We study a model for a thin liquid film dewetting from a periodic heterogeneous substrate (template). The impact of a heterogeneous substrate on the stationary film profiles, their linearizations [19] as the Sharma model. The impact of a heterogeneous substrate has very similar dynamics [18] and stationary solutions and Pomeau [17] as a starting point. We emphasize that this model derived from diffuse interface theory by Pismen shown that this model has periodic stripe solutions that are polar components of molecular interactions and reproduced the and coworkers proposed a model that contains polar and apolar components of molecular interactions and reproduced the dynamics of dewetting thin films [15]. Experimentally, the challenge of preventing the dewetting pattern from coarsening has been met by evaporation of the solvent [14], by literally freezing the system [2] or by using a heterogeneous substrate [1].

In the present paper we study the transition between coarsening and pinning for thin films on weakly structured substrates that possess spatial modulations of the molecular interaction terms. Thin films on homogeneous substrates can be unstable to spinodal dewetting, see e.g. [13, 14]. Sharma and coworkers proposed a model that contains polar and apolar components of molecular interactions and reproduced the dynamics of dewetting thin films [15]. Recently, it has been shown that this model has periodic stripe solutions that are unstable to coarsening [10]. Here we use a slightly different model derived from diffuse interface theory by Pismen and Pomeau [17] as a starting point. We emphasize that this model has very similar dynamics [13] and stationary solutions [19] as the Sharma model. The impact of a heterogeneous substrate on the stationary film profiles, their linear stability and resulting conditions for morphological transitions are presented. The dynamics of thin films on periodic stripe templates have been studied in [10] with the original Sharma model by numerical integration and for a given heterogeneity of large amplitude. Using bifurcation and stability analysis, we can provide, however, a more systematic study of the effects of parameters like average film thickness \( \bar{h} \), amplitude \( \epsilon \) and spatial period \( P_{\text{het}} \) of the heterogeneity.

Our starting point is a homogeneous or weakly heterogeneous substrate. We choose parameters in the unstable regime (cross in Fig. 1(a)). Then a striped solution of a spatial period \( P = P_{\text{het}} \) is considered. For illustration we display a system of length \( 2P_{\text{het}} \) (see Fig. 1(b)-(e)). The periodic stripe pattern (Fig. 1(b)) is now unstable against several transversal (Fig. 1(c)) and longitudinal (Figs. 1(d),(e)) perturbations. Stability analysis allows us to trace the corresponding eigenvalues. Increasing the strength of the heterogeneity, they all will acquire negative real parts and the desired pattern in Fig. 1(b) is pinned, i.e. becomes stable against small perturbations.

The evolution equation for the film thickness profile \( h(x, y, t) \) contains a disjoining pressure that is derived by combining the Stokes equation in long wave approximation [20] with diffuse interface theory [17]:

\[
\partial_t h = -\nabla \left( (h - \ln \alpha)^3 \nabla [\Delta h - \partial_h f(h, x)] \right)
\]

(1)

with a free energy \( f(h, x) = \kappa(x) e^{-h} (e^{-h} - 2) + \frac{1}{4} Gh^2 \) and the ratio \( G \) of gravitation to mean molecular interactions as well as the spatially varying strength of the molecular interactions \( \kappa(x) \). \( \alpha > 0 \) is a small parameter describing the wetting properties in the regime of partial wetting [18, 19].

This dimensionless form is obtained after scaling the original quantities as in Ref. [19]. The molecular interactions that become important on the nanometer scale [21] are incorporated through the disjoining pressure \( \Pi(h) \) contained in the derivative of the free energy \( \partial_h f(h, x) = -\kappa(x) \Pi(h) + Gh \). The chosen \( \Pi(h) \) is qualitatively equivalent to other pressures consisting of destabilizing short-range and stabilizing long-
range interactions [23] but does not suffer from the usual divergency for vanishing film thickness [19]. In the absence of heterogeneity, the model possesses two control parameters, the dimensionless quantity $G$ and the average film thickness $\bar{h}$ that is chosen as conserved quantity. A phase diagram in $G$ and $\bar{h}$ indicating the region of spinodal dewetting is shown in Fig. 1(a).

Heterogeneous substrates with a smooth change in the wettability are modelled by a spatial sinusoidal modulation of the overall strength of the disjoining pressure

$$\kappa(x) = 1 + \epsilon \cos(2\pi x / P_{\text{het}}).$$

(2)

The system behaviour is controlled by the amplitude, $\epsilon$, and the imposed periodicity, $P_{\text{het}}$ of the heterogeneity. Locally small $\kappa$ correspond to effectively larger $G$ [19]. Droplets are preferably located at minima of $\kappa(x)$.

We choose the system size, $L$, as a multiple of $P_{\text{het}}$, apply periodic boundary conditions and vary $\epsilon \geq 0$. The Lyapunov functional

$$E = \frac{1}{L} \int_0^L \left[ \frac{1}{2} (\partial_x h)^2 + f(h, x) \right] dx$$

(3)

gives the energy of a striped solution $h(x, t)$ [19]. During the time evolution of a given initial film thickness profile this energy decreases and eventually settles in a minimum when the system approaches a linearly stable stationary solution of Eq. (1). One can determine these solutions directly by setting $\partial_t h = 0$ in Eq. (1) and integrating twice [19], yielding

$$0 = \partial_x e h - \partial_x f(h, x) + C_1.$$ 

(4)

The integration constant $C_1$ and the spatial period $P$ now parametrize a two-parameter family of periodic solutions, i.e. periodic patterns of holes and droplets, that can be calculated by continuation techniques [23]. $P$ can be equal to $P_{\text{het}}$ or its multiples. Focusing on situations with conserved liquid volume we adopt the mean film thickness $\bar{h} = 1/L \int_0^L h(x) dx$ as the second parameter beside the period, using $C_1$ as a Lagrange multiplier. Typical film profiles are shown in Fig. 2(a),(b).

For homogeneous substrates with $\epsilon = 0$, flat films are stationary solutions that, depending on mean film thickness and the parameter $G$, may be unstable to infinitely small (spinodal dewetting) or finite (nucleation) disturbances of the film surface. Rupture due to the spinodal mechanism occurs for perturbations with periods larger than a critical value, $P_c = 2\pi / k_c$ with $k_c^2 = -\partial_x f(h, x)|_{h = \bar{h}}$ [19]. On a slower time scale the initially formed holes coalesce, the pattern becomes coarser and tends to the absolute minimum of the energy at the largest possible $P$, i.e. the system size.

(i) Perturbation theory - If the heterogeneity is switched on, the flat film is no longer a solution to Eq. (4). However, for very small $\epsilon \ll 1$ an analytical expression for the weakly varying stationary film profile can be calculated. Rewriting the heterogeneity as $\epsilon (\epsilon^{k_{\text{het}}^2} + c.c.) / 2$ with $k_{\text{het}} = 2\pi / P_{\text{het}}$ and using the volume conserving ansatz $h(x) = \bar{h} + \alpha (\epsilon^{k_{\text{het}}^2} + c.c.) / 2$ with $O(\alpha) = O(\epsilon)$ in Eq. (4), gives to first order in $\epsilon$

$$\alpha = -\frac{\Pi(\bar{h})}{k_c^2 - k_{\text{het}}^2} \epsilon.$$ 

(5)

This solution is only valid for $\alpha \ll 1$. For $P_c < P_{\text{het}}$, the solution is modulated in phase with the heterogeneity, whereas for $P_c > P_{\text{het}}$ the phase is shifted by $\pi$. Results obtained by perturbation theory are depicted in Fig. 3(b).

(ii) Numerical bifurcation results - Suppose a variety of heterogeneous substrates with appropriate period $P_{\text{het}}$ but different $\epsilon$ is available and a dewetting pattern with spatial period $P = P_{\text{het}}$ is desired. We choose a linearly unstable mean film thickness $\bar{h}$ such that the critical wavelength of spinodal dewetting $P_c$ is of the same order as $P_{\text{het}}$. As an example, we choose $P_c \approx P_{\text{het}}/1.5$ with $P_{\text{het}} = 50$ and $G = 0.1; \bar{h} = 2.5$. This ratio of $P_{\text{het}}/P_c$ is known to give good templating for large heterogeneities [10]. The stationary solutions with $P = P_{\text{het}}$ and $P = 2P_{\text{het}}$ are computed [23] as $\epsilon$ is increased using the weakly modulated solutions as a starting point for the continuation [23]. Figs. 3(a),(b) and 3(a) show profiles of the solutions and the bifurcation diagram and Fig. 3(b) compares the results with the small $\epsilon$ approximation Eq. (5). The weakly modulated solutions are indeed in line with the results of perturbation theory. Breaking the translational symmetry at $\epsilon = 0$ gives rise to two branches of solutions starting at the large amplitude solution known from the homogeneous case [19]. Only the branch of largest amplitude possesses a phase shift. The branches of solutions in phase cease to exist in a saddle-node bifurcation at $\epsilon \approx 0.22$.

(iii) Energy and longitudinal stability - Thick curves in Fig. 3(a) compare the energies (calculated with Eq. (3)) of the different solution branches given in Fig. 3(b). For the chosen parameter values the solutions in phase have always a larger energy than the ones out of phase. When increasing $\epsilon$ the energy of the lower branch decreases further indicating that the heterogeneity favors this pattern with $P = P_{\text{het}}$. Thin curves in Fig. 3(a) denote solutions with $P = 2P_{\text{het}}$. To gain

![FIG. 2: (a) Stationary film profiles to Eq. 1 with $P = P_{\text{het}}$ (thick) and $P = 2P_{\text{het}}$ (thin). (b) Portraits of all solutions with $P = P_{\text{het}}$. Only the solid profile is linearly stable. (c) The heterogeneity and (d) the two coarsening modes due to translation (dashed) and transfer (c.c.) in Eq. (1) and integrating twice [19].](image-url)
more insight into the conditions of pinning the pattern by a heterogeneity, we analyse the linear stability of the stationary solutions in systems of different sizes [24]. For the stability analysis of periodic solutions, one usually employs a Floquet ansatz. This enables us to get the stability of periodic solutions in large systems corresponding to large ratios \( N = L/P_het \).

We find however that the most dangerous, potentially unstable longitudinal modes that induce coarsening of dewetting films are already present in systems for \( N = 2 \). Hence, we constrain the discussion to system sizes \( L \leq 2P_het \) in \( x \)-direction. In the transversal \( y \)-direction, we had to use much larger length \( \approx 30P_het \) for a stability analysis, see below.

In a system of size equal to one period of the heterogeneity, i.e. \( L = P_het \), the entire lower branch in Fig. 3(a) is linearly stable, whereas the two other branches are unstable. For \( \epsilon = 0 \) the linearly stable solution possesses two zero eigenvalues (Goldstone modes) corresponding to translation symmetry and mass conservation. For \( \epsilon \neq 0 \) the translation symmetry is broken and the corresponding eigenvalue becomes negative (thin solid line in Fig. 3(c)). Mass conservation is maintained and the corresponding eigenvalue remains zero for all \( \epsilon \) (thick solid line in Fig. 3(c)).

In a larger system with \( L = 2P_het \), the first stage of coarsening can be studied which is the fastest since nearest neighbours interact and the energy gain is largest. If templating shall be successful then this first stage needs to be prevented by pinning. In the stability analysis of the two periods, two new eigenvalues appear that correspond to asymmetric combinations of the Goldstone modes (see Fig. 3(d)). They represent two possible modes of coarsening: (a) Shift of droplets towards each other caused by a combination of opposite translational modes (dashed arrows in Fig. 3(a) and dashed curves in Figs. 3(d) and 3(c)); (b) Mass transfer between neighbouring unmoved droplets caused by a combination of opposite volume modes (dotted arrows in Fig. 3(a) and dotted curves in Figs. 3(d) and 3(c)). These modes have first been recognized in the Cahn-Hilliard equation \([24]\). For small \( \epsilon \) both eigenvalues are positive, implying the instability of the wanted pattern to coarsening. The mass transfer proceeds faster than the shift of droplets. But, as \( \epsilon \) increases, both become negative, rendering the solution with period \( P_het \) linearly stable. At the two crossing points period doubling bifurcations occur where stationary solutions of period \( P = 2P_het \) emerge (compare thin branches in Fig. 3(a)). Altogether, the desired pinning solution with \( P = P_het \) is linearly stable for \( \epsilon > 0.002 \).

The value of this critical \( \epsilon \) depends on parameters and the specific form of \( \Pi(h) \). Since the two symmetries connected with the coarsening modes are present for arbitrary choices of \( \Pi(h) \) the result does not depend on this choice. Accordingly, two pairs of solutions with \( P = 2P_het \) appear in any given system at finite \( \epsilon \).

These four branches of solutions with \( P = 2P_het \) (thin curves in Fig. 3(a)) have the following linear stability. Solutions on the dotted branch carry two positive eigenvalues. The short-dashed branch has still one positive eigenvalue that leads to a shift of the pattern towards solutions of the solid branch. The long-dashed branch has one positive eigenvalue and is a saddle that divides evolutions by translation of two droplets towards one on the solid branch or back to the \( P = P_het \) branch. The entire thin solid branch is linearly stable in \( L = 2P_het \) and represents the coarse solution competing with the desired pattern (see Fig. 1(e) resp. the thin profile in Fig. 3(a)). Here, at large \( h \), the coarse profile of lowest energy emerges from the translation mode, whereas for smaller mean film thicknesses \( (h \leq 2 \text{ for } G = 0.1) \) the coarse profile corresponding to the transfer mode is stable (see Fig. 1(d)) and has lowest energy \([25]\).

(iv) Coarsening versus pinning - As seen in (iii) coarsening is favored for \( \epsilon < 0.002 \) and solutions with \( P = 2P_het \) are the only stable ones. Consequently they also have the lowest energy (for \( L = 2P_het \)). For \( \epsilon > 0.002 \) multistability between linearly stable solutions with \( P = P_het \) and \( P = 2P_het \) occurs and the initial condition becomes crucial for the final dewetting structure. Below \( \epsilon \approx 0.157 \) the coarse solution has lowest energy, whereas at larger \( \epsilon \) the desired pinned pattern is energetically favored. Choosing suitable initial conditions enables pinning at much smaller \( \epsilon \). But coarsening will still occur at larger \( \epsilon \) if initial conditions are chosen accordingly. At even larger \( \epsilon > 0.5 \) the pinned pattern is the only possibility because the coarse solutions cease to exist.

Summarizing the results for a range of values \( P_het \) at fixed \( G = 0.1 \) and \( h = 2.5 \) we obtain the “morphological phase diagram” Fig. 4. The product \( \epsilon \cdot P_het \) emerges as a rough fundamental parameter: Coarsening prevails when it has low values

![FIG. 3: (a) Relative energy of stationary solutions to Eq. (1) with \( P = P_het \) (thick) and \( P = 2P_het \) (thin) versus \( \epsilon \). A flat film at \( \epsilon = 0 \) yields \( E(h) \approx 0.155 \). Solid curves correspond to coexisting linearly stable solutions with. (b) Bifurcation diagram representing maximum (upper half) and minimum (lower half) of the solutions with \( P = P_het \). The approximation \( \lambda \) is denoted by the thin dot-dashed lines and other line styles match with (a) and Fig. 3(b). (c) Eigenvalues \( \lambda \) with largest real part of the lowest energy solutions with \( P = P_het \) (thick solid branch in (a)). Solid curves correspond to Goldstone modes at \( \epsilon = 0 \) and broken curves to interaction modes with period 2\( P \). Line styles match the profiles in Fig. 3(d). Triangles correspond to period doubling bifurcations where solutions with \( P = 2P_het \) emerge. Parameters are \( a = 0.1, G = 0.1, h = 2.5, P_het = 50 \) which yields \( \alpha / \epsilon \approx 0.7 \).](image)
while for large values the pattern pins to the heterogeneity as desired. At intermediate values multistability is found where
the initial condition selects the final outcome.

(v) Transversal stability - The transversal stability of the pinned profiles \((P = P_{\text{het}})\) can be obtained from the eigenvalues \(\lambda\) of small perturbations \(\delta h(x) \exp(\lambda t) + c.c.\). We observe a long wavelength instability at small \(\epsilon\) on a length scale much larger than the longitudinal modes. The most dangerous branch of transversal perturbations emerges from the
zero-eigenvalue representing mass conservation in the film. For \(\epsilon = 0.001\) for instance, we found that the fastest growing mode had a wavelength of \(\approx 900 = 18P_{\text{het}}\) (see Fig.\(4\)). The transversal modes are stabilized for parameters above the solid curve in Fig. 4. For the present choice of \(\Pi(h)\) and \(G, \tilde{h}\) the transversal instability restricts the stability range of the pinned solution more than longitudinal coarsening.

(vi) Summary - We have studied the conditions for successful templating or pinning of thin films that are unstable to spinodal dewetting. The main result is that a periodic stripe pattern can be pinned if the heterogeneous substrate suppresses the transverse and longitudinal instabilities experienced by such patterns on a homogeneous substrate. While previous studies have employed direct numerical simulation to study the dynamics of thin films, we have used numerical bifurcation and stability computations. This allows an efficient scanning of parameters characterizing the heterogeneous substrate and the film dynamics. Comparing the two length scales \(P_{\epsilon}\) and \(P_{\text{het}}\) of spinodal dewetting and heterogeneity, respectively, we find that patterns are not pinned to heterogeneities on a much smaller scale than \(P_{\epsilon}\), and that smaller \(P_{\epsilon}\) need weaker heterogeneities to pin the pattern. In consequence, templating can be best controlled by choosing the initial mass of fluid which yields the smallest \(P_{\epsilon}\), i.e. the film thickness where the derivative \(-\partial h f(h, x)|_{h}\) is maximal (for constant \(G\), see also [27]). The transition from coarsening to pinning is hysteretic, giving rise to an extended region where the desired pinned pattern coexists with coarser structures. Our results and the methodology also apply to other strategies of stabilizing a periodic pattern including introduction of anisotropy or convective flows [38].
