Selecting the best strategy of treatment in newly diagnosed advanced-stage ovarian cancer patients

Lucas Minig, Cristina Zorrero, Pablo Padilla Iserte, Andres Poveda

Abstract

Although it is assumed that the combination of chemotherapy and radical surgery should be indicated in all newly diagnosed advanced-stage ovarian cancer patients, one of the main raised questions is how to select the best strategy of initial treatment in this group of patients, neoadjuvant chemotherapy followed by interval debulking surgery or primary debulking surgery followed by adjuvant chemotherapy. The selection criteria to offer one strategy over the other as well as a stepwise patient selection for initial treatment are described. Selecting the best strategy of treatment in newly diagnosed advanced stage ovarian cancer patients is a multifactorial and multidisciplinary decision. Several factors should be taken into consideration: (1) the disease factor, related to the extension and localization of the disease as well as tumor biology; (2) the patient factor, associated with patient age, poor performance status, and co-morbidities; and (3) institutional infrastructure factor, related to the lack of prolonged operative time, an appropriate surgical armamentarium, as well as well-equipped intensive care units with well-trained personnel.

Key words: Ovarian cancer; Advanced stage; Primary debulking surgery; Neoadjuvant chemotherapy; Patients' selection

Core tip: Selecting the best strategy of treatment in newly diagnosed advanced-stage ovarian cancer patients is a multifactorial and multidisciplinary decision. Surgeries performed by gynecologic oncologists with formal training in cytoreductive techniques at referral centers are crucial factors in obtaining better oncologic outcomes. However, other factors such as clinical status of the patients, the hospital's infrastructure and equipment, as well as the tumor biology of each individual patient should also be taken into account before deciding on an initial strategy of treatment in women with advanced-stage ovarian cancer.
strategy of treatment in newly diagnosed advanced-stage ovarian cancer patients. World J Methodol 2015; 5(4): 196-202 Available from: URL: http://www.wjgnet.com/2222-0682/full/v5/i4/196.html DOI: http://dx.doi.org/10.5662/wjm.v5.i4.196

INTRODUCTION

It is estimated that over 80% of women with ovarian cancer are diagnosed at advanced stages, when the disease is already extended in the abdominal cavity or beyond. Primary complete debulking surgery (PDS) followed by adjuvant chemotherapy is associated with the best oncological outcome and is considered, therefore, the standard of care[1]. Limitations, however, have been postulated with respect to this treatment strategy. First, patients with postoperative residual disease have no meaningful impact on overall survival (OS)[2-4]. Second, only in few cases is the complete primary cytoreduction rate acceptable, and only when the procedure is performed by experienced surgeons with extended formal training in cytoreductive techniques. Third, PDS is associated with a high incidence of postoperative complications[5,6]. Consequently, an alternative strategy based on neoadjuvant chemotherapy followed by interval debulking surgery (NACT-IDS) has been proposed[7]. Patients receive three to four courses of platinum-taxanes NACT and then, in the absence of progression disease, IDS is performed. The proposed advantages include a reduced risk of peri-operative morbidity, a higher rate of complete tumor resection, and a contention that deferring the initial attempt at surgical debulking does not compromise survival[8].

Nevertheless, there currently exist several controversies regarding the best strategy of treatment[9,10]. Although it is assumed that the combination of chemotherapy and radical surgery should be indicated in all newly diagnosed advanced-stage ovarian cancer patients, one of the main questions raised is how to select the best strategy for initial treatment in this group of patients, a topic that will be the focus of this review.

STEPWISE PATIENT SELECTION FOR NACT OR PDS

An algorithm of management for newly suspected or diagnosed advanced-stage ovarian cancer patients has been developed at the Instituto Valenciano de Oncologia (IVO), Valencia, Spain. Hence, patients are initially evaluated with computer tomography (CT) of thorax-abdomen and pelvis, plus tumor markers including CA-125, CA-19.9, and CEA.

Pre-operative tumor markers can also provide additional information to allow discrimination between an ovarian or extra-ovarian origin of peritoneal carcinomatosis. In this case, if the CA-125 (UI/mL)/CEA (ng/mL) ratio is < 25, mammography and endoscopy are mandatory to exclude primary breast, gastric, or colon cancer[11] (Figure 1). The main aim of the pre-operative CT scan is to localize intra-abdominal disease at non-resectable structures such as liver hilum, celiac trunk, superior mesenteric artery, supra-renal lymph node metastases, and intrahepatic metastases; as well as to identify extra-abdominal disease.

In cases of non-resectable disease at CT scan or in patients older than 75, with poor status or surgical contraindications, a core biopsy or a diagnostic laparoscopy with biopsy is performed to obtain a tissue sample. If the final diagnosis confirms an epithelial ovarian carcinoma, NACT is indicated. According to our series, a total of 30% of patients would receive NACT at this point. In the absence of the previously mentioned criteria, a mini-laparotomy is performed to rule out any extended small bowel carcinomatosis and mesentery roof retraction. These findings are present in 10% of cases, a tumor biopsy is performed and NACT is started in these patients a few days later (Figure 1). The remaining 90% of our patients undergo complete PDS, following the surgical step-wise description detailed elsewhere[12].

Patients undergoing NACT receive 3 courses of carboplatin/paclitaxel intravenously every 3 wk, and are then evaluated by using clinical examination, CA-125 and CT scan. Women with a partial response undergo IDS in an attempt to complete tumor resection. Second-line chemotherapy or inclusion in clinical trials is proposed to women with stable disease or progression to NACT.

DISCUSSION

Role of primary complete cytoreduction

Complete resection of all macroscopic disease at primary debulking surgery is the single most important independent prognostic factor in women with advanced ovarian cancer[2,4,6,13-15]. The definition of “optimal” cytoreduction has been the subject of debate for decades. Therefore, optimal residual disease, such as that measuring 1-2 cm in diameter, has been traditionally considered[16]. However, a significant improvement in survival after complete tumor resection at the time of primary surgical cytoreduction has been observed[2-4]. Thus, according to the last Gynecological Cancer Inter Group (GCIG) consensus conference, cytoreduction should be classified as “complete”, without residual disease”; or “incomplete”, if residual disease is left at the end of the surgery. In addition, the consensus established that the aim of surgical debulking should be to obtain a complete tumor resection[1]. The final decision as to whether or not to perform a tumor debulking depends on the surgeon’s training and confidence in the majority of her or his operations on patients[17]. A great body of evidence suggests that patients operated on by gynecologic oncologists with formal training in cytoreductive techniques are more likely to undergo a complete cytoreduction in comparison to those treated by general gynecologists or general surgeons, with significantly better oncologic outcome[18,19]. Therefore, the main worldwide

consensus\cite{1,12} states that gynecologic oncologists should make the decision regarding whether to start treatment with PDS or NACT in patients with advanced-stage ovarian cancer.

The decision regarding the initial strategy of treatment, based on NACT or PDS, in women with advanced ovarian cancer has been largely debated. A large meta-analysis involving 6885 patients in 53 studies after PDS demonstrated that each 10% increase in cytoreduction correlated with a 5.5% increase in median survival time. Patients with 75% or greater maximal cytoreductive efforts had a median survival of 37 mo compared with a 23 mo for patients with 25% or less maximal effort\cite{14}. On the other hand, Bristow \textit{et al}\cite{20} studied 835 patients in 22 cohorts with advanced ovarian cancer who received NACT. The study showed a median OS of 24.5 mo, range 10-42 mo. Despite the fact that this rate was shorter than what was obtained after PDS, this comparison should be taken with caution given that a bias upon the selection of patients to receive NACT might exist. On the basis regarding the extension of the disease or performance status, within patients who underwent NACT might have a worse prognosis.

The results of the first randomized controlled trial (RCT) in patients with ovarian cancer FIGO stage III C-IV of the European Organization for Treatment and Research (EORTC) and the National Cancer Institute of Canada, comparing PDS vs NACT-TDS, were published in 2010\cite{11}. The authors randomized 718 patients with stage III C-IV ovarian cancer, excluding III C by node metastases only. Surgical time was 180 min in both arms and the median OS and progression-free survival was 30 mo and 12 mo, respectively, in the two arms. One of the main criticisms of the EORTC trial was, however, that NACT was compared to a weak PDS arm. The study was conducted in non-selected centers, achieving a median OS of 30 mo, with a complete cytoreduction rate in the PDS arm of 21%. A similar RCT performed in 87 hospitals in the United Kingdom and New Zealand found the same results\cite{21}. It is interesting to note that these rates are markedly inferior to the outcomes reported by other international multicenter studies\cite{2-4}. When surgery is performed at referral oncologic centers by well-trained surgeons, the complete primary cytoreduction rate can be over 40%-50%, with a median 5-year OS of 50-60 mo\cite{2,5,6}.

Despite the fact that the radicalness of the surgery is the most important factor to obtain a better oncologic outcome, other issues should also be taken into account. These factors include: (1) the time since the first visit of the patient to the commencement of the treatment; (2) the time from the hospital discharge after primary or interval debulking surgery to the initiation of adjuvant chemotherapy. Median time should not exceed 40 d, a longer period of time is related with a high incidence of postoperative complications; (3) the number of cycles in relation to neoadjuvant chemotherapy, should not be more than four; and (4) the time from the end of neoadjuvant chemotherapy to interval debulking surgery.

Initial treatment of women with advanced-stage ovarian cancer

Table 1 Factors associated with cytoreduction rate

| Factor                        | Characteristic                                      |
|-------------------------------|-----------------------------------------------------|
| Surgeon                       | Adequate skills and training in cytoreductive tech. |
| Disease                       | Extension and localization of the disease          |
| Patient                       | Advanced age                                       |
| Institutional infrastructure   | Ovarian cancer multidisciplinary surgical team      |
|                              | Availability of prolonged operative time           |
|                              | Appropriate surgical armamentarium                  |
|                              | Well-trained ICU personnel                          |
|                              | Well-equipped ICU capability                        |

With its inability to accurately predict extensive serosal and mesenteric disease, as it was previously described, these anatomical localizations are major limits to obtaining a complete cytoreduction. In fact, several models were developed to predict suboptimal cytoreduction by using CT scan parameters, but with very poor outcome.

Clinical studies have also evaluated the role of positron emission tomography (PET) and PET/CT as part of pre-operative evaluation in women with advanced-stage ovarian cancer. However, based on the available literature, there is still no evidence that PET or PET/CT works better than CT in detecting the extension of primary ovarian cancer.

Diffusion-weighted magnetic resonance imaging (DW-MRI) is another tool under investigation used to predict resectability in women with advanced-stage ovarian cancer. The evidence for using the DW-MRI in improving detection of the true extent of the disease seems promising. The utility of DW-MRI in predicting intra-abdominal spreading in women with ovarian cancer has recently been evaluated in some investigations. A recent study of 32 patients with ovarian cancer found the main gains of using DW-MRI were the detection of bowel serosal and mesenteric disease, with an accuracy for detection of peritoneal disease of 91% on DW-MRI compared with 75% on CT and 71% on FDG-PET/CT. The results of this technique do appear to be promising for improving the detection of small volume-diffuse peritoneal disease. This encouraged data from a small number of studies; however, it should be prospectively evaluated and validated with a larger sample of patients to establish stronger conclusions in this regard.

Additional clinical factors can help surgeons to identify high-risk patients with postoperative complications and mortality after primary cytoreductive surgery. Two studies tried to correlate clinical factors with increased risk for postoperative morbidity after primary cytoreduction. The studies observed for those aged over 75 together with either FIGO stage III or IV and coincident comorbidity, or aged over 75 combined with serum albumin < 3 g/dL or ASA score of at least 3 and high initial tumor burden (FIGO IV or high volume FIGO III C) identifies a subgroup of 7%-12% of patients with advanced ovarian cancer where upfront debulking surgery is associated with unacceptably high rates of morbidity and peri-operative mortality.

**Laparoscopy vs laparotomy to evaluate the intra-abdominal extension of the disease**

The majority of women receive either NACT or PDS based upon tumor extension and on estimated tumor resectability. As has been previously detailed, there is no current imaging tool that can predict complete cytoreduction in women with advanced-stage ovarian cancer. Therefore, a direct laparoscopic or laparotomic assessment of the abdominal cavity is sometimes needed.

A pre-treatment laparoscopic score to predict tumor

Whether tumor biology or maximal up-front cytoreductive surgery is the most important determinant for better outcomes is being largely debated. At the same time that some studies found cytoreduction removal of visible disease had a more significant impact on survival than the extent of the disease before surgery, other studies observed opposite results. Thus, other factors should be taken into consideration in an attempt to classify ovarian cancers as with “bad” or “good” prognosis. Recent molecular studies, using microarray analysis, have associated overall survival with gene expression profiles in ovarian cancer patients after up-front surgical treatment. Although future large analysis should confirm these findings, it should be expected that molecular studies using genes and proteomic pattern might represent the tools to select patients for the best individual treatment rather than to generalize one strategy over the other for all women with ovarian cancer.

However, beyond the surgeon factor previously described, the cytoreduction rate is also associated to other variables such as: (1) the disease factor, related to the extension and localization of the disease as well as tumor biology; (2) the patient factor, associated with patient age, poor performance status, and co-morbidities; and (3) institutional infrastructure factor, related to the lack of prolonged operative time, an appropriate surgical armamentarium, as well as well-equipped Intensive Care Units with well-trained personnel (Table 1). It is crucial, moreover, to establish an adequate ovarian cancer multidisciplinary surgical team that includes other specialists such as general surgeons, anesthesiologists, infectologists, etc. (Figure 2).

**Pre-operative evaluation in women with suspected advanced stage ovarian cancer**

CT scan is recommended as the most appropriate imaging test prior to treatment planning in women with a suspected advanced stage ovarian cancer. However, limitations with CT scan have been associated with its inability to accurately predict extensive serosal

Figure 2 Multidisciplinary surgical team for treating women with advanced-stage ovarian cancer. ICU: Intensive care unit.

Surgical training plays a crucial role in treating women with advanced-stage ovarian cancer[18]. Given the complexity of surgical procedures in obtaining a complete primary cytoreduction, as well as its positive impact on OS, not surprisingly, many studies from several countries have shown better OS when ovarian cancer patients were initially operated by a gynecologic oncologist rather than general gynecologist[41-43] or general surgeon[44].

Several authors have proposed the centralization of care of ovarian cancer[14,18,42,45] as an approach for improving the quality of care and outcomes. The main demonstrated benefits include better optimal cytoreduction rate[42,45], better chemotherapeutic administration rate and schemes[44,45], and better overall quality of treatment; therefore, improving the patient’s quality of life. Thus, in comparison with unspecialized hospitals, patients who receive care at specialized centers may prolong their OS by almost a year[19,45]. Nevertheless, despite these clear advantages and according to population-based studies, fewer than 40% of patients with ovarian cancer have access to a specialized center in developed countries[43,44]. More recently, a study-population performed in California,

The surgeons begin the resection of the abdominal cavity to carefully determine the extension of the disease on the liver surface, abdominal wall, hilium, to establish the extent of the disease. In this sense, before starting the removal of the disease, a stepwise systematic evaluation of the abdominal cavity is performed in order to avoid the so-called “point of no return” with unnecessary patient morbidity[12]. This standardized strategy has been well described previously[12], and includes two points of stop-or-go decisions. Initially, the ligamentum falciforme is resected, and the peritoneum of the paracolic gutters and the omentum are dissected from the transverse colon. Then, the lesser sac is opened allowing the evaluation of the pancreas, the truncus coeliacus, the liver, and the hepatoduodenal ligament with portal vein, hepatic artery and ductus choledochus. If a non-resectable tumor is present, surgery is stopped. If not, the second point of decision is the evaluation of the radix mesenterii and the small bowel surface by dissecting the adherions and separating the small bowel from the colon and the greater omentum[12].

CENTRALIZATION OF CARE

Surgical steps to obtain complete tumor resection

At our center, if complete tumor resectability is possible at the time of mini-laparotomy, patients undergo an immediate xiphio-pubic midline incision with full exposure of the abomino-pelvic organs in order to establish the true extent of the disease. In this sense, before starting the removal of the disease, a stepwise systematic evaluation of the abdominal cavity is performed in order to avoid the so-called “point of no return” with unnecessary patient morbidity[12]. This standardized strategy has been well described previously[12], and includes two points of stop-or-go decisions. Initially, the ligamentum falciforme is resected, and the peritoneum of the paracolic gutters and the omentum are dissected from the transverse colon. Then, the lesser sac is opened allowing the evaluation of the pancreas, the truncus coeliacus, the liver, and the hepatoduodenal ligament with portal vein, hepatic artery and ductus choledochus. If a non-resectable tumor is present, surgery is stopped. If not, the second point of decision is the evaluation of the radix mesenterii and the small bowel surface by dissecting the adherions and separating the small bowel from the colon and the greater omentum[12].
