We study the non-Arrhenius behavior of surface diffusion near the second-order phase transition boundary of an adsorbate layer. In contrast to expectations based on macroscopic thermodynamic effects, we show that this behavior can be related to the average microscopic jump rate which in turn is determined by the waiting-time distribution \( W(t) \) of single-particle jumps at short times. At long times, \( W(t) \) yields a barrier that corresponds to the rate-limiting step in diffusion. The microscopic information in \( W(t) \) should be accessible by STM measurements.

PACS numbers: 68.35.Fx, 82.20.Pm

The migration of atoms and molecules is one of the most important processes taking place on solid surfaces. It appears in many phenomena such as catalytic reactions and surface growth that are important for practical applications. In most experimental and theoretical treatments up to fifth nearest neighbors and some three-body interactions [11], the substrate remains unreconstructed [12], the oxygen atoms have well-defined adsorption sites [13], and desorption of oxygen occurs only at high temperatures. For this coverage at a low temperature, the adlayer is in the ordered \( p(2\times1) \) phase, while at \( T_c \approx 710 \) K it undergoes a second-order transition to a disordered phase [14]. For details of the model and MC simulations, see Refs. [10,11].

Our simulation results for the tracer and collective diffusion coefficients \( D_T \) and \( D_C \) (for definitions see e.g. Ref. [2]), respectively, are given in Fig. 1. We first note that their qualitative behavior is similar and that the effective diffusion barrier \( E_A^D \) defined as

\[
E_A^D \equiv -\frac{\partial (\log D)}{\partial (1/k_BT)}
\]

is approximately constant at low and high temperatures away from \( T_c \). This implies that the diffusion constants obey simple Arrhenius behavior. Near \( T_c \), however, the
temperature dependence of the diffusion constants is strongly non-Arrhenius.

In the Green-Kubo formalism, the expression for $D_C$ contains a thermodynamic factor $\xi$ inversely proportional to the compressibility, which is governed by the global number fluctuations of the adlayer. It is often assumed that a possible non-Arrhenius behavior of $D_C$ near the phase transition boundary is predominantly due to the critical behaviour of this factor. We show below that this is not the case here: The non-Arrhenius behavior of both $D_T$ and $D_C$ has a dynamic origin and can be traced back to the temperature dependence of the local single-particle jump rate $\Gamma$. To demonstrate this, we show in Fig. 1 the temperature dependence of $\xi$ and $\Gamma$ as well as that of $D_T$ and $D_C$. It can be seen from Fig. 1 that while the diffusion constants have a turning point and sharp temperature variations close to $T_c$, the thermodynamic factor $\xi$ has only a relatively weak temperature dependence in this region and cannot account for the non-Arrhenius behavior of the diffusion constants. On the other hand, the single-particle jump rate $\Gamma$ has exactly the same behavior near $T_c$ as $D_T$ and $D_C$. These observations can be understood theoretically within the dynamical mean field theory (DMF), which yields $D_T \propto \Gamma$ and $D_C \propto \xi \Gamma$. We conclude that the strong temperature dependence of both $D_T$ and $D_C$ near $T_c$ is indeed of the same dynamic origin, coming from the average single-particle transition rate $\Gamma$.

We next focus on the effective diffusion barrier $E_A^{D}$ as extracted from Eq. (1) for $D_T$. As shown by squares in Fig. 2, $E_A^{D}$ has a sharp peak near $T_c$. This peak in $E_A^{D}$ is accompanied by a strong increase in the value of the corresponding prefactor $D_0$ shown in the inset of Fig. 2. This is yet another example of the well-known compensation effect. Here the compensation simply results from the fact that when the temperature dependence is non-Arrhenius, there is no unique way of separating the prefactor and the barrier contributions. Since the temperature dependence of the diffusion constant itself near $T_c$ is smooth and nonsingular, any dramatic change in the temperature dependence of the effective barrier $E_A^{D}$ must be followed by a corresponding change in the effective prefactor $D_0$. We note that the same phenomenon occurs for collective diffusion as well.

To understand the observed strong temperature variation of $E_A^{D}$ near $T_c$, we need to consider the energetics of the microscopic jump processes which determine the average jump rate $\Gamma$. At finite coverages, there is a very complex distribution $P(E_a)$ for the instantaneous activation barriers $E_a$ which an adatom needs to overcome in a jump attempt from one configuration to another. At high $T$, $P(E_a)$ is strongly peaked at small values of $E_a$, while at low temperatures the situation is completely the opposite. The change in the distribution takes place around $T_c$, thus characterizing the ordering of the adlayer as the temperature is decreased below $T_c$. This change in turn results in a strong temperature dependence of the average transition rate $\Gamma$ around $T_c$, as shown in Fig. 3. We point out that the instantaneous activation barriers $E_a$ cannot explain the peak of the effective barrier $E_A^{D}$ in Fig. 2, since the largest value of $E_a$ in our model system is only about 0.4 eV. Thus, the peak does not refer to any microscopic rate-limiting process. Instead, it arises from an entropic contribution to $\Gamma$ which has a strong temperature dependence in the vicinity of $T_c$.

To gain more insight into the microscopic dynamical processes and the anomalous temperature dependence near $T_c$, we next introduce the waiting-time distribution $W(t)$ of single-particle jumps. Suppose a single particle (in the presence of other particles) had performed its last transition at time $t = 0$. Then $W(t)$ is the probability density that the particle in question performs its next transition at time $t$ after it remained still until $t$. Here the most practical definition of “time” in the MC simulations is to consider the time scale as the number of jump attempts of the particle, denoted by $n$. Then the waiting-time distribution is simply $W(n)$. This provides a direct connection with the dynamic jump rate $\Gamma$ discussed above via

$$\langle n \rangle \equiv \frac{1}{\Gamma} \sum_{n=1}^{\infty} n W(n), \quad (2)$$

where $\langle n \rangle$ is the average waiting-time of the particle.

At very long times, we expect $W(t)$ to decay as $W(t) \sim \exp(-t/\tau)$. Here the characteristic time $\tau$ describes the longest time scale among the various microscopic processes, which constitutes the rate-limiting factor for mass transport. This expected exponential decay at long times is indeed observed for our model system, as demonstrated in Fig. 3. We can then define an effective activation barrier $E_A^{W}$ via $\tau$ by considering the jump probability $p = 1/\tau = p_0 \exp(-E_A^{W}/k_BT)$. As shown by circles in Fig. 3, the activation barrier $E_A^{W}$ extracted from the asymptotic region of $W(t)$ decreases monotonically with increasing temperature, and agrees with the effective diffusion barrier $E_A^{D}$ extracted from an Arrhenius analysis of $D_T$ far from $T_c$. Additional studies in our model system indicate that the value of $E_A^{W}$ is closely related to the instantaneous activation barrier characterizing the dominant microscopic processes. In our model the microscopic barriers have a maximum value of about 0.4 eV and thus the barrier $E_A^{W}$ does not have the sharp peak displayed by the effective diffusion barrier $E_A^{D}$.

It turns out that the temperature dependence of the barrier $E_A^{D}$ results mainly from the short-time behavior of $W(n)$. This is demonstrated by dividing the sum in Eq. (2) into two parts, the first of which is the short-time contribution $\langle n \rangle_S = \sum_{n=1}^{n_{co}} n W(n)$. This quantity accounts for the contribution up to a crossover time $n_{co}$, which separates the short-time regime from the asymptotic exponential decay. What remains is the long-time
contribution $\langle n \rangle_L = \langle n \rangle - \langle n \rangle_S$. As expected, from Fig. 4 we observe that the short-time regime gives the dominant contribution to $\Gamma$. Further, the short-time regime of $W(n)$ is strongly affected by the critical fluctuations, being mainly responsible for the anomalous temperature dependence of the diffusion constants near $T_c$.

To summarize, within the present model of $O/W(110)$, the non-Arrhenius behavior near $T_c$ was found to have a mainly dynamic origin, reflecting the dependence of the single-particle jump rate $\Gamma$ on the critical fluctuations close to $T_c$. Surprisingly, in our studies the thermodynamic factor gives only a minor contribution to the temperature dependence of the collective diffusion constant $D_C$, and the anomalous temperature dependence for both $D_T$ and $D_C$ results from the dynamic factor $\Gamma$. We find that the single-particle waiting-time distribution $W(t)$ gives the most detailed picture of the microscopic processes. It has been recently demonstrated by Swartzentruber [9] that this distribution function in the presence of several different microscopic activation barriers can indeed be measured using the STM. From the long-time tail of $W(t)$ one can obtain information on the energetics of the rate-limiting processes of diffusion in the form of an effective activation barrier $E^{\text{D}}_A$. On the other hand, the temperature variation of the effective diffusion barrier $E^{\text{D}}_A$ directly reflects that of the microscopic jump rate $\Gamma$, and depends not only on the long-time tail of $W(t)$ but also on its short-time behavior. In the short-time regime near $T_c$, $W(t)$ is strongly affected by the critical fluctuations. The fluctuations there lead to a strong temperature dependence of the transition entropy and an additional contribution to the effective barrier $E^{\text{D}}_A$.

[17] In our MC studies, we used the so called TDA algorithm [10]. In this method, the transition of an adatom from the initial state with energy $E_i$ to the final state with energy $E_f$ proceeds by two successive steps via the intermediate state with energy $E_i$. For $E_f$, we used the form $E_f = (E_i + E_f)/2 + \Delta$, where $\Delta$ characterizes the activation barrier in the zero coverage limit due to the substrate-adatom interaction. The instantaneous activation barrier $E_a$ for a jump attempt from a filled to a vacant site is then $E_a = \max(E_i - E_f, E_f - E_i, 0)$. For further details and for the choice of $\Delta$, see Refs. [10].

[19] Within the framework of the Transition State Theory [P. Hänggi, P. Talkner, and M. Borkovec, Rev. Mod. Phys. 62, 251 (1990)], the diffusion rate is proportional to $\exp(-\Delta F/k_BT)$, with the free energy difference $\Delta F = \Delta E - T\Delta S$, where $\Delta E$ is the energy barrier, and the prefactor arises from the transition entropy $\Delta S$. In the case studied here, the entropy is strongly temperature-dependent due to critical fluctuations, which leads to an additional contribution to the effective diffusion barrier $E^{\text{D}}_A$ as obtained from an Arrhenius plot.

[21] In this work, the crossover time $\tau_c$ was chosen to be the value of $n$, at which the relative deviation of $\log W(n)$ from its asymptotic form was half percent. [3].
FIG. 1. Results for $D_T$ and $D_C$ as a typical Arrhenius plot in the O/W(110) system at $\theta = 0.45$. We also show the behavior of the average transition rate $\Gamma$ and the thermodynamic factor $\xi$. The quantities $D_T$, $D_C$, and $\Gamma$ have been made dimensionless by expressing them in units of $a^2/t_0$, $a^2/t_0$, and $1/t_0$, respectively, where $a$ is the lattice constant and $t_0$ is one Monte Carlo step per particle. The value of $\xi$, which is a dimensionless quantity, has been scaled by a factor of seven to make the graphic representation more readable while other quantities are expressed directly in the units given above. The critical temperature of the order-disorder phase transition is denoted by $T_c$ and a dotted line.

FIG. 2. Results for the effective activation barriers. The squares denote results based on the Arrhenius form (see Eq. (1)) for tracer diffusion, while open circles represent the data based on the tail of $W(n)$. Behavior of the prefactor $D_0$ is illustrated in the inset. The critical temperature is denoted by a dotted line.

FIG. 3. An example of a waiting-time distribution $W(n)$ at a temperature of $0.774 T_c$ showing an exponential decay at long times. For clarity, only some of the data points are shown here. The full curve is an exponential fit to the tail of $W(n)$. The approximate crossover time $n_{co}$ for the crossover from the small-time regime to the asymptotic long-time regime is indicated by an arrow.

FIG. 4. Comparison of the short-time contribution $\langle n \rangle_S$ and the long-time contribution $\langle n \rangle_L$ to the average waiting-time $\langle n \rangle$. The slight increase of $\langle n \rangle_L$ at small $T$ is due to $n_{co}$ whose value is difficult to determine accurately at very low temperatures. The quantities $\langle n \rangle_S$, $\langle n \rangle_L$, and $\langle n \rangle$ are all expressed in units of one Monte Carlo step per particle.
