Metallic surface of a Mott insulator -
Mott insulating surface of a metal

Abstract
The dynamical mean-field theory (DMFT) is employed to study the correlation-
driven metal-insulator transition in the semi-infinite Hubbard model at half-filling
and zero temperature. We consider the low-index surfaces of the three-dimensional
simple-cubic lattice and systematically vary the model parameters at the very sur-
face, the intra- and inter-layer surface hopping and the surface Coulomb interaction.
Within the DMFT the self-energy functional is assumed to be local. Therewith, the
problem is self-consistently mapped onto a set of coupled effective impurity mod-
els corresponding to the inequivalent layers parallel to the surface. Assuming that
the influence of the high-energy Hubbard bands on the low-energy quasi-particle
resonance can be neglected at the critical point, a simplified “linearized DMFT” be-
comes possible. The linearized theory, however, is formally equivalent to the Weiss
molecular-field theory for the semi-infinite Ising model. This implies that qualit-
atively the rich phenomenology of the Landau description of second-order phase
transitions at surfaces has a direct analogue for the surface Mott transition. Moti-
vated by this formal analogy, we work out the predictions of the linearized DMFT in
detail. It is found that under certain circumstances the surface of a Mott insulator
can be metallic while a Mott-insulating surface of a normal metal is not possible.
We derive the corresponding phase diagrams, the (mean-field) critical exponents
and the critical profiles of the quasi-particle weight. The results are confirmed by a
fully numerical evaluation of the DMFT equations using the exact-diagonalization
(ED) method. By means of the ED approach we especially investigate the non-
critical parts of the phase diagrams and discuss the $U$ and layer dependence of the
quasi-particle weight. For strong modifications of the surface model parameters, the
surface low-energy electronic structure dynamically decouples from the bulk.

1 Introduction

The correlation-driven transition from a paramagnetic metal to a paramagnetic Mott-Hubbard insulator [1, 2] constitutes one of the fundamental problems in solid-state theory. The Mott transition is interesting since strong electron correlations lead to low-energy electronic properties that are qualitatively different from those predicted by band theory.

Since it has been recognized that the limit of infinite spatial dimensions ($D = \infty$) is a well-defined and meaningful limit also for itinerant-electron models [3] and since the invention of dynamical mean-field theory (DMFT) [4, 5], there is a renewed interest in the Mott transition [6]. The DMFT provides an in principle exact description of the transition in infinite dimensions. While this is a somewhat artificial limit, the DMFT, as a mean-field concept, represents a powerful approach also for the study of finite-dimensional systems. Analogous to the Weiss molecular-field theory for localized spin models, the DMFT can be expected to give a valuable mean-field picture of the physics of three-dimensional itinerant-electron models [4].

Presumably, the simplest model that includes the essentials of the Mott transition is the Hubbard model [8, 9, 10]. From the application of the iterative perturbation theory (IPT) [11] to the $D = \infty$ Hubbard model at half-filling and zero temperature, the following scenario for the Mott transition has emerged [3]: For small Coulomb interaction $U$, the system is a metallic Fermi liquid with a quasi-particle peak at the Fermi energy in the one-electron spectrum. As $U$ approaches a critical value $U_{c2}$ from below, the quasi-particle weight vanishes continuously, similar as in the Brinkman-Rice approach [12]. For strong $U$ the system is a Mott-Hubbard insulator with an insulating gap in the one-electron spectrum, similar to the Hubbard-III approach [13]. The insulating solution ceases to exist when $U$ approaches another critical value $U_{c1}$ from above. In the entire coexistence region $U_{c1} < U < U_{c2}$ the metallic solution is stable, and thus the transition is of second order. The pre-formed gap opens discontinuously at $U = U_{c2}$.

It has been questioned [14, 15, 16, 17] whether the picture given by the IPT is correct. Recent numerical renormalization-group calculations (NRG) [18, 19], however, corroborate the IPT results qualitatively, although $U_c$ is found to be significantly smaller than in the perturbational approach [20]. On the other hand, there is a remarkable agreement of the NRG with the result for $U_c$ in the projective self-consistent method (PSCM) [21].

The NRG calculations show that for $U \to U_c$ the quasi-particle resonance becomes more or less isolated from the high-energy Hubbard bands [13]. The resonance basically reproduces itself in the self-consistent evaluation of the mean-field equations. This fact can be used for a simplified treatment of the DMFT where the influence of the Hubbard bands on the low-energy peak is neglected [22]. This “linearized DMFT” yields a simple algebraic equation for the quasi-particle weight at the critical interaction and thereby allows for an analytical estimate of $U_c$. The results are in good agreement with the numerical values for $U_c$ obtained from NRG and PSCM on different lattices [22]. For inhomogeneous systems, the linearized DMFT also determines the critical profile of the quasi-particle weight and the dependence of $U_c$ on the system geometry. Comparing with the numerical results obtained from the exact diagonalization method (ED), a convincing qualitative agreement with respect to the thickness and geometry dependence of $U_c$ has been found for thin Hubbard films [23].

It has been noticed [23] that the equation of the linearized DMFT is of the same form
as the linearized mean-field equation of the Weiss molecular-field theory for the Ising model (at the critical temperature). There is a one-to-one correspondence if one identifies the quasi-particle weight \( z \) with the magnetization \( m \), the squared interaction \( U^2 \) with the temperature \( T \), and the squared hopping integral \( t^2 \) with the exchange coupling \( J \):

\[
z \leftrightarrow m, \quad U^2 \leftrightarrow k_B T, \quad 36t^2 \leftrightarrow J/2.
\]

The Weiss theory, on the other hand, can be considered as being a coarse-grained realization of the classical Landau theory of second-order phase transitions \[24\]. Consequently, the results of Landau theory (for \( T = T_c \)) can be translated back into predictions concerning the Mott transition in the Hubbard model (for \( U = U_c \)).

While the Landau theory of phase transitions is rather simple for homogeneous systems, the mean-field theory of critical behavior at surfaces is much more involved and numerous non-trivial results can be derived \[25\]. The idea of the present paper is thus to take the Landau theory as starting point and motivation to work out the predictions of the linearized DMFT for Hubbard surfaces and finally to test the predictions, as far as possible, by comparing with a fully numerical solution of the DMFT equations.

Within the classical Landau theory, the free energy is expanded in terms of the local order parameter \( m(x) \). For a semi-infinite system (surface geometry) one additionally considers a surface contribution to the free energy \[25\]. Laterally, the order parameter is assumed to be homogeneous. We take the \( x \) axis be parallel to the surface normal and pointing into the volume \( (x > 0) \), then \( m = m(x) \), and \( m(x = 0) \) is the surface value of the order parameter. Let us list those mean-field predictions derived from the Ginzburg-Landau free energy \[25\] which – by means of the above-mentioned formal analogy – have a direct counterpart for the Mott transition:

1. The transition in the bulk of the semi-infinite system occurs exactly at the same critical temperature \( T_{c,\text{bulk}} \) as for the infinitely extended system: \( T_{c,\text{bulk}} = T_c \).

2. Near the surface the order-parameter profile \( m(x) \) vanishes at a distance \( \Lambda \) beyond the surface if linearly extrapolated from the boundary. The so-called “extrapolation length” \( \Lambda \) as well as the (bulk) correlation length \( \xi \) are the two length scales that characterize the order-parameter profile in the continuum model. Microscopically, the extrapolation length is related to the model parameters at the surface. In the molecular-field approximation of the Ising model we have \( \Lambda^{-1} \propto (\Delta_c - \Delta) \) where \( \Delta \) is the modification of the exchange coupling within the surface layer, \( J_{11} = J(1+\Delta) \), and \( \Delta = \Delta_c \) corresponds to \( \Lambda = \infty \).

3. For uniform parameters \( (\Delta = 0) \) the mean field is smaller at the surface due to missing neighbors. This implies a weaker tendency to order. \( m(x = 0) \) is smaller than \( m(x \to \infty) = m_{\text{bulk}} \), and \( m(x) \) monotonously increases with increasing \( x \) (this implies \( \Lambda > 0 \)). There is a finite order parameter \( m(x = 0) > 0 \) at the surface only for \( T < T_c \), i. e. only when there is spontaneous order also in the bulk. The transition at \( T_c \) is termed the “ordinary transition”.

4. For \( \Lambda < 0 \ (\Delta > \Delta_c) \) the surface layer orders at a temperature \( T_{c,\text{surf}} > T_{c,\text{bulk}} \) ("surface transition"). In the regime \( T_{c,\text{bulk}} < T < T_{c,\text{surf}} \), the bulk correlation length \( \xi \) is finite, and the order parameter decays exponentially fast from its maximum value
\( m(x = 0) \) at the surface towards zero in the bulk. At \( T = T_{c, \text{bulk}} \) ("extraordinary transition"), the divergence of \( \xi \) and the onset of order in the bulk induce singularities in the behavior of surface response functions. For the order parameter at the surface \( m(x = 0) \), there is a discontinuity of its second derivative only. At \( T = T_{c, \text{bulk}} \) the order-parameter profile decays algebraically, \( m(x) \propto 1/x \).

5. It holds: \( (T_{c, \text{surf}} - T_{c, \text{bulk}})/T_{c, \text{bulk}} \propto \Lambda^{-2} \). The transition at \( T = T_{c, \text{surf}} = T_{c, \text{bulk}} \) in the case \( \Lambda = \infty \) is called the "special transition". For \( \Lambda = \infty \) the order-parameter profile is flat in the ordered phase; the trivial solution \( m(x) = m_{\text{bulk}} = \text{const} \) minimizes the Ginzburg-Landau free energy. In this situation the effect of missing neighbors at the surface is compensated exactly. The topology of the phase diagram (ordinary, extraordinary, surface and special transition) should be correct whenever the surface can support independent order \[26\]. For example, there is no surface transition in the semi-infinite two-dimensional Ising model since the "surface" is one-dimensional \[27\].

6. There are two critical exponents that are merely related to the critical temperatures (instead of describing the critical behavior of order parameter and response functions), the "shift exponent" \( \lambda_s \) and the "crossover exponent" \( \phi \). They are defined as \( (T_c(d) - T_c(d = \infty))/T_c(d = \infty) \propto d^{-\lambda_s} \) for \( d \to \infty \) where \( T_c(d) \) is the critical temperature of a film of finite thickness \( d \), and \( (T_{c, \text{surf}}(\Delta) - T_{c, \text{bulk}})/T_{c, \text{bulk}} \propto (\Delta/\Delta_c - 1)^{1/\phi} \) for \( \Delta \to \Delta_c \) (special transition). Within Landau mean-field theory one has \( \lambda_s = 2 \) and \( \phi = 1/2 \).

7. Spontaneous order in the bulk always induces a finite order parameter at the surface, \( m(x = 0) > 0 \).

The Landau theory also makes additional statements concerning e.g. the bulk and surface critical exponents of the order parameter as well as the exponents of response functions with respect to an external applied field. We do not mention such results in the present context, since either they have no obvious analogue for the Mott transition (applied field) or they refer to temperatures \( T \to T_c \) but \( T \neq T_c \) where the mean-field equation cannot be linearized and where the formal analogy \[1\] breaks down. We will, however, discuss a simple extension of the linearized DMFT for \( U \to U_c \) but \( U \neq U_c \) which recovers the result \( z \propto (U_c - U) \) of the PSCM \[21\].

To a certain extent, the phase diagram predicted by the Landau theory or, respectively, by the linearized DMFT can be tested by comparing with a fully numerical evaluation of the DMFT equations. We need an approach that is sufficiently simple for a systematic study of a large number of geometries and model parameters. For this purpose the exact-diagonalization method of Caffarel and Krauth \[28\] is well suited. We mainly focus on the non-critical parts in the phase diagram where the ED is able to give reliable results. Critical exponents, for example, cannot be calculated reliably. The ED has successfully been employed beforehand for the discussion of the Mott transition in thin Hubbard films \[29\] and at Hubbard surfaces \[24\] where the film and surface electronic structure has been discussed in detail. Contrary, the present paper focuses on the surface modification of the model parameters and on surface phases and thereby substantially extends the previous studies.
The Mott transition at a surface of the semi-infinite Hubbard model has recently been investigated in a paper of Hasegawa [30] on the basis of the Kotliar-Ruckenstein slave-boson theory [31]. With the present study we methodically improve upon Hasegawa’s work. We will also show that for $U \mapsto U_c$ the perturbation of the system that is introduced by the presence of the surface deeply extends into the bulk. It is thus insufficient to assume (local) physical quantities to be different from their value in the bulk only in the first few surface layers. Such a restriction gives rise to unphysical singularities, e. g. in the $U$ dependence of the quasi-particle weight as they are seen in Ref. [30]. Within the slave-boson theory it is found that under certain circumstances a metallic surface can coexist with an insulating bulk [30]. Crucial for the existence of this surface phase is a considerable decrease of $U$ at the surface. This is an interesting and also plausible result although the required strong decrease of $U$ at the surface appears to be quite unrealistic for real systems.

A physically more relevant modification of the model parameters is, in first place, the enhancement or decrease of the hopping integrals at the surface. This may be caused by a relaxation of the interlayer distance, for example. According to the scaling law $t \sim r^{-5}$ for $d$ electrons (cf. e. g. Ref. [22]), a top-layer relaxation $\Delta r/r$ of a few per cent results in a strong change of the hopping integral. A surface modification of $t$ up to about 10%-20% appears to be realistic. Besides the hopping we will also discuss a modification of $U$ at the surface. In 3d transition metals, however, this effect seems to be less important [33, 34]. In any case, $U$ is expected to be enhanced at the surface [34]. On the contrary, it will be shown that the interesting surface phase occurs for lowered surface $U$. Another important aspect is the surface geometry which is expected to affect the surface phase diagram considerably. Open surfaces with a strong reduction of the surface coordination number will show the most pronounced surface effects in the electronic structure. We thus consider different low-index surfaces of a $D = 3$ simple-cubic lattice.

The basic assumption of DMFT is the strict locality of the self-energy functional. For $D = 3$ dimensions this represents a strong simplification of the problem. The local approximation is well justified for the weak-coupling regime, also for the case of surface geometries (see the discussion in Refs. [29, 35, 36]). For the intermediate- to strong-coupling regime, however, the assumption may be questioned. One could alternatively investigate a surface of a $D = \infty$ lattice where the DMFT becomes exact. While this will be discussed briefly, we otherwise consider surfaces in $D = 3$ dimensions. As in Refs. [28, 29] we expect the mean-field concept to be a good starting point for $D = 3$.

The plan of the paper is the following: The next section introduces into the model. The application of DMFT for surface geometries is briefly discussed in Sec. 3. We use two different methods to solve the DMFT equations: The first one is the approximative linearization of the equations for $U = U_c$ [22]. This is presented in Sec. 4. Sec. 5 then gives a discussion of the analytical results. For the full solution of the DMFT equations, we employ the exact-diagonalization method [28] which is introduced in Sec. 6. The corresponding results are discussed in Sec. 7. Finally, Sec. 8 concludes the paper.
2 Semi-infinite Hubbard model

We investigate the Hubbard model on a three-dimensional, simple-cubic and semi-infinite lattice. The system is considered to be built up by two-dimensional layers parallel to the surface. Accordingly, the position vector to a particular site in the semi-infinite lattice is written as \( \mathbf{R}_{\text{site}} = \mathbf{r}_i + \mathbf{R}_\alpha \). Here \( \mathbf{R}_\alpha \) stands for the coordinate origin in the layer \( \alpha \), and the layer index runs from \( \alpha = 1 \) (topmost surface layer) to infinity (bulk). \( \mathbf{r}_i \) is the position vector with respect to a layer-dependent origin and runs over the sites within the layer. In this notation the Hamiltonian reads:

\[
H = \sum_{ij\alpha\beta} t_{i\alpha,j\beta} c_{i\alpha\sigma}^\dagger c_{j\beta\sigma} + \sum_{i\alpha\sigma} U_\alpha n_{i\alpha\sigma} n_{i\alpha\sigma^-} .
\]  

(2)

\( \sigma = \uparrow, \downarrow \) is the spin index. \( U_\alpha \) is the (layer-dependent) Hubbard interaction strength. The hopping integrals are restricted to be non-zero between nearest neighbors. The energy zero is defined by setting \( t_{i\alpha,i\alpha} = 0 \) for sites in the bulk (\( \alpha \rightarrow \infty \)). The energy scale is given by taking the (bulk) nearest-neighbor hopping to be \( t_{i\alpha,j\beta} = -t \) with \( t = 1 \).

The presence of the surface implies a breakdown of translational symmetry with respect to the surface normal direction. Lateral translational symmetry, however, may be exploited by performing a two-dimensional Fourier transformation:

\[
\epsilon_{\alpha\beta}(\mathbf{k}) = \frac{1}{N_\parallel} \sum_{ij} e^{-i\mathbf{k} \cdot (\mathbf{r}_i - \mathbf{r}_j)} t_{i\alpha,j\beta} .
\]  

(3)

Here \( \mathbf{k} \) is a two-dimensional wave vector of the first surface Brillouin zone (SBZ), and \( N_\parallel \) denotes the number of sites within each layer (\( N_\parallel \rightarrow \infty \)). Let us briefly discuss the Fourier-transformed hopping matrix which reads:

\[
\epsilon(\mathbf{k}) = \begin{pmatrix}
t_{11} \epsilon_\parallel(\mathbf{k}) + \Delta t_0 & t_{12} \epsilon_\perp(\mathbf{k}) \\
t_{21} \epsilon_\perp(\mathbf{k}) & t_{22} \epsilon_\parallel(\mathbf{k}) + \epsilon_\parallel(\mathbf{k})
\end{pmatrix} .
\]  

(4)

For \( \alpha \geq 2 \) the intra-layer (parallel) hopping and the inter-layer (perpendicular) hopping are written as \( \epsilon_{\alpha\alpha}(\mathbf{k}) = t\epsilon_\parallel(\mathbf{k}) \) and \( \epsilon_{\alpha\alpha-1}(\mathbf{k}) = t\epsilon_\perp(\mathbf{k}) \), respectively. We consider three different low-index surfaces of the sc lattice. The hopping matrix for the sc(100) surface is obtained from:

\[
\begin{align*}
\epsilon_\parallel(\mathbf{k}) &= -2(\cos(k_x) + \cos(k_y)) , \\
|\epsilon_\perp(\mathbf{k})|^2 &= 1.
\end{align*}
\]  

(5)

The perpendicular hopping is \( \mathbf{k} \)-independent in this case. For the (110) surface we have:

\[
\begin{align*}
\epsilon_\parallel(\mathbf{k}) &= -2 \cos(k_x) , \\
|\epsilon_\perp(\mathbf{k})|^2 &= 2 + 2 \cos(\sqrt{2}k_y) ,
\end{align*}
\]  

(6)

and for the sc(111) surface:

\[
\begin{align*}
\epsilon_\parallel(\mathbf{k}) &= 0 , \\
|\epsilon_\perp(\mathbf{k})|^2 &= 3 + 2 \cos(\sqrt{3}k_x) \cos(\sqrt{3}k_y) \\
&+ 4 \cos(\sqrt{3}k_x) \cos(\sqrt{1}k_y) .
\end{align*}
\]  

(7)
Since two nearest neighbors are always located in two different (adjacent) layers, the intra-layer hopping vanishes in the last case. Note, that only the absolute square of $\epsilon_\perp(k)$ enters the physical quantities we are interested in.

At the very surface of the semi-infinite system, we consider three different possible modifications of the model parameters. Firstly, the intra-layer hopping within the topmost surface layer $t_{11}$ may differ from its bulk value (see Eq. (4)). Secondly, we allow for an altered hopping $t_{12} = t_{21} \neq t$ between the topmost and the sub-surface layer. Finally, the on-site Coulomb interaction strength is assumed to be layer-independent $U_\alpha = U = \text{const.}$ except for the topmost layer, $U_{\alpha=1} \neq U$.

We restrict ourselves to the case of manifest particle-hole symmetry, namely a bipartite (sc) lattice, nearest-neighbor hopping and half-filling ($n = 2 \langle n_{i\alpha\sigma} \rangle = 1$). In this case the Fermi energy is given by $\mu = t_0 + U/2$. It is fixed by the bulk values for the on-site hopping and for the Hubbard interaction. Consider the atomic limit $t = 0$ for a moment: The positions of the two Hubbard “bands” in the bulk spectrum are given by: $E_{\text{low}} = t_0 - \mu$ and $E_{\text{high}} = t_0 - \mu + U$, i.e. they lie symmetric with respect to $\mu$. In thermal equilibrium $\mu$ is also the Fermi energy for the top layer. The Hubbard peaks in the surface density of states lie at $E_{\text{low}} = t_0 - \mu + \Delta t_0$ and $E_{\text{high}} = t_0 + \Delta t_0 - \mu + U_1$, where we have taken into account the top-layer modification of the interaction strength and where we have introduced an additional modification $\Delta t_0$ of the atomic level for top-layer sites (see Eq. (4)). To maintain manifest particle-hole symmetry and to ensure $\langle n_{i\alpha\sigma} \rangle = 0.5$ for $\alpha = 1$, the Hubbard peaks must again lie symmetric with respect to $\mu$. Thus, we need:

$$\Delta t_0 = (U - U_1)/2. \quad (8)$$

With this choice for the top-layer on-site hopping, the local density of states (DOS) $\rho_\alpha(E) = (-1/\pi) \text{Im} \langle \langle c_{i\alpha\sigma}; c_{j\alpha\sigma}^\dagger \rangle \rangle_E$ is a symmetric function of energy for each $\alpha$.

We finally introduce the intra- and inter-layer coordination numbers $q$ and $p$ which denote the number of nearest neighbors within the same layer and in one of the two adjacent layers, respectively. We have:

\[
\begin{align*}
q &= 4, \quad p = 1 \quad \text{for sc}(100) \\
q &= 2, \quad p = 2 \quad \text{for sc}(110) \\
q &= 0, \quad p = 3 \quad \text{for sc}(111). \\
\end{align*}
\tag{9}
\]

The bulk coordination number is $Z = q + 2p$. The surface coordination number is $Z_S = q + p$.

3 Dynamical mean-field theory for surface geometries

The one-particle Green function $\langle \langle c_{i\alpha\sigma}; c_{j\beta\sigma}^\dagger \rangle \rangle$ contains any important information we are interested in. Its diagonal elements $G_\alpha(E) \equiv G_{i\alpha,i\alpha}(E) \equiv \langle \langle c_{i\alpha\sigma}; c_{i\alpha\sigma}^\dagger \rangle \rangle_E$ can be written in terms of the hopping matrix (4) and the self-energy:

$$G_\alpha(E) = \frac{1}{N_\parallel} \sum_k \left( \frac{1}{(E + \mu)1 - \epsilon(k) - \Sigma(E)} \right)_{\alpha\alpha} \quad (10).$$
The self-energy matrix is taken to be \( k \)-independent and diagonal, \( \Sigma_{\alpha\beta}(E) = \delta_{\alpha\beta}\Sigma_{\alpha}(E) \), with layer-dependent elements: We assume that the self-energy is a strictly local quantity.

In the case of an infinitely extended lattice with full translational symmetry, this basic assumption leads to the well-known equations of dynamical mean-field theory [1, 2] which self-consistently map the bulk lattice problem onto a single-impurity problem [11, 27]. The present case of reduced translational symmetry can be treated analogously: A local self-energy implies that the Luttinger-Ward functional [38] depends on the local (but layer-dependent) propagators only: \( \Phi = \Phi[... , G_{\alpha}(E), ...] \). This in turn means that the self-energy of the \( \alpha \)-th layer is solely a functional of the local propagator: \( \Sigma_{\alpha}(E) = \delta \Phi / \delta G_{\alpha}(E) = S[G_{\alpha}(E)] \). The functional \( S \) is the same as in the case of an impurity problem, e.g. the single-impurity Anderson model (SIAM), \( \Sigma_{\text{imp}}(E) = S[G_{\text{imp}}(E)] \), because the same type of skeleton diagrams occur in the expansion of the impurity self-energy \( \Sigma_{\text{imp}}(E) \). With each layer \( \alpha = 1, 2, ... \) we therefore associate a SIAM,

\[
H_{\text{imp}}^{(\alpha)} = \sum_{\sigma} \epsilon_{d}^{(\alpha)} c_{\sigma}^{\dagger} c_{\sigma} + U_{\alpha} n_{\uparrow} n_{\downarrow} + \sum_{k\sigma} \epsilon_{k}^{(\alpha)} a_{k\sigma}^{\dagger} a_{k\sigma} + \sum_{k\sigma} \left( V_{k}^{(\alpha)} a_{k\sigma}^{\dagger} c_{\sigma} + \text{H.c.} \right),
\]

with \( \epsilon_{d}^{(\alpha)} = t_{ia,\alpha} \) and where the conduction-band energies \( \epsilon_{k}^{(\alpha)} \) and hybridization strengths \( V_{k}^{(\alpha)} \) chosen such that we have

\[
\Delta^{(\alpha)}(E) = E + \mu - \epsilon_{d}^{(\alpha)} - \Sigma_{\text{imp}}^{(\alpha)}(E) - G_{\alpha}(E)^{-1}
\]

for the hybridization function \( \Delta^{(\alpha)}(E - \mu) \equiv \sum_{k}(V_{k}^{(\alpha)})^{2}/(E - \epsilon_{k}^{(\alpha)}) \). (Eq. 12) only provides an implicit definition of the hybridization function since \( \Sigma_{\text{imp}}^{(\alpha)} \) depends on \( \Delta^{(\alpha)} \). This implies at once the equality between the impurity Green function of the \( \alpha \)-th SIAM, \( G^{(\alpha)}_{\text{imp}}(E) \), and the on-site lattice Green function in the \( \alpha \)-th layer \( G_{\alpha}(E) \) and thus the equality between the respective self-energies, \( \Sigma_{\text{imp}}^{(\alpha)}(E) = S[G^{(\alpha)}_{\text{imp}}(E)] \) and \( \Sigma_{\alpha}(E) = S[G_{\alpha}(E)] \).

The following iterative procedure then allows to solve the semi-infinite Hubbard model within the dynamical mean-field approximation: Starting from a guess for the layer-dependent self-energies \( \Sigma_{\alpha}(E) \), we calculate the on-site Green function of the \( \alpha \)-th layer using Eq. (10). Via Eq. (12), \( G_{\alpha}(E) \) and \( \Sigma_{\alpha}(E) = \Sigma_{\text{imp}}^{(\alpha)}(E) \) determine the hybridization function \( \Delta^{(\alpha)}(E) \) of the \( \alpha \)-th SIAM. The crucial step consists in solving the impurity models for \( \alpha = 1, 2, ... \) to get the impurity self-energies \( \Sigma_{\text{imp}}^{(\alpha)}(E) \) which are required for the next cycle. The cycles have to be repeated until self-consistency is achieved.

Applying the DMFT to the semi-infinite Hubbard model means to map the original lattice problem onto an infinite set of impurity problems. The mapping is mediated by the self-consistency equation (12) for \( \alpha = 1, 2, ..., \infty \). For a given set of hybridization functions, each impurity model can be treated separately. There is, however, an indirect coupling via Eq. (10) in the self-consistency cycle since the on-site Green function of a given layer depends on all layer-dependent self-energies. The essential difference with respect to the case of an infinitely extended lattice with full translational symmetry where only one single-impurity model and only one self-consistency condition is needed, consists in the fact that for a semi-infinite system the sites within different layers have to be considered as non-equivalent.
4 Linearized DMFT at the critical interaction

The zero-temperature Mott transition from a paramagnetic metal to a paramagnetic insulator is actually hidden due to antiferromagnetic order which is realized in the true ground state. To study the Mott transition, the solutions of the mean-field equations have to be enforced to be spin symmetric. There have been numerous DMFT studies of the $T = 0$ Mott transition in the recent past using different methods to solve the impurity problem: the iterative perturbation theory (IPT) [11, 39, 40], the exact-diagonalization approach (ED) [28, 41, 42], the projective self-consistent method [21] as well as numerical renormalization-group calculations (NRG) [18, 19].

The IPT and, in first place, the NRG results show that for $U \rightarrow U_c$ the quasi-particle resonance at $E = 0$ is more or less isolated from the high-energy Hubbard peaks at $E \approx \pm U/2$. The resonance basically reproduces itself in the self-consistent procedure to solve the DMFT equations. A reasonable assumption is therefore that for $U = U_c$ the low-energy part of the SIAM hybridization function $\Delta^{(\alpha)}(E)$ consists of a single pole at $E = 0$ only,

$$\Delta^{(\alpha)}(E) \rightarrow \frac{\Delta^{(\alpha)}_N}{E},$$

and that the effect of the Hubbard bands can be disregarded completely. With this assumption a simplified, “linearized” DMFT becomes possible [22, 23]. There is an attractive feature of this method which outweighs the necessity for a further approximation: It allows for a fully analytic treatment of the mean-field equations, and an analytical expression for $U_c$ is obtained. Studying the dependencies of $U_c$ on the model parameters can provide a valuable first insight into the problem. The predictions of the linearized theory have been compared beforehand with fully numerical DMFT results for the Bethe and the hypercubic lattice in $D = \infty$ [22] and for the case of thin Hubbard films [23]. A satisfactory quantitative agreement has been noticed. This makes us confident that at least the correct trends can also be predicted for the case of a semi-infinite lattice.

The details of the method can be found in Ref. [22]; here we simply repeat the main idea and the final result: In the ansatz for the hybridization function (13), $\Delta^{(\alpha)}_N$ denotes the layer-dependent coefficient in the $N$-th step of the self-consistency cycle. The aim is to calculate $\Delta^{(\alpha)}_{N+1}$. The one-pole structure of the hybridization function corresponds to a well-defined SIAM with $n_s = 2$ sites which can analytically be solved for each $\alpha$. In the one-particle excitation spectrum of the $\alpha$-th SIAM there are two $\delta$-peaks at $E \approx \pm U_\alpha/2$ as well as two $\delta$-peaks near $E = 0$ corresponding to the (infinitely sharp) Kondo resonance for $U = U_c$ in the infinite ($n_s = \infty$) system. The layer-dependent weight of the resonance $z_\alpha$ can be read off from the solution. $z_\alpha$ determines the self-energy $\Sigma_\alpha(E) = U_\alpha/2 + (1 - z_\alpha^{-1})E + \cdots$ and via Eq. (11) the on-site Green function of the $\alpha$-th layer at low energies. Using these results in the self-consistency equation (12) and insisting on the one-pole structure of the hybridization function, yields a new coefficient $\Delta^{(\alpha)}_{N+1}$. At this point the possible influence of the Hubbard bands is ignored. The final equation that relates $\Delta^{(\alpha)}_{N+1}$ to $\Delta^{(\alpha)}_N$ reads:

$$\Delta^{(\alpha)}_{N+1} = \sum_{\beta} K_{\alpha\beta} \Delta^{(\beta)}_N,$$

(14)
where we have defined the following semi-infinite tridiagonal matrix:

\[ K = 36 \begin{pmatrix} q t_{11}^2 / U_1^2 & p t_{12} t / U_1 U & p t_{12} t / U_1 U \\ p t_{12} t / U_1 U & q t_{12}^2 / U^2 & p t_{12} t / U_1 U \\ p t_{12} t / U_1 U & p t_{12} t / U_1 U & q t_{12}^2 / U^2 \end{pmatrix}. \]  \hspace{1cm} (15)

A self-consistent solution of the linearized mean-field equation (14) is given by a non-trivial fixed point of \( K \). Let \( \lambda_r \) denote the eigenvalues of \( K \). We can distinguish between two cases: If \( |\lambda_r| < 1 \) for all \( r \), there is the trivial solution \( \lim_{N \to \infty} \Delta_N^{(a)} = 0 \) only. This situation corresponds to the insulating solution beyond the critical point. Contrary, if there is at least one \( \lambda_r > 1 \), \( \Delta_N^{(a)} \) diverges exponentially as \( N \to \infty \). This indicates the breakdown of the one-pole model for the hybridization function in the metallic solution below the critical point. The maximum eigenvalue thus determines via

\[ \lambda_{\text{max}} = \lambda_{\text{max}}(q, p, U, t_{11}, t_{12}, U_1) = 1 \] \hspace{1cm} (16)

the critical model parameters.

At the critical point the mean-field equation (14) can be written as

\[ z_\alpha = \sum_\beta K_{\alpha \beta} z_\beta \] since the layer-dependent quasi-particle weight \( z_\alpha \propto \Delta_N^{(a)} \). Formally, this equation can be compared with the Weiss mean-field equation for the layer magnetizations \( m_\alpha \) in the semi-infinite Ising model with coupling constant \( J \). The linearized mean-field equation for \( T = T_C \) reads:

\[ m_\alpha = \left( J/2k_B T \right)(qm_\alpha + pm_{\alpha+1} + pm_{\alpha-1}) \] (we assume the model parameters at the surface to be unmodified for the moment). The formal analogy with Eqs. (14) and (15) is obvious and justifies the identification made in Eq. (1) and the corresponding discussion in Sec. 1.

### 5 Analytical results

From the basic equation (16) we can calculate the critical parameters for different cases. First, we consider a system that is built up by a finite number of \( d \) layers (film geometry). The model parameters are taken to be uniform, i.e. \( t_{11} = t_{12} = t \) and \( U_1 = U \) (at both surfaces). The eigenvalues of the \( d \)-dimensional matrix (15) can be calculated analytically for this case [13]:

\[ \lambda_r = \frac{36 t^2}{U^2} \left( q + 2p \cos \left( \frac{r\pi}{d+1} \right) \right), \] \hspace{1cm} (17)

with \( r = 1, ..., d \). Taking the maximum eigenvalue and solving for \( U \) yields the thickness dependence of the critical interaction [23]:

\[ U_c(d) = 6t \sqrt{q + 2p \cos \left( \frac{\pi}{d+1} \right)}. \] \hspace{1cm} (18)

Expanding the result for \( U_c \) in the limit of \( d \to \infty \) yields:

\[ \frac{U_c(d) - U_c(\infty)}{U_c(\infty)} \propto d^{-\lambda_s} \] \hspace{1cm} (19)

with a “shift exponent” \( \lambda_s = 2 \).
In the limit $d = \infty$ any of the two film surfaces represents a semi-infinite system. From (18) we get for the critical interaction:

$$U_{c,\text{bulk}} = 6t \sqrt{q + 2p} = 6t \sqrt{Z},$$

(20)

which is the same result as is found when applying the method to the infinitely extended bulk system directly [22]. We notice that for the case of uniform model parameters the linearized DMFT yields a unique critical interaction for the semi-infinite system which is the same as the bulk value. No surface phase is found. This observation is fully consistent with what has been obtained in previous numerical DMFT studies of the Mott transition at Hubbard surfaces [29] for uniform parameters. Despite the fact that at the surface the electronic structure has turned out to be modified considerably, a surface critical interaction different from the bulk value has not been found.

In the following we thus concentrate on a semi-infinite system with modified parameters at the very surface. Also in this case the condition (19) can be treated analytically: To simplify the notation let us write $K_{11} = a'$, $K_{12} = K_{21} = b'$ and $K_{aa} = a$, $K_{aa \pm 1} = b$ for $\alpha \geq 2$ ($a, b, a', b' \geq 0$). Let $K(n)$ be the matrix that is obtained from the semi-infinite matrix $K = K(0)$ by deleting its first $n$ rows and columns. Furthermore, we define $G_n(\lambda) \equiv \det(\lambda I - K(n + 1)) / \det(\lambda I - K(n))$. $G_n(\lambda)$ is the $(1,1)$ or “surface” element of the Green matrix $(\lambda I - K(n))^{-1}$. Expanding the determinant $\det(\lambda I - K(n + 1))$ with respect to the upper left element, one easily verifies the recurrence relation $G_n(\lambda)^{-1} = \lambda - a - b^2 G_{n+1}(\lambda)$ for $n \geq 1$. However, all the $G_n(\lambda)$ for $n \geq 1$ must be equal since the (off-)diagonal elements of $K(n \geq 1)$ are constant. This results in a quadratic equation for $G$, the solution of which is given by:

$$G(\lambda) = G_{n \geq 1}(\lambda) = \frac{1}{2b^2} \left( \lambda - a \pm \sqrt{(\lambda - a)^2 - 4b^2} \right)$$

(21)

for $\pm(\lambda - a) > 0$. The eigenvalue spectrum of the semi-infinite matrix $K$ consists of a continuous bulk part which can be read off from Eq. (17) for $d \to \infty$ to be given by:

$$|\lambda - a| \leq 2b.$$  

(22)

This is just the region where $\text{Im} \ G(\lambda) \neq 0$. The largest eigenvalue in the bulk continuum is given by $\lambda = a + 2b$ corresponding to the bulk critical interaction given in (20). At $U = U_{c,\text{bulk}}$ the bulk undergoes the metal-insulator transition irrespective of the state of the surface.

Under certain circumstances an additional discrete (“surface”) eigenvalue $\lambda_s$ may split off the bulk continuum. If a discrete eigenvalue exists, we must have $G_0(\lambda_s)^{-1} = 0$. Using the result (21) to determine $G_0(\lambda)$ from the recurrence relation $G_0(\lambda)^{-1} = \lambda - a' - b^2 G(\lambda)$, we obtain the following equation for the eigenvalue:

$$\lambda_s - a' - b^2 \left( \frac{1}{2b^2} \left( \lambda_s - a \mp \sqrt{(\lambda_s - a)^2 - 4b^2} \right) \right) = 0.$$  

(23)

($\pm(\lambda_s - a) > 0$). Solving the equation for $\lambda_s$ yields the position of the eigenvalue in the spectrum of $K$. Since $K$ is real and symmetric, only a solution $\lambda_s$ with $\text{Im} \ \lambda_s = 0$ is meaningful; a discrete $\lambda_s$ must lie outside the bulk continuum (22). Only the maximum
eigenvalue in the spectrum is physically relevant [Eq. (16)]. Thus, we are interested in a solution that is split off the upper edge of the continuum:

\[ \text{Re } \lambda_s > a + 2b . \] (24)

Since \( b \geq 0 \) only the \( - \) sign must be considered in (23).

Whether or not the condition (24) can be met, depends on the (surface) parameters \( a' \) and \( b' \). Solving Eq. (23) for \( \lambda_s \) and inserting the solution into (24), yields the following relation for \( a' \) and \( b' \):

\[ 2b^2 + b(a - a') - b'^2 < 0 , \] (25)

which must be fulfilled to obtain a (physically relevant) surface mode. Note that the relation cannot be satisfied with uniform parameters, i.e. \( a' = a \) and \( b' = b \).

The interpretation is the following: In a semi-infinite system with surface parameters \( t_{11}, t_{12} \) and \( U_1 \) that do not obey the condition (24), there is only the “ordinary” transition from a metallic to a Mott insulating state at \( U = U_{c,\text{bulk}} \) when increasing the interaction strength. The critical interaction \( U_{c,\text{bulk}} \) is given by Eq. (20). At this point all layer-dependent quasi-particle weights \( z_\alpha \), in the bulk as well as at the surface, vanish. On the other hand, for a sufficiently strong modification of \( t_{11}, t_{12} \) or \( U_1 \), i.e. for \( a' \) and \( b' \) satisfying (25), there are two critical interaction strengths: The first one is \( U_{c,\text{bulk}} \) again. At \( U = U_{c,\text{bulk}} \) the bulk quasi-particle weight \( z_{\alpha=\infty} \) vanishes. The second critical interaction strength \( U_{c,\text{surf}} \) can be determined from \( \lambda_s = 1 \) where \( \lambda_s \) is the solution of (23). Let us assume that \( U_{c,\text{surf}} > U_{c,\text{bulk}} \). For \( U > U_{c,\text{surf}} \) the entire system is in the Mott insulating phase. For \( U_{c,\text{bulk}} < U < U_{c,\text{surf}} \), however, the bulk is a Mott insulator while the surface is still metallic. We call the transition at \( U = U_{c,\text{bulk}} \) the “extraordinary” and the transition at \( U = U_{c,\text{surf}} \) the “surface transition” in analogy with the terminology for magnetic phase transitions at surfaces [25].

The remaining question is whether or not \( U_{c,\text{surf}} < U_{c,\text{bulk}} \) can be possible. In such a situation we would have a quasi two-dimensional Mott insulator on top of a metallic bulk for interactions \( U_{c,\text{surf}} < U < U_{c,\text{bulk}} \). However, this possibility is ruled out: Eq. (24) can be rewritten as \( \lambda_s > U_{c,\text{bulk}}^2/U^2 \). Furthermore, at the critical point \( U = U_{c,\text{surf}} \) the value \( \lambda_s = 1 \) fulfills Eq. (23). But this implies \( 1 > U_{c,\text{bulk}}^2/U_{c,\text{surf}}^2 \). We can state that the linearized theory predicts that a metallic surface coexisting with a Mott insulating bulk is possible while the opposite scenario cannot be realized.

Arguing physically, if (at the Fermi edge) there is a finite (local) density of states in the second and all subsequent layers, this must always induce a non-zero, though possibly low density of states in the top layer, and thus an insulating surface phase is excluded: Consider the free-standing two-dimensional layer at an interaction strength \( U_1 \) being sufficiently strong to force the system to the insulating phase. Let the monolayer be coupled to the second and all subsequent layers by switching on the hopping between the top and the second layer \( t_{12} \neq 0 \). If \( t_{12} \) is finite but too small, the low-energy bulk excitations cannot propagate into the top layer and are reflected at the Hubbard gap. However, virtual hopping processes are possible which cause (an exponentially damped) weight of bulk excitations in the top layer. The exponential damping becomes unimportant in this case since it is effective in one layer only.

For the opposite case of a metallic surface on top of a Mott insulator, however, it does become essential: Low-energy excitations can propagate within the surface region since
Because $U > U_{c,\text{bulk}}$, they cannot propagate into the bulk but are reflected at the (bulk) Hubbard gap. While virtual processes always generate some non-zero spectral weight at the Fermi edge in each layer, the weight is infinitesimally small asymptotically, for $\alpha \to \infty$.

Since critical fluctuations spread out all over the system at a second-order critical point, different parts of a system should undergo the transition at a common and unique critical value of the external control parameter. The exponential damping of low-energy excitations over large distances explains why there can be two critical interactions. This is analogous to the case of magnetic phase transitions at surfaces: In a system where a magnetic surface coexists with a paramagnetic bulk, the layer magnetization must decay exponentially when passing from the surface to the crystal volume. Vice versa: A magnetic bulk always induces a finite magnetization in the top layer. The exception is the somehow artificial case where the top layer is completely decoupled from the rest system (e.g. $t_{12} = 0$).

### 5.1 Modified intra-layer surface hopping

Some more aspects of the metallic surface phase shall be addressed in the following. In particular, to discuss the effects of the surface geometry, we refer to the different low-index surfaces of the sc lattice mentioned above. Furthermore, it is helpful to consider the different types of surface modifications separately.

We start by considering a modified intra-layer hopping in the top layer: $t_{11} \neq t$. We have:

$$a' = \frac{t_{11}^2}{t^2} a, \quad b' = b.$$  \hfill (26)

From Eq. (25) we can deduce that there are two critical interactions provided that

$$t_{11} > t \cdot \sqrt{1 + \frac{p}{q}}.$$  \hfill (27)

According to (16) and (23), the critical interaction strength at which the surface transition takes place, is given by:

$$U_{c,\text{surf}} = 6t \cdot \sqrt{\frac{t_{11}^2}{q t_{11}^2} + \frac{p^2}{q} \frac{t^2}{t_{11}^2 - t^2}}.$$  \hfill (28)

The corresponding phase diagram is shown in Fig. [1].

For the (111) surface there is no intra-layer hopping at all ($q = 0$). A rather moderate enhancement of $t_{11}$ (about 12%) is sufficient to obtain a metallic surface phase for the sc(100) surface. In the case of the sc(110) surface a stronger modification is necessary. These trends are plausible: Obviously, for both surfaces a larger $t_{11}$ means that electrons in the top layer are more itinerant and thus tends to delay the transition to the insulating state as $U$ is increased. A smaller intra-layer coordination number $q$ counteracts this mechanism. Consequently, one needs a stronger enhancement of $t_{11}$ for the (110) surface. The $U$-range where a metallic surface coexists with an insulating bulk quickly increases as $t_{11}$ is increased. For $t_{11} \to \infty$ one would expect that the energy scales relevant for the bulk become meaningless and that the electronic structure of the top layer decouples from
Fig. 1: $t_{11}-U$ phase diagram as obtained from the linearized DMFT. For $U < U_{c,\text{bulk}}$ the system is metallic. For $U > U_{c,\text{bulk}}$ the bulk is a Mott insulator, the surface can be either insulating (left to the phase boundary) or metallic (right). Phase boundaries for the (100) and (110) surface of the sc lattice. Energy units: nearest-neighbor hopping $t = 1$. Free band width $W = 12$.

5.2 Modified inter-layer surface hopping

For a modified inter-layer hopping between the top and the sub-surface layer $t_{12} \neq t$ we have:

$$a' = a, \quad b' = \frac{t_{12}^2}{t^2} b.$$  \hspace{1cm} (29)

A metallic surface of a Mott insulating bulk is possible for

$$t_{12} > \frac{\sqrt{2}}{t} t,$$  \hspace{1cm} (30)

irrespective of the type of the surface. The critical interaction strength for the surface transition is given by:

$$U_{c,\text{surf}} = 6t \cdot \sqrt{q + \frac{t_{12}^4}{t^2} \frac{1}{\sqrt{t_{12}^4 - t^4}}}.$$  \hspace{1cm} (31)

Fig. 2 shows $U_{c,\text{surf}}$ as a function of $t_{12}$ for the different surfaces.
An enhancement of $t_{12}$ again means to enhance the itinerancy of electrons at the surface. Hopping processes between the topmost and the sub-surface layer become more likely. A modification of about 19% is sufficient to suppress the transition to the Mott insulating phase at the surface for $U > U_{c,\text{bulk}}$. The surface critical interaction strength $U_{c,\text{surf}}$ up to which the metallic surface phase persists for a given $t_{12}$, is the largest for the sc(111) surface since here the perpendicular hopping is favored by the comparatively high inter-layer coordination number $p = 3$ anyway. In the limit $t_{12} \to \infty$ the first two layers of the surface will decouple from the bulk. The surface critical interaction strength in this limit should be the same as for a bi-layer system with strongly anisotropic hopping. Consider, for simplicity, the sc(111) surface where $q = 0$. In this case all sites in the bi-layer system have the same coordination number $p$ and the bulk formula (20) may be applied accordingly. This yields: $U_{c,\text{surf}} = 6t_{12}\sqrt{p}$, which is consistent with the $t_{12} \to \infty$ limit of Eq. (31).

5.3 Modified surface Coulomb interaction

Finally, we consider a modified Coulomb interaction in the top layer, $U_1 \neq U$. In this case:

$$a' = \frac{U^2}{U_1^2} a, \quad b' = \frac{U}{U_1} b.$$  \hspace{1cm} (32)

As in the two other cases, we could fix the surface model parameters, vary $U$ and ask for the critical interaction strength $U_{c,\text{surf}}$. For the present case, however, it appears to be
more intuitive to consider the bulk $U$ to be a fixed quantity and to vary $U_1$.

For $U$ above the bulk critical interaction $U_{c,\text{bulk}}$ the bulk is a Mott insulator. The system may then become critical with respect to $U_1$, provided that

$$U_1 < \sqrt{\frac{q + p}{q + 2p}} U_{c,\text{bulk}}.$$  \hfill (33)

The surface transition takes place at $U_1 = U_{1,\text{surf}} = \sqrt{\frac{q + p}{q + 2p}} U_{c,\text{bulk}}$. Fig. 3 shows the corresponding phase diagram. For $U \rightarrow \infty$ we get $U_{1,\text{surf}} = 6t \sqrt{q}$. This is the critical interaction strength of the free-standing monolayer.

The results for modified surface Coulomb interaction can be compared with Hasegawa’s slave-boson approach [30]. Qualitatively, the respective $U-U_1$ phase diagrams for the sc(100) surface look similar. The critical interactions predicted by the slave-boson method are somewhat larger compared with the DMFT results. This is typical for the slave-boson method [5]. An important difference is found with respect to the “special transition” at the tri-critical point $U = U_{c,\text{bulk}}$, $U_1 = U_{1,c} \equiv \sqrt{(q + p)/(q + 2p)} U_{c,\text{bulk}}$. The linearized

\begin{align*}
U_{1,\text{surf}} &= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36qt^2}{2})^2 - 36^2p^2t^4}} \\
&= \sqrt{\frac{U^2 + 36qt^2}{2} - \sqrt{(\frac{U^2 - 36q...}
DMFT predicts

\[
\frac{U_{c,\text{surf}} - U_{c,\text{bulk}}}{U_{c,\text{bulk}}} \propto \left( \frac{U_1}{U_{c,\text{surf}}} - 1 \right)^{1/\phi}
\]  

(35)

for \( U_1 \mapsto U_{c,\text{surf}} \) with a “crossover exponent” \( \phi = 1/2 \). The same crossover exponent is found for modified surface hopping \( t_{11} \) or \( t_{12} \):

\[
\frac{U_{c,\text{surf}} - U_{c,\text{bulk}}}{U_{c,\text{bulk}}} \propto \left( \frac{t_{11(2)}}{t_{11(2),c}} - 1 \right)^{1/\phi},
\]

(36)

where \( t_{11,c} \) and \( t_{12,c} \) are defined by the r.h.s. of Eqs. (27) and (30), respectively. This follows from a direct calculation and can also be seen in Figs. 1, 2, and 3. Contrary, within the slave-boson theory of Ref. [30], \( U_{c,\text{surf}} \) seems to be constant as a function of \( U \), and a crossover exponent cannot be defined.

5.4 Profiles of the quasi-particle weight

The mean-field equation of the linearized DMFT, \( \Delta_{N+1}^{(\alpha)} = \sum_{\beta} K_{\alpha \beta} \Delta_{N}^{(\beta)} \), has a non-trivial solution only at a critical point for the Mott transition, e.g. at \( U = U_{c,\text{bulk}} \) or \( U = U_{c,\text{surf}} \). This solution is a fixed point of the matrix \( K \), \( \Delta_{N}^{(\alpha)} = \lim_{N \to \infty} \Delta_{N}^{(\alpha)} \), and can be calculated as the eigenvector of \( K \) belonging to the eigenvalue \( \lambda = 1 \) [Eq. (16)]. Since \( z_{\alpha} \propto \Delta_{N}^{(\alpha)} \), the eigenvector has the meaning of the critical profile of the quasi-particle weight, i.e. the \( \alpha \)-dependence of \( z_{\alpha} \) in the limit \( z_{\alpha} \mapsto 0 \). It is uniquely determined up to a normalization constant.

The upper left part of Fig. 4 shows the critical profile at the sc(100) surface for different values of \( t_{11} \) and \( U = U_{c,\text{bulk}} \) or \( U = U_{c,\text{surf}} \), respectively. \( z_{\alpha} \) has been normalized to its top-layer value \( z_1 \). For unmodified surface hopping \( t_{11} = t \), the profile is linear. In fact, the ansatz \( z_{\alpha} \propto \alpha \) solves the mean-field equation \( z_{\alpha} = \left( \frac{36t^2}{U^2} \right) (qz_{\alpha} + pz_{\alpha+1} + pz_{\alpha-1}) \) for \( U = U_{c,\text{bulk}} = 6t\sqrt{q + 2p} \). Physically, this means that at the critical interaction the surface effects extend into the bulk up to arbitrarily large distances. Note that this implies that actually an infinite number of inequivalent surface layers has to be considered in a fully numerical evaluation of the DMFT.

For \( U \) close to \( U_{c,\text{bulk}} \) but \( U < U_{c,\text{bulk}} \), one would expect that the profile converges to a finite bulk value: \( \lim_{\alpha \to \infty} z_{\alpha} = z_{\text{bulk}} > 0 \). In its present form, however, the linearized DMFT is not applicable here. One may consider the following extension [22] of the mean-field equation (for simplicity, we discuss the case of uniform model parameters, the generalization for modified surface hopping or \( U_1 \neq U \) is straightforward):

\[
z_{\alpha} = \frac{36t^2}{U^2} (qz_{\alpha} + pz_{\alpha+1} + pz_{\alpha-1}) - cz_{\alpha}^2.
\]

(37)

A quadratic term in \( z_{\alpha} \) with a constant coefficient \( c > 0 \) has been added. The constant \( c \) can be fixed by the value for \( z_{\text{bulk}} \) or for \( z_1 \) (Ref. [22] yields the explicit value \( c = 11/9 \) but we do not need the result here). This extension of the linearized DMFT is in the spirit of Landau theory, we simply consider the next term in an expansion with respect to the “order parameter” \( z_{\alpha} \). As in the Landau theory, higher-order terms in \( z_{\alpha} \) or quadratic terms that couple the different layers are still neglected. The additional term in Eq. (37)
ensures a linear $U$-dependence of the quasi-particle weight in each layer: $z_\alpha \propto (U_c - U)$ for $U \to U_c$. This is consistent with the (bulk) critical behavior found within the PSCM [21].

Using Eq. (37) we have calculated the profile of the quasi-particle weight for $t_{11} = 1$ and different $U < U_{c,\mathrm{bulk}}$; see Fig. 4 (upper right). For $U/U_{c,\mathrm{bulk}} = 0.9$ the quasi-particle weight significantly differs from the bulk value in the first few layers from the surface only. As $U \to U_{c,\mathrm{bulk}}$, however, the linear trend of $z_\alpha$ clearly develops.

A linear trend of the critical profile is also observed for slightly enhanced surface hopping, $t_{11}^2 = 1.1$ and $t_{11}^2 = 1.2$ (Fig. 4, upper left). For a surface hopping $t_{11} = \sqrt{1 + p/q} = \sqrt{5}/4$ we get the so-called special transition (cf. Eq. (27) and Fig. 1). At the critical interaction the profile is a constant (Fig. 4, upper left). In this case the effect of missing neighbors at the surface is exactly compensated by the enhancement of $t_{11}$.

For $t_{11} > \sqrt{5}/4$ there are two critical interactions, $U_{c,\mathrm{bulk}}$ and $U_{c,\mathrm{surf}}$. For $U = U_{c,\mathrm{surf}}$, $z_\alpha/z_1$ is at its maximum in the top layer and exponentially decays as $\alpha \to \infty$ (Fig. 4).
upper left). For $U < U_{c,\text{surf}}$ [according to Eq. (37)] the decay becomes slower until the profile converges to a finite bulk value for $U < U_{c,\text{bulk}}$ (lower left).

Finally, the lower right part of Fig. 4 shows the profile of the quasi-particle weight obtained from Eq. (37) for $U/U_{c,\text{bulk}} = 0.99$ and modified inter-layer surface hopping $t_{12}$. For $t_{12}^2 < \sqrt{2}$ the profile is a monotonously increasing function when passing from the surface to the bulk. $t_{12}^2 = \sqrt{2}$ marks the special transition [see Eq. (30)]. Here the profile would be constant for $\alpha \geq 2$ and $U = U_{c,\text{bulk}}$ as can be seen from the mean-field equation of the linearized DMFT. For $t_{12}^2 > \sqrt{2}$ the quasi-particle weight is enhanced at the surface and monotonously decreases for $\alpha \geq 2$.

## 5.5 Infinite dimensions

Dynamical mean-field theory rests on the local approximation for the self-energy functional. Since it is known that in the limit of high spatial dimensions $D \mapsto \infty$ the local approximation becomes exact [14], it may be interesting to discuss the (somewhat artificial) case of a surface of the infinite-dimensional hyper-cubic lattice.

A $D$-dimensional hyper-cubic lattice may be thought to be built up from $(D - 1)$-dimensional “layers” perpendicular to a $D$-dimensional spatial direction characterized by the set of Miller indices $[x_1, x_2, \ldots, x_D]$. Cutting the hopping between two adjacent layers, one obtains a “$(x_1, x_2, \ldots, x_D)$ surface”. Consider the low-index directions with $x_1 = \cdots = x_r = 1$ and $x_{r+1} = \cdots = x_D = 0$. For a given site there are $q = 2D - 2r$ nearest neighbors within the same layer and $p = r$ nearest neighbors in each of the adjacent layers ($Z = q + 2p = 2D$).

For $r = 1$, i.e. a (1000...) surface, a site in the topmost layer has $Z_S = q + p = 2D - 1$ nearest neighbors to be compared with $Z = 2D$ in the bulk. For $D \mapsto \infty$ the local environment of the surface sites is essentially the same as in the bulk, surface effects become meaningless. With the usual scaling of the hopping $t = t^*/\sqrt{2D}$ [3], the free top-layer local density of states (DOS) is a Gaussian $\rho^{(0)}(E) = \exp[-(E/t^*)^2/2]/(\sqrt{2\pi}t^*)$ as in the bulk.

For $r = D$ one obtains the open (1111...) surface. The surface coordination number is reduced to $Z_S = p = D$. This implies a ratio $\Delta_S/\Delta = Z_S/Z = (q + p)/(q + 2p) = 0.5$ between the variances of the top-layer and bulk DOS. The results of a simple numerical calculation are shown in Fig. 3. We notice a strongly modified and strongly layer-dependent DOS near the surface which slowly converges to the bulk Gaussian DOS for $\alpha \mapsto \infty$. In many respects the results resemble the DOS at the $D = 3$ sc(111) surface, in particular the oscillation of $\rho^{(0)}_\alpha(E = 0)$ as a function of $\alpha$ [45].

In infinite dimensions dynamical mean-field theory is exact also for the semi-infinite model. The scaling of the hopping implies $G^{(0)}_{ij} \sim 1/\sqrt{D}$ for the free propagator between arbitrary nearest-neighbor sites $i$ and $j$, and the proof that the self-energy is local, is essentially unchanged (see Refs. [3, 4, 14]). The simple linearized DMFT can be developed as in Sec. [4]. We only have to insert the general expressions for the coordination numbers $q = 2D - 2r$ and $p = D$, and to perform the limit $D \mapsto \infty$ in the equations (27) to (34), paying attention to the scaling of the hopping.

Varying $r$ we can then pass continuously from the most closed ($r = 1$) to the most open ($r = D$) surface geometry. Consider, for example, a modified intra-layer surface hopping. A surface phase is predicted to be existing for $t_{11}^* > t^*/\sqrt{1 + r/(2D - 2r)}$ [cf.
Fig. 5: $U = 0$ layer-dependent density of states $\rho^{(0)}_\alpha(E)$ at the (1111...) surface of the $D = \infty$ hyper-cubic lattice. Scaled hopping $t = t^*/\sqrt{2D}$ with $t^* = 1$. "1" stands for the topmost surface layer, "2" denotes the sub-surface layer, etc.

Eq. (27)); i.e. for all $t^*_{11} > t^*$ in the case of the closed $r = 1$ surface and not at all for the $r = D$ surface. For $r = 1$ the surface critical interaction is given by $U_{c,\text{surf}} = 6t^*_{11}$ [Eq. (28)] to be compared with the bulk critical interaction $U_{c,\text{bulk}} = 6t^*$ [Eq. (20)]. With increasing $r$, $U_{c,\text{surf}}$ decreases until $U_{c,\text{surf}} = U_{c,\text{bulk}}$ for $r = D$.

The other cases may be discussed accordingly. Upon taking the limit $D \to \infty$, we always obtain non-trivial and plausible results. The discussion is analogous to the $D = 3$ case. We conclude that the semi-infinite Hubbard model remains non-trivial for $D = \infty$ and provides a useful framework for investigating the surface phase. In principle, this can be done without approximations by employing the DMFT. Recall, however, that the linearized DMFT is still approximate (Sec. 4 and Ref. [22]).

6 Exact-diagonalization method

For a complete numerical solution of the mean-field equations at finite temperatures one may employ the Quantum-Monte-Carlo method [37, 46, 47]. For $T = 0$ the Exact-Diagonalization (ED) approach [28, 41, 42] can be applied and is chosen here. The main idea is to map onto a SIAM with a finite number of sites $n_s$. Lanczós technique [13] is used to calculate the ground state as well as the $T = 0$ impurity Green function and self-energy. The DMFT equations are solved on the discrete mesh of Matsubara energies where the (fictitious) inverse temperature $\tilde{\beta}$ introduces a low-energy cutoff. Details of the method can be found in Ref. [4]. The surface geometry can be simulated by a slab consisting of a finite but sufficiently large number of layers $d$ (for $U \neq U_c$). The numerical effort then increases linearly with $d$ at least. In Refs. [23, 29] we have discussed the application of ED to film and surface geometries.

ED is able to yield the essentially exact solution of the mean-field equations in a
parameter range where the errors introduced by the finite system size are unimportant. For the Mott problem the relevant low-energy scale is set by the width of the quasi-particle peak in the metallic solution. It has to be expected that there are non-negligible finite-size effects when this energy scale becomes comparatively small. We are thus limited to interactions strengths that are not too close to \( U_{c,\text{bulk}} \) or \( U_{c,\text{surf}} \) and cannot access the very critical regimes. This also implies that a precise determination of \( U_{c,\text{bulk}} \) and \( U_{c,\text{surf}} \) and thereby a direct comparison with the linearized DMFT is not possible. The discussion in Ref. [23], however, shows that the main trends can be derived safely.

In the following we mainly focus on the low-energy electronic structure which the ED method is able to predict reliably in the non-critical regimes. The so-called layer-dependent quasi-particle weight,

\[
z_{\alpha} = \left(1 - \frac{d\Sigma_{\alpha}(E = 0)}{dE}\right)^{-1},
\]

(38)
is the primary quantity of interest. \( z_{\alpha} \leq 1 \) is weight of the coherent quasi-particle peak in the local DOS \( \rho_{\alpha}(E) \) of the \( \alpha \)-th layer or, alternatively, the reduction factor of the discontinuous drops in \( \alpha \)-th momentum-distribution function \( n_{\alpha}(k) \) when \( k \) crosses the one-dimensional Fermi “surfaces” [23].

Routinely, the calculations have been performed with \( n_s = 8 \) sites in the effective impurity problems. For the fictitious temperature we have chosen \( \tilde{\beta}^{-1} = 0.0016 \, W \) (\( W = 12 \) is the free band width). \( n_s \) and \( \tilde{\beta} \) determine the “energy resolution” which is found to be about \( \Delta E = 0.12 = W/100 \). This implies that reliable results can be expected in a parameter region where \( z_{\alpha} > 0.01 \) (cf. Ref. [29]). A moderate number \( d \leq 25 \) of layers in the slab is sufficient to simulate the semi-infinite system – except for the very critical regime. This has been checked by comparing the results from calculations for different \( d \). We made use of the mirror symmetry at the center of the slab and of electron-hole symmetry to reduce the number of parameters, the conduction-band energies \( \epsilon_k \) and the hybridization strengths \( V_k \) \( (k = 2, ..., n_s) \), which have to be determined self-consistently. We always found a unique and fully stabilized solution.

7 Numerical results for the sc(100) surface

To keep the calculations manageable, we restrict the discussion to the \( D = 3 \) sc(100) surface in the following. We start with the case of uniform model parameters. Fig. 6 shows the bulk quasi-particle weight \( z \) (dashed line) as a function of \( U \). It starts from its non-interacting value \( z = 1 \). A quadratic \( U \) dependence is noticed for small \( U \) in agreement with perturbation theory [29]. \( z \) vanishes as \( U \) approaches \( U_{c,\text{bulk}} \). The overall dependence on \( U \) is very similar to what is known from DMFT studies of the \( D = \infty \) Bethe lattice [3].

In the top layer of the sc(100) surface the quasi-particle weight is significantly reduced (solid line). The lowered coordination number at the surface implies a reduced variance \( \Delta_S \) of the free surface DOS and thereby an increased effective interaction \( U/\sqrt{\Delta_S} \) compared with the bulk. Thus, at the surface correlation effects are enhanced, and \( z_{\alpha=1} \) is lowered. Despite this tendency towards an insulating surface, we find a common critical interaction \( U_{c,\text{surf}} = U_{c,\text{bulk}} \) which, for uniform parameters, is in agreement with the analytical results.
Fig. 6: $U$ dependence of the quasi-particle weight in the bulk and in the top layer for the sc(100) surface (uniform model parameters) as obtained from the ED method for $n_s = 8$. $U_{\text{c,bulk}} \approx 16.0$. $t = 1$ sets the energy scale.

$U_{\text{c,bulk}}$ also represents the critical interaction for all sub-surface layers. For the rather closed (100) surface, $z_\alpha(U)$ is almost identical with the bulk function for $\alpha \geq 2$.

From Fig. 6 we can read off $U_{\text{c,bulk}} \approx 16.0$ while Eq. (20) predicts $U_{\text{c,bulk}} = 14.7$. We have to bear in mind, however, the underlying assumptions that lead to (20). Moreover, as concerns the ED, finite-size effects prevent a precise estimate: $U_{\text{c,bulk}} \approx 15.1$ is found for $n_s = 10$ sites in the impurity models [29]. On the other hand, comparing the results for $n_s = 8$ and $n_s = 10$, there are no significant changes as long as $z_\alpha > 0.01$ [29]. This means (see Fig. 6) that the overall layer and $U$ dependence is predicted reliably. We also believe that the finding of a common critical interaction is not an artifact of the ED approach since this is made plausible by the linearized DMFT.

At the critical interaction the metallic solution continuously coalesces with the insulating solution that is found for $U > U_{\text{c,bulk}}$. The insulating solution persists down to another (common) critical interaction strength $U_{\text{c,1}} < U_{\text{c,bulk}}$ (we find $U_{\text{c,1}} \approx 11.5$). In the coexistence region, however, it is thermodynamically irrelevant. For details we refer to Refs. [5, 42, 19, 23].

### 7.1 Modified intra-layer surface hopping

A modification of the model parameters at the very surface may strongly affect the quasi-particle weight. As in Sec. 5 we first consider a modified hopping within the top layer: $t_{11} \neq t$.

Fig. 7 gives an overview for fixed Coulomb interaction $U = 10$. The above-mentioned tendency towards an insulating surface is enhanced when $t_{11}$ is decreased. The top-layer quasi-particle weight quickly decreases but even for $t_{11} = 0$ it does not vanish completely. For $t_{11} > t$ one can see the opposite trend. $z_{\alpha=1}$ increases with increasing $t_{11}$. In the limit $t_{11} \to \infty$ it approaches its non-interacting value $z_{\alpha=1} = 1$. For $t_{11} = 10t$ the low-energy
Fig. 7: Quasi-particle weight of the top layer ($\alpha = 1$) and the sub-surface layers ($\alpha = 2, 3$) for $U = 10 < U_{c,\text{bulk}}$ as a function of the modified intra-layer surface hopping $t_{11}$. $t = 1$.

Fig. 8: The same as Fig. 7 but on an enlarged scale.

electronic structure is almost perfectly decoupled. In the top surface layer there is a quasi uncorrelated motion of the electrons ($z_{\alpha=1} = 0.98$ at $U/t_{11} = 1$). The rest system, however, remains to be a strongly correlated Fermi liquid.

For the sub-surface layers, the dependence of the quasi-particle weight on $t_{11}$ is comparatively weak. Fig. 8 shows $z_\alpha$ for $\alpha \geq 2$. On the enlarged scale in Fig. 8 there is still a considerable $t_{11}$ dependence of $z_{\alpha=2}$ (second layer). For $\alpha \to \infty$, however, i. e. with increasing distance to the surface, this dependence diminishes: The bulk quasi-particle weight obviously cannot be affected by the surface modification of the hopping parameter. We also notice that there is a nearly constant quasi-particle weight for $t_{11} \approx 0.8t$ and all
For fixed $t_{11}$ one finds an oscillating layer dependence of $z_\alpha$. This is demonstrated in Figs. 9 and 10 for $t_{11} = t$ and $t_{11} = 10t$. For the strongly perturbed system with $t_{11} = 10$, the layer dependence is somehow irregular in the surface-near region, oscillations do not build up until $\alpha \geq 5$. In both cases the oscillation is strongly damped. For $\alpha = 13$ we have $\Delta z/z \approx 2 \cdot 10^{-4}$. Thus, for a film with thickness $d = 25$, the quasi-particle weight is nearly constant at the film center. Furthermore, the differences between the uniform and the perturbed system become smaller and smaller with increasing distance to the surface. The observed oscillations can be traced back to oscillations of the free layer DOS at the Fermi energy. It is well known [49] that the presence of the surface gives rise to a layer-by-layer oscillation of $\rho_\alpha(E = 0)$ for $U = 0$. For the present case (local self-energy, manifest particle-hole symmetry, metallic phase), the density of states at the Fermi edge is unrenormalized by the interaction (see Eq. (10) and Ref. [23]). The same oscillation is thus found for $\rho_\alpha(E = 0)$ at any $U < U_c_{\text{bulk}}$ and will also lead to oscillations of the low-energy part of the Green function and thereby to oscillations of the low-energy part of the self-energy. Finally, the oscillating behavior of $z_\alpha$ for $U = 10$ shows that we are well below the critical point: For $U$ close to $U_{c_{\text{bulk}}}$ we expect a monotonous behavior from the linearized DMFT (see Fig. 4).

Let us now tackle the question of surface phases. The scenario of an insulating surface coexisting with a metallic bulk was excluded by the linearized DMFT. The same is found by the numerical evaluation of the DMFT: Fig. 11 shows the layer-dependent quasi-
particle weight for $t_{11} = 0$ where the strongest suppression of $z_{\alpha=1}$ is expected. In fact, the top-layer quasi-particle weight quickly decreases as a function of $U$ and, compared with the bulk value, becomes very small above $U \approx 6$. However, we find a non-zero weight in the top layer up to $U = U_{c,\text{bulk}}$ which implies $U_{c,\text{surf}} = U_{c,\text{bulk}}$. Between $U \approx 6$ and $U = U_{c,\text{bulk}}$ we may speak of an induced metallic surface according to the discussion in Sec. 5.

The linearized DMFT predicted a metallic surface on top of a Mott-insulating bulk to be possible for $t_{11} > t\sqrt{5}/4$. We choose $t_{11} = 1.5t$ for the numerical calculation to be well above this threshold. Fig. 12 proves that two different critical interactions are found indeed. Over the whole $U$ range considered, the top-layer quasi-particle weight is strongly suppressed.
enhanced compared with the bulk and is finite also at $U = U_{c,\text{bulk}}$ where the bulk weight vanishes. Note that $z_{\alpha=1}(U)$ is continuous at $U = U_{c,\text{bulk}}$. The top-layer quasi-particle weight approaches zero at $U = U_{c,\text{surf}} = 20.0$ which marks the surface transition point while the extraordinary transition takes place at $U = U_{c,\text{bulk}} = 16.0$.

Evaluating the analytical formula for the surface critical interaction $U_{c,\text{surf}}$ for the present case, we get $U_{c,\text{surf}} = 18.2$ which agrees well with the numerical result if one takes into account that also for the bulk critical interaction the linearized theory yields a somewhat smaller value. We also expect that $U_{c,\text{surf}}$ (as $U_{c,\text{bulk}}$) is overestimated by the ED due to finite-size effects [23, 29]. While finite-size effects prevent a precise determination of
the critical interactions, they are irrelevant concerning the very existence of the metallic surface phase. Even for $U$ well above $U_{c,\text{bulk}}$, the top-layer quasi-particle weight is still larger than $z_{\alpha=1} = 0.01$, and thus the ED for $n_s = 8$ is still able to resolve the energy scale set by the width of the Kondo-type resonance at the surface.

Since the low-energy surface excitations cannot propagate into the bulk for $U > U_{c,\text{bulk}}$ but are reflected at the bulk Hubbard gap, the Kondo resonance represents a true surface state. Therefore, its amplitude must decay exponentially with increasing distance to the surface. Fig. [2] shows that some weight is induced in the sub-surface layers which rapidly decreases.

The surface transition is also found as a function of $t_{11}$ for fixed interaction $U > U_{c,\text{bulk}}$. Fig. [3] shows the numerical results for $U = 18$. When $t_{11} > t_{11,c} = 1.33t$ the surface becomes metallic. The critical value may be compared with $t_{11,c} = 1.48t$ which is obtained by solving Eqs. (16) and (23) for $t_{11}$.

For the $t_{11}$ range considered in Fig. [3], the number of layers in the slab $d$ that is necessary to simulate the actual surface can be lowered down to $d \approx 5$: We performed calculations for different thicknesses $d$; there are hardly any differences between the results for $z_\alpha$ at the surface as long as $d \geq 5$. This is interpreted as follows: Since the coherent part of the bulk spectrum has disappeared for $U > U_{c,\text{bulk}}$, the surface electronic structure is essentially decoupled from the bulk in the low-energy regime. The decoupling at the low-energy scale is indicated by the rapid decrease of $z_\alpha$ with increasing $\alpha$ (see Fig. [3]).

![Figure 14](image)

**Fig. 14:** Layer-dependent quasi-particle weight for $U < U_{c,\text{bulk}}$ as a function of the inter-layer surface hopping $t_{12} \leq t = 1$. 

27
Contrary, on the high-energy scale set by the charge excitations, bulk and surface modes cannot decouple. There is always a finite energetic overlap of the bulk and the surface DOS since $t_{11}$ mainly changes the effective widths but not the positions of the Hubbard peaks in the surface DOS. The effect of the Hubbard bands on the low-energy features, however, seems to be rather weak since otherwise a change of $d$ would lead to significant changes in the surface low-energy electronic structure by indirect coupling between low- and high-energy surface excitations and high-energy surface and bulk excitations. The surface Kondo resonance in the metallic surface phase is spatially confined to the first few layers and energetically isolated from the surface Hubbard bands.

7.2 Modified inter-layer surface hopping

A complete decoupling between the top layer and the rest system is obtained for vanishing inter-layer surface hopping $t_{12} = 0$. Fig. 14 shows the layer-dependent quasi-particle weight as a function of $t_{12}$. While for $U = 10$ we noticed an oscillating layer dependence for uniform hopping (Figs. 9 and 10), there is a monotonous layer dependence for $U = 12$ (Fig. 14, for $t_{12} = 1$). This is the typical behavior when the system is close to criticality as has been noted before (cf. Ref. [29] and the discussion of the analytical $z_\alpha$ profiles in Sec. 5). The layer dependence remains to be monotonous for $t_{12} \to 0$. For $t_{12} = 0$ we have essentially two independent systems. The isolated top layer is still metallic. In the rest system the $\alpha = 2$ layer represents the new top layer, the $\alpha = 3$ layer becomes the first sub-surface layer, and so on. This implies that the value of $z_\alpha$ for $t_{12} = 0$ must be equal to the value of $z_{\alpha-1}$ for $t_{12} = 1$. These relations are indicated by the dashed lines.

![Fig. 15: The same as Fig. 14 but for $t_{12} \geq t = 1$. Inset: asymptotic behavior of $z_\alpha$.](image-url)
in Fig. 14. They represent a non-trivial check of the numerics.

An effective separation into subsystems is also observed in the opposite limit of a strongly enhanced inter-layer surface hopping. Fig. 15 shows that $z_{\alpha}=1$ and $z_{\alpha}=2$ approach their non-interacting values while for $\alpha \geq 3$ the quasi-particle weight changes only slightly as $t_{12} \rightarrow \infty$. In the low-energy regime the electronic structure of the first two layers decouples from the rest system. The value of $z_{\alpha}$ for all $\alpha \geq 3$ approaches the value of $z_{\alpha-2}$ for $t_{12} = 1$ (see inset).

A somewhat artificial realization of an insulating surface phase on top of a metallic bulk can be obtained for $t_{12} \rightarrow 0$ by choosing $U_{c,D=2} < U < U_{c,\text{bulk}}$, where $U_{c,D=2}$ is the critical interaction of the two-dimensional layer. For $U > U_{c,D=2}$ the top layer must become
insulating when it is decoupled from the rest system ($t_{12} = 0$). This is demonstrated in Fig. [6]. The figure also shows that the top layer becomes metallic (with a very small quasi-particle weight) as soon as an arbitrarily small inter-layer hopping is switched on.

Finally, Fig. [7] shows the extraordinary and the surface transition for fixed $t_{12} = 3.0$. The surface critical interaction can be read off to be $U_{c,\text{surf}} = 23.8$ while the linearized DMFT with $U_{c,\text{surf}} = 21.7$ [Eq. (31)] again predicts a slightly smaller critical value.

7.3 Modified surface Coulomb interaction

We finally discuss the modification of the surface Coulomb interaction $U_1$. Fig. [8] shows the quasi-particle weight $z_\alpha$ for $\alpha = 1, 2, 3$ and $z_{\text{bulk}}$ as a function of $U_1/U$ where $U$ is fixed at $U = 10$. On decreasing $U_1$ ($U_1 < U$), $z_1$ quickly increases, and for $U_1 \rightarrow 0$ it approaches the non-interacting value $z_1 = 1$.

For enhanced $U_1 > U$ the top-layer quasi-particle weight is decreased but remains to be finite even for large large values of $U_1$, i.e. we again find an induced metallic surface. Asymptotically, however, the top-layer weight approaches zero: $z_1 \rightarrow 0$ for $U_1 \rightarrow \infty$. In this limit the low-energy resonance in the top-layer DOS essentially disappears and a large Hubbard gap $\sim U_1$ opens. This implies that – in the low-energy regime – the

![Layer-dependent quasi-particle weight for $U = 10 < U_{c,\text{bulk}}$ and modified Coulomb interaction in the top layer $U_1$. The arrow indicates the value of $z_{\alpha=1}$ for $U_1 = U$. In the inset the arrows indicate the $U_1 = U$ values of $z_{\alpha}$.](image)
sub-surface ($\alpha = 2$) DOS for $U_1 \mapsto \infty$ must become identical with the $U_1 = U$ surface ($\alpha = 1$) DOS. For $U_1 \mapsto \infty$ we thus expect $z_2(U_1 \mapsto \infty) = z_1(U_1 = U)$ and consequently $z_\alpha(U_1 \mapsto \infty) = z_{\alpha-1}(U_1 = U)$ for all $\alpha$. In fact, this “shift” of the surface by one layer can be seen in Fig. 18 and in the inset: For $U_1/U = 5$ only small differences still remain between $z_\alpha$ and $z_{\alpha-1}(U_1 = U)$.

The “shift” $\alpha \mapsto \alpha - 1$ also implies that the oscillating layer dependence of $z_\alpha$ for $U_1 = U$ must be reversed for $U_1 \mapsto \infty$: Minima are replaced by maxima and vice versa. This partly explains that between (at $U_1/U \approx 1.2$) the quasi-particle weight is nearly layer independent.

According to the linearized DMFT, a metallic surface on top of an insulating bulk can be found if $U_1 < 6t\sqrt{5}$ [Eq. (33)] and $U > U_{c,\text{bulk}} = 6t\sqrt{6}$. If we fix the ratio $U_1/U = 0.5$ and vary $U$, the surface transition should occur at $U_{1,c,\text{surf}} = 12.1$ (set $U = 2U_{1,c,\text{surf}}$ in Eq. (34) and solve for $U_{1,c,\text{surf}}$). The result of the numerical solution of the DMFT equations is shown in Fig. 19. Again, the numerically obtained value, $U_{1,c,\text{surf}} = 0.5 \cdot 26.3 = 13.15$, is somewhat larger than the analytical prediction – the discussion is the same as for the modified surface hopping.

At the extraordinary transition $U = U_{c,\text{bulk}}$, the quasi-particle weight in the top- (not shown in Fig. 19) and in the first sub-surface layers are smooth functions of $U$. This is contrary to the results found within the slave-boson theory [30] where the band-narrowing factor in the top layer shows up a discontinuous derivative at $U = U_{c,\text{bulk}}$. We believe, however, that this is an artifact due to incorrect boundary conditions. Namely, only the first two surface layers are treated as “free” in the self-consistent calculation while already the $\alpha = 3$ layer is assumed to be bulk-like in Ref. [30]. As is known from the mean-field theory of localized spin models [50], such boundary conditions may result in artificial singularities at the extraordinary transition.
8 Conclusion

We have investigated the (Mott) metal-insulator transition at surfaces within the framework of the semi-infinite Hubbard model at half-filling and $T = 0$. Basically, two approximations have been used:

First, the self-energy functional has been assumed to be reasonably local. This approximation sets the basis for the dynamical mean-field theory: The semi-infinite Hubbard model is self-consistently mapped onto a set of indirectly coupled impurity models corresponding to the inequivalent layers parallel to the surface. With the usual scaling of the (intra-layer and inter-layer) hopping, the approach becomes exact in the limit of infinite spatial dimensions. It has been shown that there are non-trivial surface effects even for $D = \infty$. Mainly, however, the DMFT has been used as a (mean-field) approach to study the $D = 3$ low-index surfaces of the simple-cubic lattice.

Second, for the approximate solution of the impurity models, we have used the exact diagonalization of finite systems. The ED method allows to deal systematically with a large number of geometries and model parameters. However, the method cannot access the very critical regime for the Mott transition because of errors due to finite-size effects. Directly at the critical point we have alternatively considered a simplification of the mean-field equations (linearized DMFT). This analytical approach is also approximate. However, a convincing qualitative and (as far as can be judged) also quantitative agreement with the numerical ED results has been found.

Referring to the points mentioned in the introduction, our results can be summarized as follows:

1. The metal-insulator transition in the bulk of the semi-infinite system occurs exactly at the same critical interaction $U_{c,\text{bulk}}$ as for the infinitely extended system: $U_{c,\text{bulk}} = U_c$.

2. There is a non-trivial layer dependence of the quasi-particle weight, even (asymptotically) at the critical point. The $z_\alpha$ profile strongly depends on the model parameters at the surface, e.g. the hopping within the top layer $t_{11}$, the hopping between the top and the sub-surface layer $t_{12}$ and the top-layer Coulomb interaction $U_1$. There is a qualitative change of the profile if certain critical values, $t_{11,c}, t_{12,c}$ and $U_{1,c}$, are exceeded. These critical values are found to be of a realistic order of magnitude.

3. For uniform model parameters the top-layer quasi-particle weight $z_1$ is smaller than the bulk value $z_{\text{bulk}}$ since a reduced surface coordination number implies correlation effects to be effectively stronger at the surface. For interactions well below $U_c$, there is always an oscillating layer dependence of the the quasi-particle weight. With increasing distance to the surface ($\alpha \rightarrow \infty$), this oscillation is strongly damped. In the critical regime, on the contrary, $z_\alpha$ monotonously increases with increasing $\alpha$, and finally, for $U = U_c$ the critical profile is linear: $z_\alpha \propto \alpha$. For uniform model parameters there is a finite weight in the top layer ($z_1 > 0$) for $U < U_c$ only, i.e. only when the bulk is metallic. The transition at $U_c$ is termed the “ordinary transition”.

4. For a sufficiently strong modification of the surface model parameters ($t_{11} > t_{11,c}, t_{12} > t_{12,c}, U_1 < U_{1,c}$), the surface becomes metallic below a critical interaction
$U_{c,\text{surf}} > U_{c,\text{bulk}}$ (“surface transition”). For $U_{c,\text{bulk}} < U < U_{c,\text{surf}}$, the quasi-particle weight exponentially decays from its maximum value $z_1$ at the surface towards zero in the bulk. At $U = U_{c,\text{bulk}}$ the bulk undergoes the transition to the metallic state (“extraordinary transition”). The top-layer quasi-particle weight is a smooth function of $U$ even at $U = U_{c,\text{bulk}}$.

5. The transition at $U = U_{c,\text{surf}} = U_{c,\text{bulk}}$ is called the “special transition”. Here the critical profile of the quasi-particle weight is flat $z_\alpha = z_{\text{bulk}} = \text{const.}$ (at least for $\alpha \geq 2$). In this situation the effect of missing neighbors at the surface is compensated by the change of the surface model parameters.

6. There are two critical exponents that are merely related to the critical interactions, the “shift exponent” $\lambda_s$ and the “crossover exponent” $\phi$. They describe the trend of the $U_c$ for a film of finite thickness $d$ in the limit $d \rightarrow \infty$ and the trend of the surface critical interaction for the semi-infinite system near the special transition, respectively. Within the linearized DMFT one finds $\lambda_s = 2$ and $\phi = 1/2$.

7. For any realistic choice of the model parameters, a metallic bulk induces a metallic surface with $z_1 > 0$. Thus, a Mott-insulating surface of a correlated metal is impossible. There are essentially two more or less trivial exceptions: The first is the static decoupling of the top layer for $t_{12} = 0$ at an interaction strength that is smaller than $U_{c,\text{bulk}}$ but larger than the critical interaction of the two-dimensional system. The second is a dynamical decoupling which occurs for infinite surface interaction $U_1 \rightarrow \infty$. Here the top-layer quasi-particle weight vanishes asymptotically.

[20] Also for finite temperatures the IPT results are quantitatively incorrect: Within the IPT the coexistence region \( U_{c1} < U < U_{c2} \) shrinks to a single point at a temperature \( T_{c,IPT} \). Recent QMC calculations by J. Schlipf et al. (cond-mat/9902267), however, do not show a coexistence of two solutions for temperatures down to at least 0.33 \( T_{c,IPT} \).
