Abstract. Using the Covariant Spectator Theory (CST), we have found One-Boson-Exchange (OBE) potentials that fit the 2006 world \textit{np} data below 350 MeV with a $\chi^2/N_{\text{data}}$ very close to 1, for a total of 3788 data. Our potentials have significantly fewer adjustable parameters than previous high-precision potentials, and they also reproduce the experimental triton binding energy without introducing additional irreducible three-nucleon forces.

The OBE mechanism played an important role in the long history of attempts to understand the nucleon-nucleon (NN) interaction. It is still the dominant feature in modern realistic potential models which describe the experimental observables with $\chi^2/N_{\text{data}} \approx 1$, such as the Nijmegen [1] and CD-Bonn [2] potentials. However, in order to achieve such a good fit, these potentials abandoned a pure OBE form and made several boson parameters partial-wave dependent, thereby increasing the number of adjustable parameters significantly. For instance, the best pure OBE potential of the Nijmegen group reached $\chi^2/N_{\text{data}} = 1.87$ with 15 parameters (Nijm93), while the impressive result of $\chi^2/N_{\text{data}} = 1.03$ was obtained at the expense of 41 parameters (Nijm 1). The Argonne group incorporated OBE only in the case of the pion, but also motivated their construction of otherwise largely phenomenological realistic potentials like AV18 by the apparent failure of the OBE mechanism to allow a perfect fit to the data [3].

We found that within the CST it is, in fact, possible to derive realistic OBE potentials, and that these require comparatively few parameters. This somewhat surprising finding contradicts the earlier conclusion and common belief that the OBE mechanism is missing some important feature of the NN interaction.

In CST, the $NN$ scattering amplitude is obtained from a covariant integral equation with a very similar structure to the nonrelativistic Lippmann-Schwinger equation, but with a covariant kernel in the place of the potential. A major difference, however, is the appearance of negative-energy nucleon states.

Previous CST models of the kernel, such as the models of [4] and the updated versions including off-shell couplings of scalar mesons used in [5], had been obtained by fitting the potential parameters to the Nijmegen [6] or VPI [7] phase shifts. Only in a second step the $\chi^2$ to the observables was determined. In contrast, the models presented here were fitted directly to the data. We found this a
significant improvement, because the best fit to the Nijmegen 1993 phase shifts did not yield the best fit to the 2006 database.

Our best new model, WJC-1, is based on the exchange of one isoscalar and one isovector meson in each of the pairs of pseudoscalar ($\eta, \pi$), scalar ($\sigma_0, \sigma_1$), vector ($\omega, \rho$), and axial vector ($h_1, a_1$) bosons. These exchanges already provide the most general spin-isospin structure of an $NN$ kernel, at least when the vector mesons have Dirac and Pauli couplings and external nucleons are on-shell. Except for the pions, the other boson masses are determined through the fits. The axial vector mesons are comparatively heavy, and we decided to treat them as contact interactions. Charge symmetry is broken by treating charged and neutral pions independently, and by adding a simplified one-photon-exchange interaction. The pions couple to nucleons through a mixture of PV and PS coupling. WJC-1 has the comparatively low number of 27 adjustable parameters. In order to better compare to older OBE potentials, like Nijm93, we constructed model WJC-2, which eliminates axial vector mesons and a number of other degrees of freedom, with only 15 adjustable parameters remaining. Details about the structure of the interaction models and the values of their parameters can be found in Ref. [8].

Table 1 shows the $\chi^2/N_{\text{data}}$ for our models, in comparison with previous high-precision potentials and with the Nijmegen phase shift analysis. It also shows, through the cut-off year for data included in the fits, how the $\chi^2$ increases with the growing database. Note that our result for PW A93 with the 1993 database is higher than the one of Ref. [6] because our database includes 3010 data prior to 1993 versus 2514 data used in the PW A93 fit.

The phase shifts of WJC-1 and WJC-2 are displayed in Figure 1, together with the Nijmegen phase shifts. While their overall behavior is very similar, in some cases differences of more than one degree occur, which may be significant.

We had already found in calculations with previous CST models that the $\sigma NN$ off-shell coupling strongly influences the triton binding energy [5], and that the best fit to the $NN$ data automatically also leads to the correct triton binding energy without additional three-body forces. It is remarkable to find this to be the case again, for both WJC-1 ($E_t = -8.48 \text{ MeV}$) and WJC-2 ($E_t = -8.50 \text{ MeV}$), which are after all quite different.

We conclude that the OBE concept, at least in the context of the CST where it can be comparatively easily extended to the treatment of electromagnetic

---

interactions and systems with $A > 2$, can be a very effective description of the nuclear force. Model WJC-1 provides also a new phase shift analysis, updated for all data until 2006, which is useful even if one does not work within the CST.
