the emergency department (17). The present study found that 7.1% of infants and young children hospitalized with acute bronchiolitis had a positive B. pertussis test, which demonstrated that B. pertussis was a common pathogen in bronchiolitis. The variation in the prevalence of B. pertussis in children hospitalized with bronchiolitis among the studies might be due to the difference in climates, recruit criteria, and vaccination. According to the finding of this study, the peak incidence of B. pertussis infection was from May to July, with a total of 33 (50.15%) patients, which has not been reported before.

Studies reported that B. pertussis coinfection with other respiratory viruses was common in children hospitalized for bronchiolitis; the incidence rate was 36–67% (9, 14, 15, 18). However, the present study reported that 45 (57.7%) patients with B. pertussis were coinfected with other respiratory viruses, which was in agreement with previous studies. Some studies (6, 15, 19) suggested that coinfection with RSV was the most common in young children hospitalized for bronchiolitis with B. pertussis infection. However, in the present study, the most common coinfection respiratory viruses in children with B. pertussis hospitalized for bronchiolitis were HRV (35.9%), followed by MP (11.4%), and HBoV (7.7%); these differences in coinfection might be due to the heterogeneity of social demography and differences in study methods and periods.

Symptom duration before admission and hospital stay were more common in B. pertussis–only infection than in RSV-only infection (p < 0.05). It indicated that patients with B. pertussis–associated bronchiolitis often presented a longer course, which was consistent with the clinical symptoms of B. pertussis infection (20) and could help distinguish B. pertussis–associated acute bronchiolitis from other acute bronchiolitis etiologies. The present study compared B. pertussis–only infection with RSV-only infection in children with bronchiolitis. Children with B. pertussis–only infection requiring supplement oxygen
were fewer than children with RSV-only infection, indicating that the former had a milder clinical presentation compared with the latter. This study also compared B. pertussis–only infection with MP-only infection and infections with other pathogens in children and revealed similar severity among these pathogens. This is a novel report explaining such associations. Several other studies (9, 14, 15, 18, 20–22) assessed the influence of B. pertussis on acute bronchiolitis, but they could not exclude the possibility of other respiratory pathogens contributing to the illness. In the present study, the leukocyte count was higher in patients with B. pertussis–only bronchiolitis infection than that in patients with RSV-only infection, MP-only infection, and infections with other pathogens (p < 0.008 for all comparisons), which could also help distinguish B. pertussis–associated acute bronchiolitis from other acute bronchiolitis etiologies. One study showed that the leukocyte count > 60 × 10^9/L was associated with death in children with B. pertussis infection (23). Another study demonstrated that the leukocyte count > 100 × 10^9/L was an independent risk factor of death in children with pertussis (24). However, no patent died of B. pertussis infection in the present study, which might be because the vast majority of infants and young children with mild-to-moderate bronchiolitis were considered, and severe bronchiolitis in the PICU setting was ignored.

Pertussis is a vaccine-preventable respiratory disease. B. pertussis could affect all individuals, but the highest morbidity and mortality rates were among newborns and unvaccinated or incompletely vaccinated young infants (21, 25, 26). In the present study, the morbidity of B. pertussis was common (31/78, 39.7%) in infants with bronchiolitis (438). In the present study, the morbidity of B. pertussis (n = 438) was 31/78 (39.7%).
and antibiotics against pertussis could limit the severity of disease if started in the catarrhal phase \(^{(27, 29)}\). In addition, several systematic reviews confirmed the safety and effectiveness of maternal pertussis vaccination during pregnancy \(^{(30–32)}\). Therefore, it is important to early recognize and initiate treatment.

This study had potential limitations. It enrolled only inpatients hospitalized with \textit{B. pertussis} infection, but more patients with \textit{B. pertussis} infection were treated in the outpatient department. Therefore, patients with more severe symptoms might have been overrepresented, and the prevalence of \textit{B. pertussis} in children with bronchiolitis-associated hospitalization might be affected.

In summary, \textit{B. pertussis} is one of the pathogens in children with bronchiolitis, and coinfection of \textit{B. pertussis} with other viruses is common in bronchiolitis. \textit{B. pertussis} should be considered when patients hospitalized with bronchiolitis present a longer course and have an elevated leukocyte count. Patients with \textit{B. pertussis}–associated bronchiolitis present a milder clinical presentation.
