Abstract Comprehensive models of stochastic, clonally reproducing populations are defined in terms of general branching processes, allowing birth during maternal life, as for higher organisms, or by splitting, as in cell division. The populations are assumed to start small, by mutation or immigration, reproduce supercritically while smaller than the habitat carrying capacity but subcritically above it. Such populations establish themselves with a probability well-known from branching process theory. Once established, they grow up to a band around the carrying capacity in a time that is logarithmic in the latter, assumed large. There they prevail during a time period whose duration is exponential in the carrying capacity. Even populations whose life style is sustainable in the sense that the habitat carrying capacity is not eroded but remains the same, ultimately enter an extinction phase, which again lasts for a time logarithmic in the carrying capacity. However, if the habitat can carry a population which is large, say millions of individuals, and it manages to avoid early extinction, time in generations to extinction will be exorbitantly long, and during it, population composition over ages, types, lineage etc. will have time to stabilise. This paper aims at an exhaustive description of the life cycle of such populations, from inception to extinction, extending and overviewing earlier results. We shall also say some words on persistence times of pop-
ulations with smaller carrying capacities and short life cycles, where the population may indeed be in danger in spite of not eroding its environment.

### 1 Introduction

From a biological viewpoint branching processes are often described as modelling the initial stage of population development, while the population is so small that it is not affected by environmental limitations, but chance events in individual life may decide the fate of the whole population. Thus, the classical Galton–Watson extinction problem emerges as the question of early extinction, and one minus the extinction probability as the establishment or invasion probability, cf. Metz et al. (1996), Dieckmann and Law (1996), Waxman and Gavrilets (2005). Classical theory also yields the Malthusian dichotomy, that populations unhampered by environmental limitations, either die out or else grow exponentially (Jagers 1975). In addition, general branching process theory provides the rate of this growth to infinity and exhibits the stabilisation of composition (Jagers 1975; Haccou et al. 2005) thus underpinning and generalising classical demographic stable population theory, but also showing that relations between individuals, like phylogenies of typical individuals, stabilise (Jagers and Nerman 1996).

It is common sense that in a finite habitat growth has its limits. These matters were first approached by simplistic macro models, like those of logistic growth. In a more sophisticated, but still deterministic, context they have been analysed through the individual based approach of structured population dynamics (Cushing 1984; Dieckmann et al. 1998, 2001; Webb 1985), generalised into adaptive dynamics, allowing also mutation and competition, matters we shall disregard here. In such a framework, it was shown that a population not dying out will stabilise at the carrying capacity. From a probabilistic aspect it is however clear that if there is realistic variation between individuals, all populations (not growing beyond all bounds) must die out (Jagers 1992), even those where there are intricate patterns of interaction, dependence loops, or external effects—exempting of course artifacts like immigration from never-ceasing sources. Essentially the sole exception is furnished by “populations” where all individuals always beget exactly one child.

The first formulations of probabilistic models with population-size-dependence are due to Klebaner (1984), whereas probabilistic formulations of adaptive dynamics have been given in Champagnat et al. (2008) and Tran (2008).

The notion of a *carrying capacity* plays a great role in biological population dynamics. It is folklore that if a virgin population does not succumb quickly, it should grow exponentially until its size approaches the capacity of the habitat. Then population size seems to stabilise, at least for the time being. Such patterns underlie many phenomena in evolutionary biology and ecology, in particular in adaptive dynamics (Champagnat et al. 2008; Geritz et al. 1998; Méléard and Tran 2009; Tran 2008; Waxman and Gavrilets 2005), just to mention a few titles in the vast literature.
In an earlier paper we studied this structure in terms of a simple but illustrative Galton-Watson type process with binary splitting (Klebaner et al. 2011). Let $K$ denote the carrying capacity and assume that the probability of an individual splitting into two is $p(z) = K/(K + z)$, if population size is $z$. Otherwise she gets no children. Clearly, the mean reproduction $2K/(K + z)$ decreases in $z$ and passes 1 precisely at the carrying capacity: the process is supercritical below and subcritical above $K$.

In a sequel (Jagers and Klebaner 2011), this toy model was rendered more realistic, by replacing binary splitting and deterministic life spans by general, population-size dependent reproduction and general life span distributions.

In such processes life-spans may be be influenced by population size, through a hazard rate $h^K_z(a)$ of an $a$-aged individual in a population of size $z$ (Not to complicate matters we mostly take life-spans to be continuous). Offspring at death (splitting) may be possible, the number of children at splitting depending upon population size $z$ as well as mother’s age $a$ at death, with expectation $m^K_z(a)$, and (female) individuals can give birth according to age-specific birth rates, $b^K_z(a)$, now to be taken as dependent on the size $z$ of the population at the time when the individual is of age $a$. What renders the thus resulting processes amenable to analysis is that they are Markovian in the age structure (Jagers 1975, p. 208).

The broadest possible framework would be completely general branching processes, supercritical below and subcritical above the carrying capacity, though some care has to be exercised in such descriptions, since the age-distribution plays a role for the fertility of the population.

We give a rigorous formulation of age- and population-size dependent processes which are Markovian in the age structure and have well defined intensities of birth and death. This framework encompasses virtually all classical population dynamics, like age-dependent branching processes as well as birth-and-death processes with age-dependent intensities, and various deterministic approaches, like age structured population dynamics. In the case of Bellman–Harris processes, where reproduction distributions are unaffected by mother’s age at death (but not of population size), conditions simplify substantially.

Thus, imagine a collection of individuals with ages $(a^1, \ldots, a^z) = A$, $z = |A|$ being the number of elements in $A$. It is convenient to regard the collection of ages $A$ as a measure

$$A = \sum_{i=1}^{z} \delta_{a^i},$$

where $\delta_{a}$ denotes the point measure at $a$. As usual, the following notation is used for a function $f$ on $\mathbb{R}$ and measure $A$:

$$(f, A) = \int f(a)A(da) = \sum_{i=1}^{z} f(a^i),$$

the right hand expression of course only if the measure is purely atomic.
For such a population, in a habitat of carrying capacity \( K \), we assume slightly more generally, that individual life and reproduction can be influenced not only by population size \( z \) but by the whole array \( A \), or some suitable aspect of it. An individual of age \( a \) thus has a random life span with hazard rate \( h_A^K(a) \). During life, she gives birth to single children with intensity \( b_A^K(a) \) at age \( a \). If she dies, she splits into a random number of children which follows a distribution that may depend upon \( A \). Its expectation is denoted by \( m_A^K(a) \) and the second moment by \( v_A^K(a) \), if the mother’s age at death was \( a \). When the carrying capacity is fixed, we often allow ourselves not to spell it out, writing \( h_A(a) \) etc. . However, what we really have in mind remains population-size-dependence, usually but not necessarily measured by the number of individuals alive, and we allow ourselves the inconsistency sometimes to suffix parameters by \( z \) rather than \( A \), or even by the “population density” \( x = z/K \).

Instead of the population size \( z = |A| = (1, A) \), we could use some other environmental load or crowding measure like \( (W, A) = \sum W(a') \), \( W(a) \) denoting the body mass or DNA content of a cell aged \( a \). Increasing \( W \) would correspond to a situation where older cells, being larger, require more of space or resources. In the deterministic literature there have been several, more or less \textit{ad hoc} choices like linear, exponential or so called von Bertalanffy growth of individual cell mass with age (Webb 1985; Chapman et al. 2007). We shall illustrate by linear growth, \( W(a) = \kappa + \lambda a \). For a stochastic approach to body mass structured population dynamics cf. O’Dwyer et al. (2009). Generally the population size could be any (additive) functional of \( (f, A) \) (Note however that a full-fledged stochastic theory should allow individual variation in the function \( W \)).

Whilst there are no deaths and no births, the population changes only by ageing. When an individual dies its point mass disappears and an offspring number of point masses at zero age appear. Similarly, when she gives birth during life a point mass appears at the origin. Thus population evolution is given by a measure-valued process \( \{A^K_t; t \geq 0\} \). Since process parameters depend upon \( K \), there is a family of such processes indexed by \( K \).

In terms of birth and death intensities and mean numbers of children at splitting, the rate of change of population size \( (f, A) \) initiated by an \( a \)-aged member should then be \( f'(a) + f(0)b_A(a) + f(0)h_A(a)m_A(a) - f(a)h_A(a) \), i.e. ageing plus bearing of newborn (zero-aged) children during life plus splitting minus death. The population as measured by \( f \) might suitably be termed \textit{strictly critical} at population configuration \( A \) if the expression vanishes. For an age-independent size measure like the number of individuals around, i.e. \( f = 1 \), \( f'(a) = 0 \), and strict criticality at \( z \) occurs if and only if \( b_z(a) + h_z(a)(m_z(a) - 1) = 0 \) for all \( a \). Another obvious criticality concept for (classical) population size could be referred to as quenched or frozen criticality: A population is \textit{frozen} critical at size \( z \) if and only if \( \mu_z(\infty) = 1 \), where \( \mu_z(da) \) denotes the expected reproduction of an individual of age \( a \) in a population of size \( z \). In terms of intensities and the corresponding life span distribution \( G_z \),

\[
\mu_z(da) = (b_z(a) + m_z(a)h_z(a))(1 - G_z(a))da.
\]

If \( b_z(a) = 0 \) identically in \( a \) and \( m_z \) is independent of age, the process reduces to a Bellman–Harris age-dependent branching process with population size dependence.
Then strict and frozen criticality coincide, and reduce to the classical condition $m_z = 1$. Similarly they coincide for birth-and-death processes. Generally, strict criticality implies frozen. A third, and fundamental, concept of criticality is that a population is **critical with respect to the age composition** $A$ if and only if

$$ (b_A + h_A(m_A - 1), A) = 0 $$

in the case of size being the number of population members, and

$$ (f' + f(0)b_A + h_A(f(0)m_A - f)), A) = 0 $$

in general. Clearly, strict criticality implies not only frozen but also age composition criticality, as defined. In the next section, we shall see that there is no trend to population change, neither to increase nor to decrease, when the population is composition critical; change is random in the sense that it has a martingale character. It is easy to check that compositional criticality for all age compositions $A$ with $|A| = z$ is the same as strict criticality at $z$. The concept of strict criticality is interesting for splitting processes, where childbirth and maternal death occur simultaneously, and for birth-and-death processes, where birth and death intensities are independent of age. For higher organisms, where there tends to be one age for reproduction and one for dying, one would prefer to work with frozen criticality or compositional with respect to age distributions $A$ in a class of limiting age distributions, as carrying capacity grows, cf. our Sect. 6.

Under fairly general assumptions, we prove first that a small population either dies out directly, without approaching the carrying capacity, or else comes close to $K$, i.e. reaches any band $[(1 - \varepsilon)K, (1 + \varepsilon)K], 0 < \varepsilon < 1$, in a time of order $\log K$. Once the population size has reached such a level, it can be expected to stay there for an exponentially long time, i.e. its expected persistence time there is $O(e^{cK})$ for some $c > 0$. Usually, such results are derived from a Large Deviation Principle yielding the time to exit from a domain of attraction of a fixed point, cf. Freidlin and Wentzell (1998). In Jagers and Klebaner (2011), we gave a proof by an exponential martingale inequality. Basically, the quick growth and fading of populations follows from a natural principle of monotonicity: if a process remains below (alternatively, above) a certain level during a time period, then it should be larger (smaller) than the similarly started classical branching process, with parameters frozen at the level in question. The long persistence time around the carrying capacity follows from the criticality there.

In the past, populations have been studied by measure-valued Markov processes with various setups, see eg. Borde-Boussion (1990), Dawson (1993), Ethier and Kurtz (1986) Section 9.4, and Champagnat et al. (2008), Métivier (1987), Oelschläger (1990), Tran (2008). We take the state space to be the finite positive Borel measures on $\mathbb{R}^+$ with the topology of weak convergence, i.e. $\lim_{n \to \infty} \mu_n = \mu$ if and only if $\lim_{n \to \infty} (f, \mu_n) = (f, \mu)$ for any bounded and continuous function $f$ on $\mathbb{R}^+$. Métivier (1987) and Borde-Boussion (1990) imbedded the space of measures into a weighted Sobolev space. Oelschläger (1990) chose the state space as the set of signed measures with yet another topology. Our model is closest to Oelschläger’s, and the French school around Méléard, cf. Champagnat et al. (2008), Tran (2008) and other papers but formu-
lated in terms of branching rather than birth-and-death processes. Like our paper, Tran (2008) allows age structure. He considers large populations, scales them, and studies the limit behaviour, obtaining in the case of fixed birth rate, no splitting, and a logistic death rate \( h_z(a) = d(a) + \eta z \) results on large deviations from a limiting process.

2 Age and population dependent processes

The basic tools in our analysis are the generator of the measure-valued Markov population process and an integral representation, known as Dynkin’s formula. An index 
\( A \) in \( \mathbb{P}_A \) and \( \mathbb{E}_A \) indicates that the population started at time \( t = 0 \) not from one newborn ancestor but rather from \( z \) individuals, of ages \( A = (a^1, \ldots , a^z) \), respectively. No index means start from some implicit age configuration. The generator of a Markov measure-valued population-age-dependent branching process was given in Jagers and Klebaner (2000). As mentioned, we switch between general and population size dependent parameters with suffixes \( A \) and \( z \), respectively: \( b_z, h_z, m_z \) and \( v_z^2 \), the latter two being the first and second moments of the number of offspring at splitting \( Y(a) \) of an individual dying at age \( a \). As pointed out, reference to the carrying capacity is suppressed, when \( K \) is fixed. The reader can easily replace population size \( z = (1, A) \) by any other measure \( (f, A) \) of size, total body mass, or environmental impact.

**Theorem 1** Jagers and Klebaner (2000) For a bounded differentiable function \( F \) on \( \mathbb{R}^+ \) and a continuously differentiable function \( f \) on \( \mathbb{R}^+ \), the limit

\[
\lim_{t \to 0} \frac{1}{t} \mathbb{E}_A \{ F((f, A_t)) - F((f, A)) \} = \mathcal{G}F((f, A)),
\]

exists, where

\[
\mathcal{G}F((f, A)) = F'((f, A))(f', A) + \sum_{j=1}^z b_z(a^j)[F(f(0) + (f, A)) - F((f, A))]
\]

\[+ \sum_{j=1}^z h_z(a^j)[\mathbb{E}_A[F(Y(a^j)f(0) + (f, A) - f(a^j))] - F((f, A))].\]

Consequently, Dynkin’s formula holds: for a bounded \( C^1 \) function \( F \) on \( \mathbb{R}^+ \) and a \( C^1 \) function \( f \) on \( \mathbb{R}^+ \)

\[
F((f, A_t)) = F((f, A_0)) + \int_0^t \mathcal{G}F((f, A_s))ds + M_t^{F,f},
\]

where \( M_t^{F,f} \) is a local martingale with predictable quadratic variation

\[
\left\langle M^{F,f}, M^{F,f} \right\rangle_t = \int_0^t \mathcal{G}F^2((f, A_s))ds - 2 \int_0^t F((f, A_s))\mathcal{G}F((f, A_s))ds.
\]
As a corollary the following representation was also obtained; see Jagers and Klebaner (2000):

**Theorem 2** For any $C^1$ function $f$ on $\mathbb{R}^+$

\[
(f, A_t) = (f, A_0) + \int_0^t (L_A f, A_s) ds + M_t^f,
\]

(2)

where the linear operators $L_A$ are defined by

\[
L_A f = f' - h_A f + f(0)(b_A + h_A m_A),
\]

(3)

and $M_t^f$ is a local square integrable martingale with the sharp bracket given by

\[
\left\langle M^f, M^f \right\rangle_t = \int_0^t (f^2(0)b_{A_s} + f^2(0)v_{A_s}^2 h_{A_s} + h_{A_s} f^2 - 2f(0)m_A h_{Z_s} f, A_s) ds.
\]

(4)

The special choice $f = 1$ yields population size $Z_s = (1, A_s)$ at time $s$ so that

\[
Z_t = Z_0 + \int_0^t (b_{Z_s} + h_{Z_s}(m_{Z_s} - 1), A_s) ds + M_t^1,
\]

(5)

provided parameters are determined by population size.

If we turn to body or DNA mass $W$, it may be noted that it (in principle) increases with age. Criticality therefore requires that the death intensity is mass or age structure dependent, reproduction parameters cannot alone regulate this. With $W(a) = \kappa + \lambda a$, $Y_t = (W, A_t)$, and $I(a) \equiv a$,

\[
Y_t = Y_0 + \int_0^t (\lambda(Z_s - (Ih_{A_s}, A_s)) + \kappa(b_{A_s} + h_{A_s}(m_{A_s} - 1), A_s)) ds + M_t^W,
\]

(6)

a quite complicated expression, in spite of the straightforward linear growth assumption. It can be slightly simplified in the cell relevant case of splitting, where the bearing term $b_{A_s} = 0$. Further, from Theorem 2.3 of Jagers and Klebaner (2000) it follows that if $f \geq 0$ satisfies the (linear growth) condition (H1)

\[
|(L_A f, A)| \leq C(1 + (f, A))
\]

(H1)

for some $C > 0$ and any $A$, and if $(f, A_0)$ is integrable, then so is $(f, A_t)$. Its expectation is bounded by

\[
\mathbb{E}[(f, A_t)] \leq \left( \mathbb{E}[(f, A_0)] + C t \right) \left( 1 + e^{C t / C} \right).
\]

(7)

We use expectation without an index to indicate that the starting age configuration $A_0$ is arbitrary and may well be random. $C$ denotes a generic constant, not necessarily
the same in different contexts. A family of functions \( f_z \) is called uniformly bounded if \( \sup_{z,a} |f_z(a)| < \infty \). The following corollary is easy to check.

**Corollary 1** Suppose that the functions \( b_z, m_z, \) and \( h_z \) are uniformly bounded. If \( f \) and \( f' \) are bounded, then the growth condition \((H1)\) is satisfied and the conclusion \((7)\) holds.

In particular, the function \( f = 1 \) satisfies \((H1)\) and so

\[
\mathbb{E}[Z_t] \leq \left( \mathbb{E}[Z_0] + Ct \right) \left( 1 + e^{Ct/C} \right). \tag{8}
\]

Further, if the functions \( v_z \) are uniformly bounded as well, then \( M^1_t \) is a square integrable martingale with the quadratic variation

\[
\left\langle M^1, M^1 \right\rangle_t \leq C \int_0^t Z_s ds. \tag{9}
\]

Similarly, it can be directly checked that the linear weight growth function \( W \) satisfies \((H1)\), so that a bounding inequality corresponding to \((8)\) holds. If there is a maximal age, so that \( W \) is bounded, the quadratic variation can also be bounded.

### 3 Extinction or growth

From now on, we consider population size, interpreted as population number, and population size dependence of demographic parameters, \( h_z, b_z, \) etc. We say that reproduction *decreases with population size* if for all \( t, z \)

\[
Z_u \leq z, u \leq t \Rightarrow Z_u \overset{d}{=} \tilde{Z}, u \leq t, \tag{10}
\]

where \( \{\tilde{Z}_t\} \) is the process with parameters frozen at \( z \) and the same starting conditions as \( \{Z_t\} \).

Following Jagers and Klebaner (2011), consider a general population-size dependent branching process with a fixed carrying capacity \( K \), as described. Let it start at time \( t = 0 \) from \( z \) individuals. To ease notation we take them all as newborn. Such a population must die out eventually Jagers (1992). What are then chances that it will reach a size in the vicinity of the carrying capacity, before extinction? We write \( T \) for the time to extinction and \( T_d \) for the time when the population first attains a size \( \geq dK, 0 < d < 1, z < dK, \) letting it equal infinity if this never occurs. Clearly,

\[
T < T_d \Rightarrow \forall t, Z_t < dK.
\]

Let units with a tilde denote entities pertaining to a population-size independent branching process with the fixed parameters \( b_{dK}, h_{dK}, m_{dK} \). Then, if reproduction decreases with population size,

\[
\mathbb{P}(T < T_d) \leq \mathbb{P}(\tilde{T} < \infty).
\]
If the initial population consists of \(z_0\) newborn individuals and \(\tilde{q}\) denotes the extinction probability of the population-size independent branching process, we can conclude that the probability of the population dying out before reaching size \(dK\) cannot exceed \(\tilde{q}z_0\).

In terms of the mean \(\tilde{m}_d > 1\) and variance \(\tilde{\sigma}_d^2\) of the total reproduction of an individual in this latter process, Haldane’s inequality yields (Haccou et al. 2005, p. 125) that the probability of the original population never reaching \(dK\) is

\[
\mathbb{P}(T < T_d) \leq \left(1 - \frac{2(\tilde{m}_d - 1)}{\tilde{\sigma}_d^2 + \tilde{m}_d(\tilde{m}_d - 1)}\right)^{z_0}.
\]

With a positive chance, the population will thus reach a size of order \(K\). Since it grows quicker than the process \(\tilde{Z}_t\) while under the level \(dK\), and the latter process grows exponentially, we can conclude that attaining \(dK\) will occur within a time of order \(\log K\).

**Theorem 3** If reproduction decreases with population size and the population is supercritical at any population size \(dK, 0 < d < 1\), then this size is attained with positive probability within a time \(T_d = O(\log K)\), as \(K \to \infty\)

4 **An era of stable size**

We proceed to investigate the population size once it has reached an interval \([K - \varepsilon K, K + \varepsilon K]\). As pointed out, it will then linger around the carrying capacity \(K\), and the property ensuring this is that the population reproduces subcritically above the level \(K\) and supercritically below. We shall first see that this forces the scaled population size to converge to one.

Define the *criticality function*

\[
\chi(z) = b_z + h_z(m_z - 1) = L_z1,
\]

in terms of the operator \(L(3)\). Then strict criticality means that \(\chi_x(a) = \chi_A(a) = 0\) for all \(a\), as soon as \(z = |A| = K\) and compositional criticality at \(A\) that \((\chi_A, A) = 0\). The superscript \(K\) is usually not spelled out and somewhat carelessly we switch between dependence on population composition, population size, and the scaled population size ("density") \(x = z/K\), writing \(\chi_x\), so that \(\chi_x = 0\) in the strictly critical case. Then compositional criticality for all age-distributions at a level implies strict, and for the next theorem we shall allow ourselves in this paper to work with a Lipschitz condition in the neighbourhood of 1, which subsumes strict criticality.

**Assumption 1** From now on the population parameters \(b_z, m_z, v_z\), and \(h_z\) are taken to be uniformly bounded. There is a constant \(C\) such that

\[
|\chi_x| = |\chi_x - \chi_1| \leq C|x - 1|.
\]
Theorem 4 Write \( X_t^K = Z_t^K / K \) for the population density. Suppose that \( \{ X_0^K \} \) is uniformly integrable and converges to 1 in probability, as \( K \to \infty \), and that Assumption 1 holds. Then, \( X_t^K \) converges in probability to 1, uniformly on any time interval \([0, T]\), \( T > 0 \). In other words, for any \( \eta > 0 \)

\[
\lim_{K \to \infty} \mathbb{P} \left( \sup_{t \leq T} |X_t^K - 1| > \eta \right) = 0.
\]

Proof By Eq. (5)

\[
X_t^K = X_0^K + \int_0^t \left( \chi_{X^K_s}, \frac{1}{K} A^K_s \right) ds + \frac{1}{K} M^{1,K}_t.
\] (13)

First we show that

\[
\lim \sup_{K \to \infty} \sup_{t \leq T} X_t^K \leq e^{CT} \text{ in probability.} \tag{14}
\]

Indeed, since the criticality function is bounded by some \( C > 0 \), and \( (1, A^K_s / K) = X^K_S \leq \sup_{u \leq s} X^K_u \),

\[
\sup_{t \leq T} X_t^K \leq X_0^K + \frac{1}{K} \int_0^T (\chi_{X^K_s}, A^K_s) |ds + \frac{1}{K} |M^{1,K}_t|
\]
\[
\leq X_0^K + \frac{1}{K} \int_0^T C (1, A^K_s) ds + \frac{1}{K} |M^{1,K}_t|
\]
\[
\leq X_0^K + \sup_{t \leq T} \frac{1}{K} |M^{1,K}_t| + C \int_0^T \sup_{u \leq s} X^K_u ds.
\]

Gronwall’s inequality in the form given in Klebaner (2005, p. 21) yields

\[
\sup_{t \leq T} X_t^K \leq \left( X_0^K + \sup_{t \leq T} \frac{1}{K} |M^{1,K}_t| \right) e^{CT}.
\] (15)

In terms of the reproduction variance \( \sigma_x^2 = v_x - m_x^2 \), the martingale quadratic variation reduces to

\[
\left( \frac{1}{K} M^{1,K}, \frac{1}{K} M^{1,K} \right)_t = \frac{1}{K} \int_0^t \left( (b_x X^K_s + \sigma_x^2 + (m_x X^K_s - 1)^2) h_{x^K_s}, \frac{1}{K} A^K_s \right) ds.
\]
Therefore, by Doob’s inequality, Assumption 1, and the convergence as well as uniform integrability of \(X^K_t\)
\[
\mathbb{P} \left( \sup_{t \leq T} \frac{1}{K} |M_t^{1,K} | > a \right) \leq \frac{1}{a^2} \mathbb{E} \left\langle \frac{1}{K} M^{1,K}, \frac{1}{K} M^{1,K} \right\rangle_T
\]
\[
\leq \frac{C}{a^2 K} \int_0^T \mathbb{E} X^K_t \, dt \leq \frac{C_1 \mathbb{E} X^K_0 + C_2}{a^2 K} \to 0,
\]
where \(C_1, C_2\) are constants, and we used (8) and (9). Hence the quadratic variation
\[
\left\langle \frac{1}{K} M^{1,K}, \frac{1}{K} M^{1,K} \right\rangle_T \to 0,
\]
as \(K \to \infty\), and
\[
\sup_{t \leq T} \frac{1}{K} M_t^{1,K} \overset{P}{\to} 0, \quad \text{as } K \to \infty.
\]

From Corollary 1,
\[
\sup_{t \leq T} |X^K_t - 1| \leq |X^K_0 - 1| + \int_0^T \left| \left( X^K_t, \frac{1}{K} A^K_t \right) \right| \, ds + \sup_{t \leq T} \frac{1}{K} |M_t^{1,K} |
\]
\[
\leq |X^K_0 - 1| + \sup_{t \leq T} \frac{1}{K} |M_t^{1,K} | + C \int_0^T \sup_{u \leq s} |X^K_s - 1| \, ds,
\]
thanks to the Lipschitz condition (12). Gronwall’s inequality (Klebaner 2005, p. 21), is there again, yielding
\[
\sup_{t \leq T} |X^K_t - 1| \leq \left( |X^K_0 - 1| + \sup_{t \leq T} \frac{1}{K} |M_t^{1,K} | \right) e^{C \sup_{t \leq T} X^K_t}.
\]
The first term converges to zero by assumption and we saw that so does the second. Relation (14) completes the proof. \(\square\)

An exponential bound on the exit time from the vicinity of \(K\) requires exponential moments of the process. Hence, we assume that the offspring distributions have exponential moments which are bounded. Then the process \(Z^K_t = (1, A^K_t)\) has exponential moments as well. Let \(\phi_A(t)(a) = \mathbb{E}_A[e^{Y(a)}]\) denote the conditional moment generating function given \(A\) of the number \(Y(a)\) of offspring at death of an \(a\)-aged individual splitting in a population with age composition \(A\). Similarly, \(\mathbb{P}_A\) denotes offspring probabilities in a population of size and composition \(A\).

The following condition (Tran 2008, Assumption 3) may seem strange at first sight, but it serves to give the process subcriticality above the carrying capacity a strict form. In it \(\phi_A(t)\) denotes the function \(\phi_A(t)(\cdot)\).
Assumption 2 For any $K$ there exists a population size $V_K > K$ such that

$$(e^{1/K} - 1)b_A + (\phi_A(1/K)e^{-1/K} - 1)h_A \leq 0, \quad \text{whenever } (1, A) > V_K,$$

and $V_K/K$ is bounded for large $K$.

Since, for large $K$

$$(e^{1/K} - 1)b_A + (\phi_A(1/K)e^{-1/K} - 1)h_A \sim \frac{1}{K}(b_A + (m_A - 1)h_A),$$

which should be negative for large $z = (1, A)$, this certainly comes forth as a natural presumption. The requirement added is that this occurs not too far away from $K$, when also the latter is large.

An example is provided by the binary splitting with $b = 0$ and $Y = Y(a)$ independently of age at split, mentioned in the Introduction and further explored in Klebaner et al. (2011): $P_A(Y = 2) = K/(K + z), z = (1, A)$. Then $V_K$ is determined from

$$\frac{z}{K + z}e^{-1/K} + \frac{K}{K + z}e^{1/K} = \mathbb{E}_z[e^{(Y-1)/K}] = 1.$$ 

Solving in $z$ gives $V_K = e^{1/K}K$.

Theorem 5 Let $X^K$ be the population size scaled by the carrying capacity $K$. Suppose that exponential moments of the offspring number at split exist and that Assumptions 1 and 2 are in force. Then, there is a constant $C$, independent of $K$, such that for any $t$

$$\mathbb{E}[e^{X^K_t}] \leq \mathbb{E}[e^{X^K_0}]e^{Ct}. \quad (16)$$

Proof Since we consider a process for fixed $K$, dependence upon the latter is suppressed in notation. The statement follows by taking $F$ in (1) as the exponential function, or rather, to be precise, by letting it equal smooth bounded functions that agree with the exponential on bounded intervals and using a localizing sequence $T_n = \inf\{t : Z_t > n\}$.

With $x = z/K$ we have

$$G(F(1, A)) = F'(((f, A))(f', A) + \sum_{j=1}^z b_A(a^j)(F(f(0) + (f, A)) - F((f, A)))$$

$$+ \sum_{j=1}^z h_A(a^j)[\mathbb{E}[F(Y_A f(0) + (f, A) - f(a^j))] - F((f, A))]$$

$$= (e^{x+1/K} - e^x) \sum_{j=1}^z b_A(a^j) + \sum_{j=1}^z h_A(a^j)\left(\mathbb{E}[e^{x+(Y_A-1)/K}] - e^x\right)$$

$$= e^x \left((e^{1/K} - 1)(b_A, A) + (\mathbb{E}[e^{(Y_A-1)/K}] - 1)(h_A, A)\right).$$

Hence we obtain by (1)

$$e^{X_t} = e^{X_0} + \int_0^t e^{X_s} \left((e^{1/K} - 1)b_A + (\mathbb{E}[e^{(Y_A-1)/K}] - 1)h_A, A_s\right)ds + M^\text{exp}_t. \quad (17)$$
where $M^\text{exp}_t$ is a local martingale. Localising and taking expectation,

$$
\mathbb{E}\left[e^{X_{T_n}}\right] = \mathbb{E}\left[e^{X_0}\right] + \mathbb{E}\left[\int_0^{T_n} e^{X_s} \left(\left(e^{1/K} - 1\right) b_{A_s} + \left(\mathbb{E}\left[e^{(Y_{A_s} - 1)/K}\right] - 1\right) h_{A_s}, A_s\right) ds\right].
$$

Now we use that the parameters $b_A$ and $h_A$ are bounded, and that the function under the integral is negative for values of $Z_s > V_K$ or $X_s > V_K/K$. For $Z_s < V_K$, the inequalities $(e^{1/K} - 1 \leq C/K$ and $|\phi^K_A(1/K)e^{-1/K} - 1| \leq C/K$ show that the integrand does not exceed $CV_K/K$.

$$
\mathbb{E}\left[e^{X_{T_n}}\right] \leq \mathbb{E}\left[e^{X_0}\right] + C\mathbb{E}\left[\int_0^{T_n} e^{X_s} ds\right],
$$

where $C$ is a constant independent of $K$, since $V_K/K$ is assumed bounded. Gronwall’s inequality, again, yields

$$
\mathbb{E}[e^{X_{T_n}}] \leq \mathbb{E}[e^{Z_0}]e^{CT},
$$

where $C$ does not depend on $K$.

Letting $n \to \infty$, we have obtained (16).

The main result on persistence time is from Jagers and Klebaner (2011).

**Theorem 6** Assume that $X^K_0 \to 1$ in probability. For any $\varepsilon > 0$, let $\tau^K = \inf\{t : |X^K_t - 1| > \varepsilon\}$. Suppose that the previous assumptions hold, and also that the number of offspring through splitting at death is bounded by some constant. Then $\mathbb{E}[\tau^K]$ is exponentially large in $K$, i.e., for some positive constants $C, c$

$$
\mathbb{E}[\tau^K] > Ce^{cK}.
$$

**Proof** We start from Eq. (13) for $X^K_t$ and recall from Corollary 1 that the predictable quadratic variation of the martingale is bounded,

$$
\left\langle \frac{1}{K} M^1, \frac{1}{K} M^1 \right\rangle_t \leq \frac{C}{K} \int_0^t X^K_s ds
$$

(19)

since the parameter functions are uniformly bounded.

In order to get an exponential moment bound for the integral $\int_0^1 X^K_s ds$, we shall use the following inequality, obtained by Jensen’s inequality for the uniform distribution on $[0, 1]$ combined with an exponential function: for any integrable function $g$ on $[0, 1]$.

$$
\int_0^1 e^{g(s)} ds \geq e^{\int_0^1 g(s) ds}.
$$

(20)
By the bound (16) for the exponential moment $\mathbb{E}[e^{X^K_s}]$,

$$
\mathbb{E}\left[e^{\int_0^1 X^K_s ds}\right] \leq \mathbb{E}\left[\int_0^1 e^{X^K_s} ds\right] \leq Ce^C,
$$

(21)

the constant $C$ generic and the final bound independent of $K$.

The next step is to establish an exponential bound for the probability of exit up to time 1, when the normed population started at $x \in (1 - \eta, 1 + \eta)$ for $\eta < \varepsilon / 6$:

$$
\mathbb{P}_x(\tau \leq 1) = \mathbb{P}_x\left(\sup_{t \leq 1} |X^K_t - 1| > \varepsilon\right) \leq e^{-CK}.
$$

To this end, write

$$
\int_0^t \left(b X^K_s + (m X^K_s - 1) h X^K_s, \frac{1}{K} A^K_s\right) ds = I^K_t.
$$

Since $X^K_0 = x$, and $|X^K_t - 1| \leq |X^K_t - x| + |x - 1| \leq \eta + |X^K_t - x|$, we have:

$$
\mathbb{P}_x\left(\sup_{t \leq 1} |X^K_t - 1| > \varepsilon\right) \leq \mathbb{P}_x\left(\sup_{t \leq 1} |I^K_t + \eta| > \varepsilon / 2\right) + \mathbb{P}_x\left(\sup_{t \leq 1} \frac{1}{K} M^K_1 > \varepsilon / 2\right)
$$

$$
\leq \mathbb{P}_x\left(\sup_{t \leq 1} |I^K_t| > 2 / 3\varepsilon\right) + \mathbb{P}_x\left(\sup_{t \leq 1} \frac{1}{K} M^K_1 > \varepsilon / 2\right)
$$

As $X^K_0 \to 1$, $X^K_t \to 1$ in probability, by Theorem 4, and consequently $\chi_{X^K_t} \to \chi_1 = 0$, all convergences taking place in probability. Hence $\left(\chi_{X^K_s}, A^K_s\right) = o(K)$. By the exponential form of Chebyshev’s inequality,

$$
\mathbb{P}_x\left(\sup_{t \leq 1} |I^K_t| > 2 / 3\varepsilon\right) \leq \mathbb{P}_x\left(\int_0^1 |(\chi_{X^K_s}, A^K_s)| ds > 2 / 3\varepsilon K\right)
$$

$$
\leq e^{-2 / 3\varepsilon K} \mathbb{E}_x\left[e^{\int_0^1 |(\chi_{X^K_s}, A^K_s)| ds}\right] = e^{-2 / 3\varepsilon K + o(K)} \leq e^{-CK}
$$

for some $C > 0$.

The second probability $\mathbb{P}(\sup_{t \leq 1} |M^K_1| > K\varepsilon / 2)$ is controlled by an exponential martingale inequality due to Chigansky and Liptser, see Chigansky and Liptser (2010) Lemma 4.2,

$$
\mathbb{P}_x\left(\sup_{t \leq 1} |M^K_1| > \varepsilon, \left|M^K_1, M^K_1\right|_1 \leq q\right) \leq 2e^{-\frac{\varepsilon^2}{2q(1+q)}},
$$

(22)
where \(k\) is a bound on the jumps of \(M^1\). In our case \(k = B\), \(B\) the maximal number of children at splitting. Hence replacing \(\varepsilon\) by \(K\varepsilon/2\), we obtain

\[
\mathbb{P}_x \left( \sup_{t \leq 1} \frac{1}{K} |M^1_t| > \varepsilon/2 \right) \leq 2e^{-\frac{\varepsilon^2 K^2/2}{2nK^2}} + \mathbb{P}_x \left( \left( \frac{1}{K} M^1, \frac{1}{K} M^1 \right)_1 > q \right) \leq Ce^{-c(\varepsilon)K},
\]

by (19), and Chebyshev’s inequality with the exponential moments (21),

\[
\mathbb{P}_x \left( \left( \frac{1}{K} M^1, \frac{1}{K} M^1 \right)_1 > q \right) \leq \mathbb{P}_x \left( \frac{C}{K} \int_0^1 X^K_s ds > q \right) \leq e^{-CK} \mathbb{E}_x \left[ e^{\int_0^1 X^K_s ds} \right] \leq Ce^{-CK},
\]

where the last inequality is by (21). The final step is a recursive argument, formulated in terms of the filtration \(\mathcal{F}_n := \sigma(\{A_t^K, t \leq n\})\):

\[
\mathbb{P}(\tau^K > n) = \mathbb{P}(\sup_{t \leq n} |X^K_t - 1| < \varepsilon)
\]

\[
= \mathbb{P} \left( \sup_{t \leq n-1} |X^K_t - 1| < \varepsilon, \sup_{n-1 \leq t \leq n} |X^K_t - 1| < \varepsilon \right)
\]

\[
\geq \mathbb{P} \left( \sup_{t \leq n-1} |X^K_t - 1| < \varepsilon, \sup_{n-1 \leq t \leq n} |X^K_t - 1| < \varepsilon, |X^K_{n-1} - 1| < \eta \right)
\]

\[
= \mathbb{E} \left[ \mathbb{P} \left( |X^K_{n-1} - 1| < \eta, \sup_{n-1 \leq t \leq n} |X^K_t - 1| < \varepsilon | \mathcal{F}_{n-1} \right) \right]
\]

\[
\geq \inf_{x \in (1-\eta,1+\eta)} \mathbb{P}_x (\sup_{t \leq 1} |X^K_t - 1| < \varepsilon) \mathbb{P}_0 (\tau > n - 1)
\]

\[
\geq \left( \inf_{x \in (1-\eta,1+\eta)} \mathbb{P}_x (\sup_{t \leq 1} |X^K_t - 1| < \varepsilon) \right)^n.
\]

So

\[
\mathbb{E}[\tau^K] > \sum_n \mathbb{P}(\tau^K > n) > \sum_n \left( \inf_{x \in (1-\eta,1+\eta)} \mathbb{P}_x (\sup_{t \leq 1} |X^K_t - 1| < \varepsilon) \right)^n
\]

\[
= \frac{1}{1 - \inf_{x \in (1-\eta,1+\eta)} \mathbb{P}_x (\sup_{t \leq 1} |X^K_t - 1| > \varepsilon)} \geq Ce^{cK}.
\]

5 A simple example with far-reaching conclusions

The main drawback of results like Theorem 6, and generally large deviations principles, is the implicitness of the constants involved. In the “bare bones” binary splitting case
(Klebaner et al. 2011), the situation is more transparent. Indeed, let each individual live for one season (=generation), begetting two children in the next with probability $K/(K+z)$, and none otherwise, if the population size is $z$. Then, the constants $C$ and $c$ in Theorem 6 can be chosen as 1 and

$$c = \frac{d(1-d)^2}{8(1+d)},$$

(23)

for any $0 < d < 1$ and any starting population size $z \geq dK$ [This corrects a misprint in the statement, without proof, of this result in Klebaner et al. (2011)].

If $d = 0.5$, say, then $c = 0.01$. Thus even a population in a habitat with a biologically small carrying capacity of say one thousand individuals, will probably persist for many generations, $e^{11.25} \approx 20,000$, if it does not die out during the first few rounds. Only with very short generation times, like one hour, for certain cells or bacteria, this will be of the magnitude a couple of years. Simulations further indicate that this approximation is excellent: biologically small carrying capacities may well be mathematically large.

By analogy, endangered more longlived species, say of a size of a couple of thousand individuals, seem not threatened by demographic stochastic fluctuations during time periods of human scales. This certainly corresponds to established beliefs, but further investigation may not be unwarranted. Anyhow, the conclusion at this stage is that real dangers rather lie in trends or in varying environments, not included in this type of models, describing unvarying carrying capacities. We intend to study randomly varying carrying capacities in a sequel paper. In the present context more pertinent questions would seem to concern population properties during the long lingering around high carrying capacities.

But first the proof (due to V. A. Vatutin) of (23).

Define $\tau^K$ as the hitting time of $dK$, in slight disagreement with earlier notation.

**Theorem 7** For any $K > 0$, $n \in \mathbb{N}$, and $z \geq dK$, $0 < d < 1$,

$$P_z(Z_1 > dK) \geq 1 - e^{-cK},$$

$$P_z(\tau^K > n) \geq (1 - e^{-cK})^n,$$

and

$$E_z[\tau^K] \geq e^{cK}$$

with $c$ as defined in (23).

**Proof** Janson’s inequality for binomial distributions (Janson 1994) tells that a binomial random variable $X$, with parameters $k$, $p$, satisfies

$$\mathbb{P}(X \leq kp - a) \leq e^{-a^2/(2kp)},$$

for any $a > 0$. Of course, the bound remains correct when the inequality $X \leq kp - a$ is multiplied by two. But with $p(z) = K/(K+z)$ and $Z_0 = z$, $Z_1 \sim 2\text{Bin}(z, p(z))$, and so
On the establishment, persistence, and inevitable…

\[ \mathbb{P}_Z(Z_1 \leq dK) = \mathbb{P}_Z(Z_1 \leq 2zp(z) - 2a) \]
\[ \leq \exp \left( -\frac{(2zp(z) - dK)^2}{8zp(z)} \right) = \exp \left( -\frac{K(f(x) - d)^2}{4f(x)} \right), \]

where \( x = z/K, f(x) = 2zp(z), \) and the constant \( a \) of Janson’s theorem is \( (2zp(z) - dK)/2 \). This is ok, since for \( 1 > d, x > d, f(x) > f(d) > d \), and therefore \( a > 0 \). Further, \( (u - d)^2/(4u) \) is an increasing function of \( u > d \) so that for \( x > d \)
\[ \frac{(f(x) - d)^2}{4f(x)} > \frac{(f(d) - d)^2}{4f(d)} = c. \]

Hence, for any \( x > d \), i.e. \( z > dK \),
\[ \mathbb{P}_Z(Z_1 \leq dK) \leq e^{-cK}, \]
as claimed.

For the second assertion,
\[ \mathbb{P}_Z(\tau^K > 1) = \mathbb{P}_Z(Z_1 > dK) \geq 1 - e^{-cK}. \]

We use induction to show that for any \( z \geq dK \) and natural number \( n \)
\[ \mathbb{P}_Z(\tau^K > n) > (1 - e^{-cK})^n. \]

By the Markov property,
\[ \mathbb{P}_Z(\tau^K > n + 1) = \mathbb{P}_Z(Z_1 > dK, \ldots, Z_{n+1} > dK) \]
\[ = \sum_{k > dK} \mathbb{P}_Z(Z_1 = k, Z_2 > dK, \ldots, Z_{n+1} > dK) \]
\[ = \sum_{k > dK} \mathbb{P}(Z_2 > dK, \ldots, Z_{n+1} > dK|Z_1 = k)\mathbb{P}_Z(Z_1 = k) \]
\[ = \sum_{k > dK} \mathbb{P}_k(\tau^K > n)\mathbb{P}_Z(Z_1 = k). \]

Induction yields that this is
\[ \geq (1 - e^{-cK})^n \mathbb{P}_Z(Z_1 > dK) \geq (1 - e^{-cK})^{n+1}, \]
as required. The last assertion follows from the relation \( \mathbb{E}[\tau^K] = \sum_n \mathbb{P}(\tau^K > n). \)

There is a corresponding assertion for the waiting time until population size leaves a band around the carrying capacity upwards:

**Theorem 8** For any \( d > 1 \) write \( c_1 = \frac{(d-1)^2}{8(d+1)}, \) Then for any \( K \) and \( z \leq dK \),
\[ \mathbb{P}_Z(Z_1 < dK) \geq 1 - e^{-c_1K}. \]
Moreover, for any $z \leq dK$

$$\mathbb{P}_{z}(\tau^K > n) > (1 - e^{-c_1 K})^n,$$

and

$$\mathbb{E}_{z}[\tau^K] > e^{c_1 K}.$$

**Proof** Since $k - \text{Bin}(k, p) \overset{d}{=} \text{Bin}(k, 1 - p)$,

$$\mathbb{P}(\text{Bin}(k, p) \geq kp + a) = \mathbb{P}(k - \text{Bin}(k, p) \leq k(1 - p) - a) = \mathbb{P}(\text{Bin}(k, 1 - p) \leq k(1 - p) - a) \leq e^{-a^2/(2k(1-p))}.$$ 

Again, the bound remains after multiplication of the inequality by 2. Thus, with $Z_0 = z$, and $2a = dK - 2zp(z)$ and $f$ as above,

$$\mathbb{P}_z(Z_1 \geq dK) = \mathbb{P}(2\text{Bin}(z, p(z)) \geq dK) = \mathbb{P}(2\text{Bin}(z, p(z)) \geq 2zp(z) + dK - 2zp(z)).$$

Now $a > 0$ is equivalent to $d - f(x) > 0$. But since $f$ increases and $x < d$, $f(x) < f(d)$, and so $f(d) < d$ as $d > 1$ now. Hence,

$$\mathbb{P}_z(Z_1 \geq dK) \leq \exp\left(-\frac{(dK - 2zp(z))^2}{8z(1 - p(z))}\right) = \exp\left(-K\frac{(d - f(x))^2}{4(2x - f(x))}\right).$$

Now, the smallest value of $d - f(x)$ provided $x < d$ is $d - f(d)$ by the monotonicity of $f$. The function $2x - f(x) = \frac{2x^2}{1+f(x)}$ is positive and increasing. Therefore its largest value in $(0, d)$ is $2d - f(d)$. Hence

$$\frac{(d - f(x))^2}{4(2x - f(x))} \geq \frac{(d - f(d))^2}{4(2d - f(d))} = \frac{(d - 1)^2}{8(d + 1)} = c_1,$$

and

$$\mathbb{P}_z(Z_1 \geq dK) \leq e^{-c_1 K}.$$ 

The rest follows as in the preceding theorem.

In our context it is leaving downwards that is crucial. It may however be worth noting that if $d = 1 \pm \epsilon$, with $0 < \epsilon < 1$, then $c < c_1$ works for both cases.
6 Stabilisation of the population composition

Thus, we turn to the long period of lingering around the carrying capacity. Will the population composition have the time to stabilise, and then how can the pseudo-stable age-distribution and other aspects of the composition be described? The age distribution was recently investigated in Hamza et al. (2013), resulting in the following two main theorems, on tightness, and convergence, respectively. The convergence of $D$ is tight in distribution was recently investigated in Hamza et al. (2013), resulting in the following stable age-distribution and other aspects of the composition be described? The age population composition have the time to stabilise, and then how can the pseudo-

Lemma 1 If $\mu^K$ is a sequence of measures such that $\mu^K/K \Rightarrow \bar{\mu}^\infty$, then $m_{\bar{\mu}^\infty} := \lim_{K \to \infty} m_{\mu^K}$ is a Lipschitz function of its argument. Similarly, $h_{\bar{\mu}^\infty}(u) := \lim_{K \to \infty} h_{\mu^K}(u)$ and $b_{\bar{\mu}^\infty}(u) := \lim_{K \to \infty} b_{\mu^K}(u)$ exist, and are Lipschitz functions of $\bar{\mu}^\infty$.

Theorem 10 In a demographically smoothly density dependent population process, the processes $\bar{A}^K$ converge weakly in the Skorokhod space $\mathcal{D}(\mathbb{R}^+, \mathcal{M}(\mathbb{R}^+))$. The limiting measure-valued process, $\bar{A}^\infty$, displays no randomness, and for any test function $f$, $\bar{A}$ satisfies the integral equation

$$ (f, A_t) = (f, \bar{A}_0^\infty) + \int_0^t (L_A^\infty f, A_s) ds, \quad (24) $$

where $A_t$ is short for $\bar{A}_t^\infty$,

$$ L_A^\infty f = f' - h_A^\infty f + f(0)(b_A^\infty + h_A^\infty m_A^\infty), $$

and infinity superscripts denote the proper limiting demographic parameters from Lemma 1.

Remark 1 Equation (24) is the weak form of the classical McKendrick–von Foerster equation for the density of $A_t$, $a(t, u)$

$$ \left( \frac{\partial}{\partial t} + \frac{\partial}{\partial u} \right) a(t, u) = -a(t, u) h_{A_t}(u), \quad a(t, 0) = \int_0^\infty m_{A_t}(u) h_{A_t}(u) a(t, u) du. $$

It can be obtained by integration by parts and the adjoint operator $L^*$,

$$ (f, A_t) = (f, A_0) + \int_0^t (f, L^*_A A_s) ds. $$

Of course, smoothness of the density must also be proved. The derivation of the equation in the present context further underpins prevailing deterministic theory.

Once the unique existence of a time limiting age distribution with a density has been established, its form follows in the usual manner from the transport equation above, letting $t \to \infty$. The derivative of $a$ with respect to time vanishes in the limit, and $h_{A_t} \to$ some $h(u)$, to be inserted in the limiting equation.

It is important to note, though, that the latter has a trivial null solution, if the population starts from a bounded number of ancestors, a mutant or a limited number of invaders, so that $\lim_{K \to \infty} |\bar{A}_0^K| = 0$. As we have seen, such populations either grow to reach a band around the carrying capacity or die out before that. It is an interesting task to describe the asymptotic age distribution at time $T^K_\delta$, as $K \to \infty$, and then the evolution of the process in a suitable evolutionary time scale that starts when the population enters a band around the carrying capacity, provided it so does.
7 The time of decay

The last stage of a population’s existence is that when it left a band around the carrying capacity, never to return. Its duration is the time to extinction $T$, from a level $x = aK$, given that the maximum of the process $\bar{Z}$ will never exceed $y = bK$, $0 < a < b < 1$, and $b$ is suitably chosen so as to avoid excessive random overshooting. Since the process is supercritical below the carrying capacity, conditioning upon a maximum value being less than $K$ implies extinction of the various concerned branching processes with frozen parameters, all supercritical. Since supercritical general branching processes, conditioned to die out, are subcritical (Jagers and Nordvall Lagers 2008), one should expect a behaviour in line with the path to extinction of large subcritical processes. For those the survival time of a $K$-sized population, $K \to \infty$, is of the form, cf. Jagers et al. (2007),

$$T = (\log K - c + \eta + o(1))/|\alpha|,$$

where $c > 0$ is a constant, $\eta$ a Gumbel distributed random variable, and $\alpha$ the (negative) Malthusian parameter of the subcritical process.

In the present case, there is no well defined Malthusian parameter, since rates vary with population size. Furthermore, extinction is only guaranteed if extinction probabilities of the frozen processes involved stay away from zero (Haccou et al. 2005; Jagers 1992), as $K$ grows. Below, $q_z = q_z(K)$ denotes the extinction probability of the process with parameters frozen at population size $z$, started from one newly born ancestor, and $m_z = m_z(K) < 1$ is the expected number of offspring per individual for $K$ given in the same population, conditioned to die out.

Before formulating the extinction time theorem, we give a lemma, of some independent interest, about subcritical Galton–Watson processes, which are regular in the sense that there is an $r > 1$ such that the process reproduction generating function $f$ satisfies $f(r) = r$. The reader may note that this always is the case for a subcritical process which is at bottom a supercritical one, but conditioned to die out. Indeed, if $q < 1$ denotes the extinction probability of the supercritical process, then the conditioned generating function $h$ will satisfy $h(s) = f(sq)/q$, so that $h(1/q) = f(1)/q = 1/q$. For a related result cf. also Lemma 3.2 of Dembo et al. (1996) (telling that the moments of the total progeny of a subcritical Galton–Watson process in random environments are finite together with the moments of its reproduction distribution).

Lemma 2 Consider a subcritical Galton–Watson process $\{\xi_n, \xi_0 = 1\}$ with the generating function $f$, $f(r) = r$ for an $r > 1$. Then, the probability generating function $g$ of the total progeny $\eta = \sum_{n=0}^{\infty} \xi_n$, $g(s) = E[s^\eta]$, will converge for some $s$, $1 < s < r$.

Proof As well established, $g$ will satisfy $g(s) = sf \circ g(s)$, $0 \leq s \leq 1$, cf. Harris (1963, 1989), Haccou et al. (2005) or any branching process monograph. It is bounded and strictly increasing on the unit interval, and so has an inverse $g^{-1}$ on $[g(0), g(1)]$, $g(0) = 0$, $g(1) = r$, since $g(1) > 1$ and $f$ has precisely two fixpoints, 1 and $r$. Clearly,

$$g^{-1}(u) = u/f(u).$$
The right hand side is defined on $[0, r]$ and increases strictly from zero to a maximum at the point $v$, $1 < v < r$ where $f(v) = \frac{v}{f(v)}$. Hence, $g$ is well defined and bounded on the interval $[0, g^{-1}(v)]$, where the right end point equals the asked for $s = v/f(v) > 1$.

**Theorem 11** Beyond earlier assumptions, in particular the monotonicity of frozen processes and the stabilisation of individual life and reproduction laws as $K \to \infty$, assume that for any $0 < d < 1, q_{4K} - q_1 = o(1/K)$ and $\lim_{K \to \infty} m_1(K) = m_1 < 1$. Let $0 < a < b(1 - m_1), b < 1$. Consider the process, started at a $K$ and write $\tilde{Z}$ for its maximum. Then, as $K \to \infty$, $T|\tilde{Z} \leq bK = O(\log K)$.

**Proof** On the same probability space we define processes $Z^{(k)}$, all sharing starting size with $Z$, but parameters frozen at the population size $k$. This can be so done that, for all $t$, $Z_t^{(y)} \leq Z_t \leq Z_t^{(1)}$ on the set where $\tilde{Z} \leq y$, and also $Z_0^{(y)} = Z_0 = Z_0^{(1)} = x$. We write $Q^{(k)} = \{Z^{(k)} \to 0\}$ and $T^{(k)}$ for the corresponding (possibly infinite) extinction times. Bars indicate process maxima throughout,

$$\mathbb{P}(T \leq t, \tilde{Z} \leq y) = \mathbb{P}(Z_t = 0, \tilde{Z} \leq y) \geq \mathbb{P}(Z_t^{(1)} = 0, \tilde{Z}^{(1)} \leq y)$$

$$= \mathbb{P}(Z_t^{(1)} = 0, \tilde{Z}^{(1)} \leq y; Q^{(1)}) = \mathbb{P}(Z_t^{(1)} = 0; Q^{(1)})$$

$$\geq \mathbb{P}(Z_t^{(1)} = 0; Q^{(1)}) - \mathbb{P}(\tilde{Z}^{(1)} > y; Q^{(1)}).$$

But $\mathbb{P}(\tilde{Z}^{(1)} > y; Q^{(1)}) = \mathbb{P}(\tilde{Z}^{(1)} > y|Q^{(1)})\mathbb{P}(Q^{(1)})$. Now, if $\{Z_t^{(1)}\}$ were a Galton Watson process, we could conclude from Lindvall (1976), $q_1 = \mathbb{P}_1(Q^{(1)})$, that

$$\mathbb{P}\left(\tilde{Z}^{(1)} > y|Q^{(1)}\right) \leq \frac{q_1^{y-x} - q_1^y}{1 - q_1^y} = O\left(q_1^{y-x}\right), \quad (25)$$

tending to zero for $K \to \infty$, if $x = aK, y = bK, 0 < a < b < 1$ without further ado.

In the general case, many generations can overlap and we can only assert that the maximum of a subcritical process cannot exceed the total progeny $Y^1$ of the ancestors, which in its turn is the sum of the i.i.d. total progenies of each of the ancestors, to be denoted by $\eta_i$, and of course coinciding with the total progenies of the embedded Galton-Watson processes. However, by the lemma above, we know that these have all moments finite. In particular $\mathbb{E}[\eta_i] = 1/(1 - m_1(K)) \to 1/(1 - m_1)$, by the stabilisation of processes, as $K \to \infty$. The law of large numbers (or central limit theorem) applies to show that

$$\mathbb{P}_x\left(\tilde{Z}^{(1)} > y|Q^{(1)}\right) \leq \mathbb{P}\left(\sum_{i=1}^x \eta_i > y\right) = \epsilon_K \to 0, \quad (26)$$

precisely under the stated conditions.
Further,
\[ P(\bar{Z} \leq y) \leq P(Q^{(y)} \leq y) = P(Q^{(y)}(1 - P(\bar{Z}^{(y)} > y|Q^{(y)})) \leq q_y^x. \]

In other words,
\[ P(T \leq t|\bar{Z} \leq y) \geq q_1^y (P(T^{(1)} \leq t|Q^{(1)}) - \epsilon_K)/q_y^x, \]

where we keep in mind that \( x = aK, y = bK \), the starting point \( x \) is subsumed, and extinction probabilities also depend upon \( K \). Since
\[ \left( \frac{q_1}{qbK} \right)^aK \rightarrow 1, \]
as \( K \rightarrow \infty \), we can conclude that asymptotically \( T = O(\log K) \).

Acknowledgments This research has been supported by the Australian Research Council Grant DP120102728. We thank the handling editor and referees for ideas for further work, in particular on forms of periodicity during the lingering stage and on more realistic types of criticality in crowded environments.
