\textbf{Abstract}
\underline{Background:} Peanut allergy develops after primary sensitization to peanut allergens and/or IgE cross-sensitization with homologous allergens from various plants. Therefore, heterogeneous patterns of sensitization to individual peanut allergens are observed in different countries. The aim of this study was to examine the IgE sensitization patterns of Austrian peanut-allergic patients.

\underline{Methods:} Sera from 65 peanut-allergic patients and 20 peanut-tolerant atopics were obtained in four Austrian allergy clinics. Sensitization patterns against peanut allergens Ara h 1–3, 6, 8 and 9 were identified by ImmunoCAP and ImmunoCAP ISAC.

\underline{Results:} Austrian peanut-allergic patients were sensitized to Ara h 2 and 6 (71%), followed by Ara h 1 (62%), Ara h 8 (45%), Ara h 3 (35%) and Ara h 9 (11%). All sera containing Ara h 2-specific IgE were also positive for Ara h 6, with Ara h 6-specific IgE levels significantly ($p < 0.05$) higher compared with Ara h 2. Twelve percent displayed IgE reactivity exclusively to Ara h 8. Peanut extract and Ara h 8 showed low diagnostic specificities of 25 and 10%, respectively. The other peanut allergens showed 100% specificity. Diagnostic sensitivities determined by ImmunoCAP ISAC and ImmunoCAP were highly similar for Ara h 2, 3 and 8. \underline{Conclusions:} The majority of symptomatic peanut-allergic patients are sensitized to Ara h 2 and Ara h 6. In peanut-symptomatic patients with additional birch pollen allergy, other peanut allergens, especially Ara h 8, should be tested when IgE reactivity to Ara h 2 is absent.

\underline{Introduction}
By using component-resolved diagnosis (CRD) heterogeneous patterns of sensitization to peanut allergens have been reported across different areas of the world. Furthermore, marked differences in the allergen recognition profiles could be related to distinct clinical manifestations of peanut allergy. The peanut seed storage proteins Ara h 1, Ara h 2, Ara h 3 and Ara h 6 are largely recognized...
as the major allergens in patients who are primarily sensitized to peanut. Among them, Ara h 2 has been described as the most important peanut allergen, with a sensitization rate of 42–100% depending on the study population, whereas the sensitization rate to Ara h 1 and Ara h 3 is lower, in the range of 30–80 and 16–61%, respectively [1–6]. The diagnostic value of Ara h 6, which has only recently become available on ImmunoCAP ISAC, has been shown to be equivalent to Ara h 2 with a positive predictive value of 95% [7]. Although only Ara h 2 is considered as a predictor of clinical reactivity to peanut [8–10], polysensitization to Ara h 2 and Ara h 1 and/or Ara h 3 appeared to be predictive of more severe reactions [11–13].

Ara h 8, a homologue of the major birch pollen allergen Bet v 1, and Ara h 5, a profilin, are mostly involved in pollen-associated peanut allergy due to cross-reactivity with their homologues in birch and grass pollen. Consequently, high sensitization rates to Ara h 8 were primarily found in patients allergic to Fagales tree pollen such as birch in Central and Northern Europe (65–70%) [2, 3, 5] or alder in Japan (42%) [6]. Ara h 8 sensitization usually indicates tolerance to peanuts or occasionally only causes mild oral symptoms [14]. Sensitization rates to profilin among peanut-sensitized patients were reported to be 3.3% in the USA, 9–16% in Northern and Central Europe, and 24% in Spain [5, 11].

The nonspecific lipid-transfer protein Ara h 9 is involved in the so-called nsLTP-syndrome, mainly in peach-allergic patients from the Mediterranean area, but also in some nsLTP-sensitized patients from Central Europe [5]. A recent study showed that asymptomatic peanut-sensitized children from sub-Saharan Africa had IgE almost exclusively specific to cross-reactive carbohydrate determinants (CCDs) induced by glycoproteins from parasitic Schistosoma species [15].

Although the oral food challenge is considered to be the most accurate test for the diagnosis of peanut allergy, evaluating IgE binding to individual peanut allergens provides additional diagnostic information over peanut extract testing, such as the differentiation of IgE binding to allergens predictive of clinically relevant peanut sensitization or to cross-reactive peanut allergens with a smaller risk of severe reactions [16].

To date, no information regarding CRD and clinical characteristics of peanut-allergic patients in the Austrian population has been available. Therefore, we investigated the profile of IgE antibody responses from peanut-allergic patients to individual peanut allergens and compared them with the IgE response to total peanut allergen extract. Furthermore, CRD results obtained by traditional singleplexed ImmunoCAP were compared with those obtained by the multiplexed ImmunoCAP ISAC microarray technology.

**Methods**

**Study Population**

Serum samples from 65 patients (33 adolescents/adults and 32 children) with a convincing clinical history of peanut allergy and 20 peanut-tolerant atopic patients were evaluated in this study. Subjects were enrolled in four Austrian specialized outpatient allergy clinics. Peanut allergy was assessed based on the combination of a clinically convincing history and sensitization to peanut (positive skin prick test or positive sIgE to peanut). Symptoms suggestive of allergy were classified into groups according to Sampson et al. [17]. Two of the patients had no detectable peanut-specific IgE but a positive clinical history of peanut allergy. An additional control group consisted of 8 nonatopic subjects. At the time of inclusion, all control patients indicated consuming peanut regularly without allergic symptoms. Ethical approval was obtained by the respective institutional review boards and signed informed consent was obtained from the patients. The clinical data and demographic and clinical characteristics of the two groups are summarized in Table 1.

**Serological Analysis**

All sera were subjected to allergen-specific IgE determination using the ImmunoCAP and ImmunoCAP ISAC 112 according to the manufacturer’s recommendations. Total IgE, peanut extract-specific IgE and IgE reactivity to individual peanut individual allergens rAra h 1, rAra h 2, rAra h 3, rAra h 8 and rAra h 9 were tested using the ImmunoCAP system (Thermo Fisher Scientific, ImmunoDiagnostics, Uppsala, Sweden). The measuring range was between 0 and 100 kU/l. IgE antibody concentration >100 kU/l were assigned the value of 100 kU/l for statistical evaluations. At the time of the study, the ImmunoCAP ISAC microarray contained 112 allergens, including the following peanut allergens: rAra h 1, rAra h 2, rAra h 3, rAra h 6, rAra h 8 and rAra h 9. MUXF1 was used as a marker of sensitization to CCDs and Phl p 12, and Bet v 2 as markers of profilin sensitization. IgE levels >0.35 kU/l for the ImmunoCAP and >0.3 ISU-E for the ImmunoCAP ISAC were considered positive.

**Statistics**

The nonparametric Wilcoxon rank-sum test was applied to compare the distributions of unpaired scale variables. Accordingly, the Wilcoxon signed-rank test was used in paired situations. Correlations were calculated by the Spearman’s rank correlation coefficient. Absolute coefficients >0.5 were considered to be moderate and >0.7 as strong correlation. p values <0.05 were considered significant. Fisher’s exact test was employed to compare groups with binary outcome (anaphylaxis/no anaphylaxis) and low frequencies. Sensitivities were calculated as TP/(TP + FN), where TP is the number of true positives (patients with peanut allergy and positive CAP/ISAC results) and FN is the number of false negatives (patients with peanut allergy and negative CAP/ISAC results). Specificities were calculated as TN/(TN + FP), where a true negative (TN) result is defined as a patient without a reported peanut allergy and negative CAP/ISAC results, and a false positive
(FP) as a patient without peanut allergy but with positive CAP/ISAC. The range is a measure of dispersion and is calculated by subtracting the minimum from the maximum value. Data analysis was performed using SPSS (SPSS Inc., Chicago, Ill., USA).

Results

Patient Characteristics

The study population, comprising 65 Austrian peanut-allergic patients, included 33 adults (mean age 29.6 ± 11.5 years) and 32 children (mean age 7.4 ± 2.9 years). There was a female predominance in adults and a male predominance in children. Table 1 summarizes the patients’ demographical and clinical characteristics. All 65 patients were sensitized to one or more aeroallergen source, such as birch and grass pollen, house dust mite or animal dander. In addition to peanut allergy, patients had allergy to hazelnut (37%), soy (17%), other nuts, such as almond, walnut and/or cashew (14%), apple (11%) and sesame seeds (6%). Ten patients reported symptoms after exposure to peanut localized to the oral

Values are presented as n (%) or mean ± SD, unless otherwise indicated.
cavity (itching lips, throat and face), 24 patients had gastrointestinal symptoms (abdominal pain, diarrhea, vomiting) or other systemic reactions (e.g. urticaria, angioedema, dyspnea). Of 65 patients with clinical signs of peanut allergy, 31 fulfilled the criteria of anaphylaxis (i.e. skin symptoms and involvement of the respiratory and/or gastrointestinal tract) following the consumption of traces of peanut. Of those, 11 had asthma, 20 were also sensitized to other food and 28 to inhalant allergen sources. No anaphylactic reactions to foods other than peanut were reported in the history. However, most of the patients with peanut-induced anaphylaxis were also sensitized to birch and/or grass pollen with clinical symptoms of pollen allergy. In addition, 20 peanut-tolerant atopic controls with a mean age of 32.5 ± 9.5 years were included. Three patients had allergy exclusively to birch pollen, 5 patients had both birch and grass pollen allergy and 12 patients had additional house dust mite and/or animal dander allergy in addition to birch and grass pollen allergy. Nine patients experienced Bet v 1-related oral allergy syndrome (OAS) to apple (35%), hazelnut (15%), soy or carrot (5% each).

Performance of Two Commercially Available in vitro Techniques, ImmunoCAP and ImmunoCAP ISAC, in the Diagnosis of Peanut Allergy

Conventional ImmunoCAP analysis detected peanut extract specific-IgE in 63 (97%) peanut-allergic patients and in 15 (75%) atopic controls, resulting in high sensitivity but low specificity of the commercial ImmunoCAP peanut extract. Nevertheless, the control group showed significantly lower levels (p < 0.001) of peanut-specific IgE at a mean level of 1.7 kU/L (range 6.0) compared with the peanut-allergic group with a mean level of 32.7 kU/L (range 99.6; table 3). Peanut-allergic children had higher peanut-specific IgE levels than peanut-allergic adults (mean 38.3 kU/L, range 99.6 vs. mean 27.0 kU/L, range 99.3).

Peanut-specific IgE, as quantified by traditional ImmunoCAP, was moderately but significantly correlated (p < 0.01) with IgE specific to Ara h 1 (CAP: r = 0.63 and ISAC: r = 0.55), Ara h 2 (CAP: r = 0.66 and ISAC: r = 0.63), Ara h 3 (CAP: r = 0.67 and ISAC: r = 0.65) and Ara h 6 (ISAC: r = 0.64). No correlation between peanut-specific IgE and IgE specific to Ara h 8 or Ara h 9 was observed.

A high degree of correlation was demonstrated when comparing the ISAC and CAP data among each other for all 5 peanut allergen components, with particularly high correlation coefficients in the cases for Ara h 2 (r = 0.95), followed by Ara h 1 (r = 0.93), Ara h 8 (r = 0.91) and Ara h 3 (r = 0.86; fig. 1; table 2). A weaker, although still significant correlation between the two methods was detected for Ara h 9 (r = 0.65). All correlations were significant at the 0.01 level. None of the sera from nonatopic controls reacted with either the extract or with individual peanut allergens tested by ImmunoCAP and ImmunoCAP ISAC.

Specific IgE was detected against at least one of the five tested peanut allergens by ImmunoCAP (Ara h 1, Ara h 2, Ara h 3, Ara h 8 and Ara h 9) in 62 of 65 (95%) sera of patients with peanut allergy. Sera of 59 (91%) peanut-allergic subjects contained specific IgE against at least one of the six peanut allergens by ImmunoCAP ISAC and of 62 (95%) when sera containing Phl p 12 or MUXF3-specific IgE as markers of sensitization to profilin or CCDs were included. The high diagnostic sensitivity was however not accompanied by diagnostic specificity, as all sera from peanut-tolerant patients recognized pollen-associated allergens such as Ara h 8 (95%) and/or Phl p 12 and CCDs.

All peanut-tolerant but birch pollen-allergic subjects had IgE specific for Ara h 8 with a mean of 9.3 versus 11.2 ISU-E for peanut-allergic subjects, resulting in very low specificity for this allergen. All sera containing Ara h 8-specific IgE also had Bet v 1-specific IgE and the levels of IgE strongly correlated with those against Bet v 1 (r = 0.82, p < 0.01). A diagnostic specificity of 100% and a sensitivity of 72% were observed for the related peanut seed storage protein allergens, Ara h 1, Ara h 2, Ara h 3 and Ara h 6 as no IgE was detected in sera of control individuals (table 3).
Recognition Patterns of Specific IgE to Individual Peanut Allergens

The frequencies of sensitization and means of IgE levels for individual peanut allergens tested by ImmunoCAP and ImmunoCAP ISAC are shown in Table 2. Due to high qualitative correlation between the two assays, the allergen sensitization patterns (Fig. 2) and diagnostic sensitivities and specificities of individual peanut allergens are only shown for data obtained by ImmunoCAP ISAC (Table 3).

Peanut-allergic patients were mainly sensitized to Ara h 2 and Ara h 6 (71% for both), followed by Ara h 1 (62%) and Ara h 8 (45%). IgE reactivity to Ara h 3 was found in 35% and to Ara h 9 in 11% of peanut-allergic patients. In addition to Ara h 8, the two other pollen allergy-associated allergens, Phl p 12 and CCDs, were recognized by 22 and 31%, respectively. Both peanut-allergic patients with a positive history but negative peanut-specific IgE were sensitized to Ara h 8.

Polysensitization to more than 3 allergens was observed for 72% of patients and monosensitization to Ara h 8 was observed in 4 patients. Three patients were sensitized exclusively to Ara h 2 and Ara h 6. All sera containing Ara h 2-specific IgE were also positive for Ara h 6 and Ara h 8.
Table 3. CRD analysis performed by ImmunoCAP ISAC: positive subjects and levels of peanut extract-specific and allergen-specific IgE in peanut-allergic and peanut-tolerant subjects

| Peanut allergic (n = 65) | Peanut tolerant (n = 20) | Sensitivity, Specificity, % |
|-------------------------|-------------------------|-----------------------------|
| positive, n             | positive, n             |                             |

IgE Sensitization Patterns to Homologues of Peanut Allergens

We evaluated IgE-binding patterns to homologues of peanut allergens which have been immobilized on the ImmunoCAP ISAC (fig. 5). Five of 40 rAra h 1-positive sera contained IgE specific to both of two other members of the vicilin family, nGly m 5 from soy and nJug r 2 from walnut, while 9 recognized only nGly m 5 and 8 only nJug r 2. Six of the 8 rAra h 1- and nJug r 2-positive sera showed a simultaneous positivity to the CCDs marker, nMUXF3. Sensitization to nJug r 1 but not to rAra h 1 was strongly associated with sensitization to nMUXF3 and also present in the group of atopic peanut-tolerant patients. Sensitization to other 2S albums was observed only with 20% of rAra h 2- and nAra h 6-positive sera, most of them sensitized to rJug r 1 from walnut (8/46) followed by nSes i 1 from sesame (4/46) and rBer e 1 from Brazil nut (1/46). None of the rAra h 2- and nAra h 6-positive sera contained IgE specific to nFag e 2 from buckwheat. Legumin-like allergens such as nGly m 6 from soy were recognized by 65% of rAra h 3-positive sera. Only 2 rAra h 3-positive sera were positive to all three legumin-like allergens presented on the ImmunoCAP ISAC, namely nGly m 6 from soy, rAra a 2 from cashew and nCor a 9 from hazelnut.

The three pollen Bet v 1 homologues (rAln g 1, rBet v 1, rCor a 1.0101) presented on the ImmunoCAP ISAC were recognized by all rAra h 8-positive sera, with one serum recognizing only Bet v 1. The same sera also contained IgE specific to the Bet v 1 homologues from foods such as rMal d 1 from apple, rCor a 1.0401 from hazelnut and rPru p 1 from peach. Exceptions were rApi g 1 from celery and rGly m 4 from soy, which were recognized by 48 and 76% of the Ara h 8-positive sera, respectively. No differences in sensitization to Bet v 1 homologues between peanut-allergic and peanut-asymptomatic atopic controls were observed (fig. 5). Among nsLTPs, all 7 rAra h 9-sensitized patients were also sensitized to rPru p 3, and 6 of them to nJug r 3. Only one serum contained IgE specific to pollen nsLTPs, such as nArt v 3 from Artemisia and nOle e 7 from olive pollen.

Discussion

In this study we analyzed the peanut allergen recognition patterns of 65 Austrian allergic patients with a convincing history of clinical immediate hypersensitivity to peanut. Specific IgE against peanut allergens was identified by the ImmunoCAP system for 5 single recombinant peanut allergens (Ara h 1–3, Ara h 8 and Ara h 9), and by
the ImmunoCAP ISAC, which at present includes 6 peanut allergens (Ara h 1–3, Ara h 6, Ara h 8, Ara h 9). Furthermore, we compared the performance of those two assays to the traditional extract-based ImmunoCAP (fl3) for in vitro diagnosis of peanut allergy.

Peanut allergen-specific IgE recognition patterns and diagnostic sensitivities of individual allergens determined by ImmunoCAP ISAC and singleplexed ImmunoCAP were highly comparable. Similarly, good correlations between these two techniques were obtained by Klemans et al. [2], who evaluated the sensitization patterns of 22 adults and 15 children with a positive double-blind, placebo-controlled peanut challenge. However, in our study we used convincing clinical history and sensitization to peanut to define peanut allergy, which could have influenced the diagnostic performance of the two assays.

The sensitivity of more than 90% of both CRD-based tests (at least one allergen positive) approached that of the peanut extract-based ImmunoCAP analysis (97%). Our findings confirm observations from other peanut CRD studies that have demonstrated that this allergen panel enables the majority of peanut-allergic patients to be
identified [1, 18]. However, although the peanut extract was absolutely discriminative between patients with suspected peanut allergy and nonatopic controls, a positive sIgE result for peanut extract did not reflect the clinical relevance as it was also found in 75% of individuals without an apparent peanut allergy. The major cause for these false-positive peanut sIgE results seems to be the presence of cross-reactive IgE due to sensitization to Bet v 1, profilin or CCDs. In contrast, none of the sensitized but peanut-asymptomatic subjects demonstrated specific IgE reactivity to the peanut seed storage proteins Ara h 1, Ara h 2, Ara h 3 and Ara h 6, resulting in specificities of 100% for those allergens. In contrast, recent studies have shown that 26% of sensitized but tolerant patients’ sera contained IgE specific to Ara h 2 [19], and that a 95% probability of a positive peanut challenge could only be established for sIgE specific to Ara h 2 with a threshold of 42.2 kU/A/l and above [20]. We showed that 72% of Austrian peanut-allergic subjects had IgE specific to at least one of those four allergens. Most common was IgE specific to Ara h 2 and Ara h 6. All but 1 of the patients who were sensitized to Ara h 2 and Ara h 6 showed concomitant sensitization to Ara h 1 and/or Ara h 3. Our findings are in line with others showing that Ara h 2 is the most important peanut allergen [1–6, 11, 21, 22]. Data about the prevalence and diagnostic value of Ara h 6 are rare, but in accordance with our results two studies showed that both peanut 2S albums are recognized by IgE from the same patients in almost all cases and that the diagnostic accuracy of IgE specific to Ara h 6 in adults is as good as for Ara h 2 [1, 7]. The study performed by Klemans et al. [7] identified similar IgE levels for those two allergens when performing ImmunoCAP ISAC [1, 7]. Interestingly, we found significantly higher levels of Ara h 6-specific IgE compared with IgE levels specific for Ara h 2, possibly due to the higher IgE affinity and IgE epitope availability of the purified natural Ara h 6 compared with recombinant Ara h 2 presented on the ImmunoCAP ISAC 112. In contrast to earlier studies, recent studies have increasingly suggested a positive correlation between the severity of symptoms and the level of specific IgE, especially to Ara h 2, but also to Ara h 1 and Ara h 3 [3, 6, 9, 23]. We showed that patients experiencing anaphylaxis after exposure to peanut had significantly higher levels of sIgE against Ara h 1, Ara h 2, Ara h 3 and Ara h 6 as compared to patients suffering from milder symptoms such as OAS, although not all patients with severe reactions had high IgE levels to Ara h 2. This is in line with the general statement to date that peanut-specific or Ara h 2-specific IgE levels do not clearly predict the severity of symptoms, and other
variables not related to the in vitro test might be more relevant, such as target organ reactivity, exposure to allergen dose or the state of health [16].

It emerged that patterns of IgE binding to peanut proteins may vary according to geographical location [1–6, 11, 21, 24]. Sensitization to Ara h 8 is more prominent in peanut-allergic patients exposed to pollen from Fagales trees, such as birch or alder, and, according to recent studies from Sweden, isolated Ara h 8 sensitization is a marker of a mild reaction if any [11, 14]. While 42–70% of peanut-allergic patients from Sweden, Japan or the Netherlands were sensitized to Ara h 8, only 19% of the patients from the USA and 2–7% of Spanish patients had Ara h 8-specific IgE. In a study of children from a Swedish population-based cohort, only 18% of children with IgE reactivity exclusively to Ara h 8 had peanut allergy confined to mild symptoms [11]. In our study, 45% of peanut-allergic patients were sensitized to Ara h 8, but only 12% (8/65), almost all with mild symptoms, had IgE reactivity to Ara h 8 without concomitant sensitization to Ara h 1, Ara h 2, Ara h 3, Ara h 6 and Ara h 9. Four of them were sensitized exclusively to Ara h 8 and 4 also had IgE against profilin and/or CCDs. On the other hand, our results also clearly indicate that the presence of IgE antibodies to Ara h 8 is in most cases not sufficient for the diagnosis of peanut allergy as most of the peanut-tolerant but birch pollen-allergic subjects showed IgE reactivity to Ara h 8. Ara h 8 testing might add important additional diagnostic information, but evaluation of the medical history and, if applicable, oral food challenges are necessary for the accurate diagnosis of peanut allergy in these cases.

In our study, 7 subjects with allergic symptoms to peanut and with peanut extract-specific IgE displayed no IgE reactivity to any of the tested peanut allergens. The analysis of ImmunoCAP ISAC data revealed that 4 of them were sensitized to CCDs and 2 of those 4 were sensitized to profilins, but the remaining 3 subjects showed no sensitization to allergens with potential cross-reactivity to peanut. This observation, also reported by others [11, 14, 18], indicates that additional peanut allergens might be implicated in peanut hypersensitivity in these patients. Although the peanut oleosins (Ara h 10, Ara h 11), peanut defensins (Ara h 12, Ara h 13) and an additional 2S albumin (Ara h 7) have been identified as allergens, data about their clinical relevance for peanut-allergic patients are very scarce [25], suggesting that large-scale studies to evaluate the sensitization patterns to these components in peanut-allergic patients are required.

The evaluation of sensitization patterns to allergens related to peanut presented on the ImmunoCAP ISAC showed that about half of the patients’ sera positive to Ara h 1 and Ara h 3 were also positive to related allergens from soy, Gly m 5 and Gly m 6. The high sequence identities between these allergens [26] indicate the presence of cross-reactive IgE antibodies. A study by Peeters et al. [27] revealed that 87% of peanut-allergic patients were sensitized to soy, but based on DBPCFC only 35% had symptoms to soy. IgE-binding to Jug r 2 was in nearly all cases accompanied by IgE-binding to MUXF3, a marker of CCDs without clinical significance [28]. Interestingly, only 20% of Ara h 2- and Ara h 6-positive sera recognized other members of the 2S family. Although sharing a well-conserved characteristic structure, 2S albumins have low or almost no overall sequence identity, suggesting that IgE reactivity to these allergens indicates cosensitization rather than IgE cross-reactivity. On the other hand and in line with previous studies, high sequence identities among Bet v 1-homologous allergens were accompanied by a high IgE cross-reactivity, with similar frequencies of sensitization to Bet v 1-related allergens in peanut-allergic and peanut-tolerant patients [29, 30]. Among nsLTP, sensitization to Ara h 9 was strongly associated with sensitization to Pru p 3, but not with the pollen nsLTPs, corroborating the hypothesis that Pru p 3 in peanut-allergic patients acts as a primary sensitizer [31].

For the in vitro diagnosis of peanut allergy especially in children, ImmunoCAP ISAC may provide additional benefit compared to the ImmunoCAP as it permits simultaneous assessment of specific IgE to six different peanut allergens, including the major allergen Ara h 6, with a minimal amount of serum (0.04 ml of serum for each individual allergen on ImmunoCAP vs. 0.02 ml for ImmunoCAP ISAC). Recently, a high reproducibility of the ImmunoCAP ISAC analysis, in intra- as well as in inter-lab assays, has been shown for peanut allergens, suggesting the applicability of the technique for diagnosis and the follow-up of peanut-allergic patients [32]. However, due to its higher costs, the application of the ImmunoCAP ISAC is especially recommended in polysensitized patients for risk assessment or selection for immunotherapy, with the potential to not only identify symptom-related allergens, but also to rule out cross-reacting allergens without clinical relevance in one single measurement.

In conclusion, similar to other populations, the majority of Austrian peanut-allergic subjects are sensitized to Ara h 2. Additional tests for other peanut allergens, especially Ara h 8, should be considered when Ara h 2 is negative in peanut-symptomatic patients with birch pollen allergy. We found that results obtained with the ImmunoCAP ISAC assay are highly comparable to data obtained by CRD using the traditional ImmunoCAP. The
results of this study clearly demonstrate the greater ability of CRD in distinguishing between clinically relevant peanut allergy and asymptomatic sensitization to peanuts as compared with the diagnosis of peanut allergy based only on the peanut extract.

Acknowledgments

The authors would like to thank Phadia Austria, Thermo Fisher Scientific, for supporting this study, and Julia Lindenberg, MSc, for performing ImmunoCAP ISAC analysis. Daniela Acker-bauer, Heimo Breiteneder (grant SFB 4608) and Karin Hoffmann-Sommergruber (grant SFB 4603) were supported by the Austrian Science Fund.

Disclosure Statement

Thermo Fisher Scientific supplied the material for the ImmunoCAP and the ImmunoCAP ISAC required for the study. Heimo Breiteneder, Christine Hafner and Karin Hoffmann-Sommergruber received speaking fee lecture honoraria and Merima Bublin received a travel grant from Phadia Austria, Thermo Fisher Scientific.
