(Dated: March 22, 2022)

We investigate the sensitivity of a disordered system with diffractive scatterers to a weak external perturbation. Specifically, we calculate the fidelity $M(t)$ (also called the Loschmidt echo) characterizing a return probability after a propagation for a time $t$ followed by a backward propagation governed by a slightly perturbed Hamiltonian. For short-range scatterers we perform a diagrammatic calculation showing that the fidelity decays first exponentially according to the golden rule, and then follows a power law governed by the diffusive dynamics. For long-range disorder (when the diffractive scattering is of small-angle character) an intermediate regime emerges where the diagrammatics is not applicable. Using the path integral technique, we derive a kinetic equation and show that $M(t)$ decays exponentially with a rate governed by the classical Lyapunov exponent.

I. INTRODUCTION

Quantum manifestations of the classical chaotic dynamics represent a central issue for the field of quantum chaos. To characterize quantitatively the stability of quantum motion, Peres \textsuperscript{\dag} proposed to consider the fidelity

$$M(t) = |\langle \psi | \exp(i\hat{H}t) \exp(-i\hat{H}t)|\psi \rangle|^2,$$  \hspace{1cm} (1)

where $\hat{H}'$ differs by a small perturbation from the Hamiltonian $\hat{H}$ of the system under consideration, and $|\psi \rangle$ is some original state (wave packet). The quantity $|\langle \psi | \exp(i\hat{H}t) \exp(-i\hat{H}t)|\psi \rangle|^2$ is the probability to return into the state $|\psi \rangle$ after propagation for a time $t$ governed by the Hamiltonian $\hat{H}$ followed by a backward propagation with a slightly perturbed Hamiltonian $\hat{H}'$. Recently, Jalabert and Pastawski \textsuperscript{\dag} argued that for a system whose classical counterpart is chaotic the fidelity $|\langle \psi | \exp(i\hat{H}t) \exp(-i\hat{H}t)|\psi \rangle|^2$ will decay exponentially in time, with the rate given by the classical Lyapunov exponent. Their work was motivated by measurements of a spin-echo decoherence rate in nuclear magnetic resonance experiments \textsuperscript{\dag}, and they gave a name "quantum Loschmidt echo" to the overlap $|\langle \psi | \exp(i\hat{H}t) \exp(-i\hat{H}t)|\psi \rangle|^2$. The paper \textsuperscript{\dag} triggered a considerable outbreak of research activity devoted to the sensitivity of quantum chaotic systems to external perturbations. In a number of subsequent publications \textsuperscript{\dag,1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18} the Loschmidt echo was studied (predominantly by means of numerical simulations) for a variety of classically chaotic systems and its relation to decoherence problems was discussed. These numerical works have confirmed the key prediction of \textsuperscript{\dag} that in an appropriate parameter range the decay rate of the Loschmidt echo is governed by the classical Lyapunov exponent.

In the present paper, we study the Loschmidt echo $|\langle \psi | \exp(i\hat{H}t) \exp(-i\hat{H}t)|\psi \rangle|^2$ in a different context, namely that of a quantum disordered system. Specifically, we consider a particle moving in a weak quantum random potential. The word "quantum" means here that the scattering on this disorder is of diffractive nature. For a Gaussian random potential assumed here this is equivalent to the condition

$$d \ll l_s,$$  \hspace{1cm} (2)

where $l_s$ is the quantum mean free path. This situation should be contrasted with the opposite case of a classical disorder, for which the disorder-induced contribution to the action on a distance $\sim d$ is much larger than $\hbar$, and the representation of propagators in terms of a sum over classical orbits (as used e.g. in \textsuperscript{\dag}) is justified. On the other hand, the standard theoretical tool for the quantum-disorder regime is the impurity diagram technique. It is therefore natural to attempt to apply the diagrammatics to the Loschmidt echo problem.

We show that indeed the diagrammatic technique can be used to calculate the fidelity for short times (where it is given simply by the golden rule formula), as well as for sufficiently long times (where it decays according to a power law reflecting the diffusive character of the classical motion). We demonstrate however that for a sufficiently smooth (but still quantum as defined by \textsuperscript{\dag}) disorder an intermediate time range emerges, where the diagrammatic method breaks down. Using the path-integral approach, we calculate the Loschmidt echo in this regime and find that it does show the decay governed by the classical Lyapunov exponent, which is highly non-trivial in view of the diffractive character of disorder.

The rest of the paper is organized as follows. In Sec. \textsuperscript{\dag} we consider the case of a short-range disorder ($d \ll \lambda_0$, where $\lambda_0$ is the electron wavelength) when the diagrammatic calculation works in the whole range of times. We identify diagrams corresponding to the short-time (golden rule) and the long-time (diffusion-induced power law) behavior of the fidelity and evaluate them. Section \textsuperscript{\dag}, which is the central one for the paper, is devoted to the case of a long-range random potential ($d \gg \lambda_0$) when the scattering is of small-angle character. Our conclusions are summarized in Sec. \textsuperscript{\dag}. In particular, we discuss there a connection between the Loschmidt echo...
problem and a recent activity \cite{19, 20, 21, 22, 23} devoted to quantum interference effects in the regime of quantum chaos.

II. LOSCHMIDT ECHO FOR THE SHORT RANGE POTENTIAL

As discussed in Sec. I, we consider a model of the particle moving in a random potential inducing a quantum (diffusive) scattering. The Hamiltonians $H$ and $H'$ describing the forward and the backward propagation in (1) correspond to two slightly different potentials,

$$
\hat{H} = \frac{p^2}{2m} + U; \quad \hat{H}' = \frac{p^2}{2m} + U',
$$

where $m$ is a mass of the particle. In this section we study the case of a short-range disorder, with the correlation length $d \ll \lambda_0$, which is essentially equivalent to a $\delta$-correlated (white-noise) random potential. Thus, we have the following expressions for the correlators

$$
\langle U(r_1)U(r_2) \rangle = \langle U'(r_1)U'(r_2) \rangle = \frac{1}{2\pi\nu\tau}\delta(r_1 - r_2),
$$

where $\tau$ is the mean free time (to simplify notations, we assume it to be exactly the same for $U$ and $U'$), and $\nu$ is a density of states at the Fermi energy. The difference between the potentials $\delta U = U' - U$ is characterized by another time scale $\tilde{\tau}$,

$$
\langle \delta U(r_1)\delta U(r_2) \rangle = \frac{1}{\pi\tilde{\tau}}\delta(r_1 - r_2).
$$

Clearly, we want to study the effect of a weak perturbation $\delta U \ll U$ or, in the other words, $\tilde{\tau} \gg \tau$. Finally, we take the initial state $|\psi\rangle$ in the form of a Gaussian wave packet

$$
\psi(r) = \left(\frac{1}{\pi\sigma^2}\right)^{D/4}\exp\left[\frac{i\mathbf{p}_0 \cdot \mathbf{r} - \mathbf{r}^2}{2\sigma^2}\right],
$$

where $\sigma \gg \lambda_0 = 2\pi/p_0$ is a width of the packet and $D$ is a number of space dimensions (we set $\hbar = 1$ throughout the paper).

To translate (I) into the diagrammatic language, we represent the ensemble-averaged fidelity as an average product of four Green’s functions

$$
M(t) = \int dr_1 \ldots dr_6 \langle \psi(r_1)G^{R}(r_1, r_2; t)G^{A}(r_2, r_3; -t)\rangle
\times \langle \psi^*(r_3)G^{R'}(r_4, r_5; t)G^{A'}(r_5, r_6; -t)\psi^*(r_6) \rangle,
$$

where

$$
G^{R}(r, s; t) = \int \frac{dE}{2\pi} (E - \hat{H} + i0)^{-1} e^{-iEt},
$$

$$
G^{A}(r, s; t) = \int \frac{dE}{2\pi} (E - \hat{H} + i0)^{-1} e^{-iEt},
$$

The diagrams are then obtained by connecting four lines representing the Green’s functions in (I) via the diffusion ladders. At sufficiently short times the leading contribution is given by the simplest diagram shown in Fig. 1.

The solid lines in Fig. 1 correspond to the impurity-averaged Green’s functions,

$$
\tilde{G}^{R,A}(\epsilon, \mathbf{p}) = \frac{1}{\epsilon - \epsilon_p \pm i/2\tilde{\tau}},
$$

with $\epsilon_p = p^2/2m$, and the shaded box represents the diffusion (see Fig. 2),

$$
\tilde{\Pi}(Q, \omega) = \frac{1}{2\pi\nu\tau^2(DQ^2 - i\omega + 1/\tilde{\tau})},
$$

where $D = v_0^2\tau/D$ is the diffusion coefficient and $v_0 = p_0/m$. Note that this diffusion has a non-zero “mass” $1/\tilde{\tau}$, since it represents an averaged product of two Green’s functions in different potentials, $(G^R G^A)$. We will only need this diffusion for zero momentum $Q$ and integrated with two Green’s functions, therefore it is convenient to introduce

$$
\tilde{\Gamma}(\omega) = \int \frac{d\mathbf{p}}{(2\pi)^D} \tilde{G}^{R}(\epsilon + \frac{\omega}{2}, \mathbf{p})\tilde{G}^{A}(\epsilon - \frac{\omega}{2}, \mathbf{p})\tilde{\Pi}(0, \omega).
$$

To shorten notations, we will also denote $\tilde{G}^{R,R'}(\epsilon, \mathbf{p}) = \psi(\mathbf{p})\tilde{G}^{R,R'}(\epsilon, \mathbf{p})$ and $\tilde{G}^{A,A'}(\epsilon, \mathbf{p}) = \psi^*(\mathbf{p})\tilde{G}^{A,A'}(\epsilon, \mathbf{p})$,

where $\psi(\mathbf{p}) = (4\pi\sigma^2)^{D/4}e^{-i\mathbf{p}\cdot \mathbf{r}_0\sigma^2/2}$ is the wave function in the momentum representation.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{Fig1.png}
\caption{Diagram determining the short-time (golden-rule) behavior of the fidelity.}
\end{figure}

With the above definitions, the expression corresponding to the diagram Fig. 1 has the form

$$
M(t) = \int \frac{d\mathbf{p}}{(2\pi)^D} \frac{d\epsilon}{2\pi} \frac{d\epsilon'}{2\pi} e^{-i(\epsilon - \epsilon')t}
\times \tilde{G}^{R}(\epsilon, \mathbf{p})\tilde{\Pi}(\epsilon - \epsilon')\tilde{G}^{A}(\epsilon', \mathbf{p})^2.
$$

After a straightforward calculation, we get the following result for the fidelity,

$$
M(t) = e^{-2t/\tilde{\tau}}.
$$
The dotted line corresponds to the correlator
Fig. 5, yielding
the Hikami box, is given by a sum of diagrams shown in
FIG. 3: Diagram determining the long-time diffusive asymp-
totic behavior of the Loschmidt echo is independent of τ, i.e. of the perturbation strength.

The diffuson “collision” vertex, conventionally termed
the Hikami box, is given by a sum of diagrams shown in
Fig. 3, with two massive diffusons “colliding” and transforming into two conventional, massless diffusons (Fig. 3),

\[
\Pi(Q, \omega) = \frac{1}{2\pi\nu^2} \frac{1}{DQ^2 - i\omega}. \tag{14}
\]

The diffuson “collision” vertex, conventionally termed
the Hikami box, is given by a sum of diagrams shown in
Fig. 4, yielding

\[
\chi(Q, \epsilon - \epsilon') = \frac{4\pi\nu\tau^2}{\tau} \frac{1}{(\epsilon - \epsilon')^2 + (1/\tau)^2}. \tag{15}
\]

Note the unconventional form of the expression for the
Hikami box: due to \langle UU' \rangle \neq \langle UU \rangle, the diagrams on

\[
\Pi(Q, \omega) = \frac{1}{2\pi\nu^2} \frac{1}{DQ^2 - i\omega}. \tag{16}
\]

Performing all the energy integrations, we get the following
result:

\[
M(t) = \int \frac{dp\ dp'}{(2\pi)^D} e^{-2DQ^2 t} e^{-Q^2\sigma^2/2} e^{-(p-p_0)^2/2} \frac{1}{\pi\nu^2} \frac{1}{(\epsilon_p - \epsilon_{p'})^2 + (1/\tau)^2}. \tag{17}
\]

Before writing down the final result, we should be more
specific about the width \sigma of the original wave packet.
When it is large compared to the mean free path, \sigma \gg v_0\tau, the characteristic deviations \|p - p_0\|, \|p' - p_0\| are of
the order of 1/\sigma due to Gaussian factors, and we can set
\|p\| = \|p'\| in the last factor in (17). In the opposite case
\sigma \ll v_0\tau the difference \|p - p_0\| is of order 1/(v_0\tau) \ll 1/\sigma and can be neglected in the above Gaussian factors. Thus we have

\[
M(t) = \frac{v_0\tau}{2\pi\nu^2} \frac{\Gamma(D/2)}{(p_0\sigma)^D-1} \frac{2\sigma^2}{4Dt + \sigma^2} \frac{1}{(4D\tau + \sigma^2)}, \quad \sigma \gg v_0\tau, \tag{18}
\]

\[
M(t) = \frac{1}{2\sqrt{2\pi}} \frac{\Gamma(D/2)}{(p_0\sigma)^D-1} \frac{\sigma^2}{2Dt} \frac{1}{2\sqrt{2pi}}, \quad \sigma \ll v_0\tau, \tag{19}
\]

where \Gamma(x) is the Euler gamma function. Remarkably,
this large-t behavior of the Loschmidt echo is independent of \tau, i.e. of the perturbation strength.

Therefore, the long-time asymptotic behavior of the
fidelity is a power-law decay governed by the diffusion,
with \( M(t) \) proportional to the inverse diffusion volume
\( V_{\text{diff}} = (Dt)^D/2 \). Clearly, this result obtained from the
diffusion diagram technique is not specific for the white
noise disorder considered in this section but rather yields
a generic form of the long-t behavior of \( M(t) \) in diffusive
III. LOSCHMIDT ECHO FOR LONG RANGE POTENTIAL

After having understood the behavior of the fidelity in a white-noise disorder, we turn to the case of our main interest: a long-range potential with a correlation length \( d \gg \lambda_0 \). For this kind of potential, the characteristic angle of diffraction for each scattering event is small, \( \delta \phi \sim \lambda_0/d \), so that many scattering events are needed to change strongly the velocity direction. As a result, the motion in such a disorder is characterized by two relaxation times. The first one is the quantum (or, in another terminology, single-particle) relaxation time \( \tau_{\text{R}} \), which is the mean time between scattering events. This time determines the decay rate of the averaged Green’s function \( \langle G^R(r,t) \rangle = G^R_0(r,t)e^{-t/2\tau_{\text{R}}} \). The second one, the momentum (or, transport) relaxation time \( \tau_{\text{T}} \), sets the time scale on which the velocity direction changes by an angle of order \( \pi \). It is parametrically larger, \( \tau_{\text{T}} \sim (d/\lambda_0)^2 \tau_{\text{R}} \). The transport time determines, in particular, the diffusion coefficient \( D = v_{\text{T}}^2 \tau_{\text{T}}/D \).

The condition (2) implies that in the diagrammatic approach the leading contribution is given by diagrams with non-crossing impurity lines. In particular, \( \tau_{\text{S}} \) is determined by the Born-approximation self-energy diagram, \( \tau_{\text{T}} \) is obtained by taking into account the ladder-type vertex correction, and the diffusion propagator can be calculated by solving the equation corresponding to the sum of the ladder diagrams \( \equiv \). Furthermore, even in the ballistic range of frequency and momenta \( q \chi_{\text{B}} > 1, \omega \tau_{\text{T}} > 1 \), the average product of two Green’s functions \( \langle G_R G_A \rangle \) is determined by a sum of ladder diagrams, the “ballistic diffusion”. One might thus expect that the diagrammatic calculation of the preceding section can be generalized to the case of a long-range disorder. Indeed, both the golden rule short-time behavior corresponding to Fig. 1 and the long-time diffusion power-law asymptotics determined by the diagram of Fig. 2 do retain their validity for a long-range disorder. However, as we demonstrate below, an intermediate time range emerges, where the diagrammatic approach is not applicable. The reason for this is a necessity to average a product of four Green’s functions describing four electronic trajectories propagating close to each other. As was shown in \( \equiv \), in a certain time range (specified below) these four Green functions do not decouple into two (ballistic) diffusons, but rather are coupled all together by impurity correlators into a more complicated object, a “4-diffusion”. In view of the failure of the ballistic-diffusion diagrammatics, we will use the path integral approach developed in \( \equiv \). For simplicity, we consider a two-dimensional system.

We begin by defining the disorder correlation functions (replacing the white-noise formulas (2) and (3)),

\[
\langle U(r)U(r_1) \rangle = \langle U'(r)U'(r_1) \rangle = W(|r - r_1|), \\
\langle U''(r)\delta U(r_1) \rangle = 2\delta W(r - r_1). 
\]

Introducing the Feynman path integral representation and averaging over the disorder we rewrite the product of four Green’s functions in (1) as

\[
\langle G_R(R_1, R_2, T)G_A(R_2, R_3, -T) \rangle \times G_R'(R_4, R_5, T)G_A(R_5, R_6, -T) = \\
= \int_{r_1(0) = R_1}^{r_1(T) = R_4} \int_{r_2(0) = R_2}^{r_2(T) = R_5} \int_{r_3(0) = R_3}^{r_3(T) = R_5} \int_{r_4(0) = R_5}^{r_4(T) = R_6} \prod_{i=1}^{4} Dr_i \exp[iS_{\text{kin}} - S_W]; \\
S_{\text{kin}} = \frac{m}{2} \int_0^T dt \left( \dot{\mathbf{r}}_1^2 + \dot{\mathbf{r}}_2^2 - \dot{\mathbf{r}}_3^2 - \dot{\mathbf{r}}_4^2 \right); \\
S_W = \frac{1}{2}(S_{11} + S_{22} + S_{33} + S_{44}) + S_{12} + S_{34} - S_{13} - S_{14} - S_{23} - S_{24} - \delta S_{12} - \delta S_{34} + \delta S_{13} + \delta S_{24};
\]
\[ S_{ij} = \int_0^T \int_0^T W(r_i(t) - r_j(t')) dt dt', \]
\[ \delta S_{ij} = \int_0^T \int_0^T \delta W(r_i(t) - r_j(t')) dt dt', \quad (22) \]

where the paths \( r_1, r_2 \) correspond to the retarded, and \( r_3, r_4 \) to the advanced Green’s functions. The path integral (22) is similar to the one evaluated in Ref. [23], a difference being in boundary conditions and in the additional terms \( \delta S_{ij} \) in the action induced by the perturbation \( \delta U \). As in [23], it is useful to perform the change of variables, introducing \( R_+ = (r_1 + r_2 + r_3 + r_4)/4 \), \( R_- = (r_1 + r_2 - r_3 - r_4) \), \( r_+ = (r_1 - r_2 + r_3 - r_4)/2 \), \( r_- = (r_1 - r_2 - r_3 + r_4)/2 \). The boundary conditions in terms of the new variables are as follows. At \( t = T \) we have \( R_+(T) = 0 \) and \( r_-(T) = 0 \), while the integration over \( R_+(T) \) and \( r_+(T) \) are unrestricted. At \( t = 0 \) the integration over \( R_\pm(0) \) and \( r_\pm(0) \) is performed with the weight
\[ \psi(R_1)\psi^*(R_3)\psi(R_4)\psi^*(R_6) = \left(\frac{1}{\pi \sigma^2}\right)^2 \times \exp \left\{ -\frac{4R_+^2(0)^2 + R_-^2(0)^2 + r_+^2(0)^2 + r_-^2(0)^2}{2\sigma^2} + i\mathbf{p}_0 \mathbf{R}_-(0) \right\}. \quad (23) \]

The kinetic part of the action reads in the transformed variables as
\[ S_{\text{kin}} = m \int_0^T dt \left( \dot{r}_+ \dot{r}_- + \dot{R}_+ \dot{R}_- \right). \quad (24) \]

As was shown in [23], the pairs of variables \((R_+, R_-)\) and \((r_+, r_-)\) decouple. On ballistic distances \( \ll l_\tau \), the integral over the first pair is essentially of the free-particle type, and its saddle-point yields the classical equation of motion for the “center of mass” coordinate \( R_+ \),
\[ R_+(t) = R_+(0) + (R_+(T) - R_+(0)) \frac{t}{T}. \quad (25) \]

After integrating out \( R_+, R_- \), the action (24) is reduced to the form
\[ S_{\text{kin}} = m \int_0^T dt \left( \dot{r}_+ \dot{r}_- + \dot{R}_+ \dot{R}_- \right). \quad (26) \]

Since we are interested in the ballistic scales \( \ll l_\tau \), it is convenient to split \( R_-, r_\pm, r_\perp \) into components parallel \((||)\) and perpendicular \((\perp)\) to the direction of the motion \( R_+ \). Then the disorder-induced part of the action \( S_W \) depends only on the transverse components \( R_\perp, r_\perp \) and \( r_\perp \), which we will denote \( Y_\perp \) and \( \rho_\perp \) respectively,
\[ S_W \simeq \int_0^T \mathcal{U}(\rho_-(t), \rho_+(t)) dt - 2 \int_0^T dt Y_\perp^2(t) \times \{ G(\rho_-(t)) - \delta G(\rho_-(t)) + G(\rho_+(t)) \}, \quad (27) \]

where
\[ \mathcal{U} = \mathcal{U}_0 + \delta \mathcal{U}, \]
\[ \mathcal{U}_0 = 2(F(\rho_+) + F(\rho_-)) - F(\rho_+ + \rho_-) - F(\rho_+ - \rho_-), \]
\[ \delta \mathcal{U} = -2\delta F(\rho_-) + \delta F(\rho_+ + \rho_-) + \delta F(\rho_+ - \rho_-), \quad (28) \]

and we have introduced the functions
\[ F(y) = \int_0^\infty \frac{dx}{v_0} [W(x, 0) - W(x, y)], \]
\[ \delta F(y) = \int_0^\infty \frac{dx}{v_0} \delta W(x, 0) - \delta W(x, y)], \quad (29) \]
\[ G(y) = \int_0^\infty \frac{dx}{v} \frac{\partial^2}{\partial y^2} W(x, y), \]
\[ \delta G(y) = \int_0^\infty \frac{dx}{v} \frac{\partial^2}{\partial y^2} \delta W(x, y). \quad (30) \]

Since the correlation functions \( W(r) \), \( \delta W(r) \) decay on the scale \( d \), the functions \( F, G, \delta F \), and \( \delta G \) have the following asymptotic behavior:
\[ F(0 \ll y) \simeq -G(0)y^2/2, \]
\[ F(0 \gg y) \simeq y^{-1}_{\tau}, G(0) = -m^2 v^2 / \tau_\tau, G(y) \to 0. \]

Here the times \( \tau_\tau \) are defined according to
\[ \frac{1}{\tau_\tau} = \frac{2}{v_0} \int_0^\infty W(r) dr, \quad (31) \]
\[ \frac{1}{\tau_\tau} = \frac{1}{m^2 v_0^2} \int_0^\infty dr \frac{dW(r)}{dr}. \quad (32) \]

As shown in [29], these are exactly the expressions for the single-particle and the transport times in a long-range disorder. The times \( \tau_\perp \) are defined by the equations analogous to (31), (32), but with a substitution \( W \to \delta W \).

Taking into account the boundary conditions (23) and integrating out the variables \( R_\perp \), we get the following expression for the fidelity
\[ M(T) = \int \frac{dp_+ dp_-}{\sqrt{2\pi \sigma^2}} e^{-\frac{p_+^2 + p_-^2}{2\sigma^2}} g(\rho_+, \rho_-; T) \quad (33) \]

The function \( g \) entering (33) is determined by the \( \rho_\perp \)-part of the path integral, which can be reduced in the standard way to a differential equation:
\[ \left( \frac{\partial}{\partial t} - \frac{i}{m} \frac{\partial^2}{\partial \rho_+ \partial \rho_-} + \mathcal{U}(\rho_+, \rho_-) \right) g(\rho_+, \rho_-; t) = \delta(t) \delta(\rho_-). \quad (34) \]

The l.h.s. of this equation reduces to that of Eq.(36) in [23] if the forward and backward evolution are performed in the same potential, \( \delta \mathcal{U} = 0 \) (the r.h.s. differs from [23] because of different boundary conditions). The presence of \( \delta \mathcal{U} \) [which enters the “potential energy” \( \mathcal{U} \), see Eq. (28)] in (34) is crucially important: otherwise the
solution would be simply \( g(\rho_+, \rho_-, t) = \delta(\rho_-) \) for any \( t > 0 \), since the boundary condition in (43) is independent on \( \rho_+ \) and \( \mathcal{U}_0(\rho_+, 0) = 0 \). After a substitution into (33), this would lead to \( M(t) = 1 \), which is the correct result in the absence of perturbation.

We have therefore reduced the problem of calculation of the Loschmidt echo in the ballistic time range to a solution of the kinetic equation (34). Let us consider the time evolution of the solution of Eq. (34). The initial value at \( t \to 0 \) is \( g = \delta(\rho_-) \), and as explained above, the time evolution is initially determined by the term \( \delta t \) which induces a \( \delta \) result, the distribution (33), this would lead to \( M(t) = 1 \), which is the correct result in the absence of perturbation.

As a result, the distribution \( g \) becomes quickly suppressed at \( \rho_+ \gtrsim d \) because

\[
\delta \mathcal{U}(\rho_+), 0 \simeq \frac{2}{\tau_\rho}, \quad \rho_+ \gg d. \tag{35}
\]

Thus for \( \rho_+ \gg d \) Eq. (34) reduces to

\[
\frac{\partial}{\partial t} g + \frac{2}{\tau_\rho} g = 0, \tag{36}
\]

which gives an exponential decay,

\[
g \simeq \delta(\rho_-), \quad \rho_- \ll d, \quad \rho_+ \gg d \tag{37}
\]

Therefore, for \( t \gg \tau_\rho \), the function \( g \) remains essentially non-vanishing only in the region \( \rho_+ \gg \rho_- \ll d \). In this region we can expand \( \mathcal{U} \) up to the leading terms in \( \rho_+ \) and \( \rho_- \) and rewrite Eq. (34) in the form

\[
\left( \frac{\partial}{\partial t} - \frac{i}{m} \frac{\partial^2}{\partial \rho_+ \partial \rho_-} + \frac{m^2 v_0^2 \rho^2}{\tau^2} \right) g = 0.
\tag{38}
\]

We have introduced here a new time scale

\[
\tau_L = \left( \frac{3}{2m^2 v_0^2} \int_0^\infty dr \frac{d}{dr} \left( \frac{1}{r} \frac{dW(r)}{dr} \right) \right)^{-\frac{1}{2}} \sim \tau_{\text{tr}} \left( \frac{d}{\tau_{\text{tr}}} \right)^{-\frac{1}{2}}. \tag{39}
\]

As discussed below, \( \tau_L \) is equal (up to a numerical coefficient) to the inverse Lyapunov exponent in the corresponding classical problem, and we will call it the Lyapunov time.

At the early stage of the evolution, characteristic values of \( \rho_- \) are small, and the \( \rho_+^2 \rho_-^2 \) term in (38) is small compared to the \( \rho_-^2 \) term. More specifically, at \( t \sim \tau_\rho \) we have \( \rho_- \sim \tilde{t}_L / \rho_0 d \), so that the condition for neglecting the quartic term in this time range is \( \tilde{t}_L \gg \tilde{t}_s \), where \( \tilde{t}_L = v_0 \tau_L \) is the Lyapunov length. We will assume in the sequel that this condition is fulfilled (30). Thus, Eq. (34) reduces to

\[
\left( \frac{\partial}{\partial t} - \frac{i}{m} \frac{\partial^2}{\partial \rho_+ \partial \rho_-} + \frac{m^2 v_0^2 \rho^2}{\tau^2} \right) g = 0. \tag{40}
\]

Performing further a Fourier transformation \( \rho_+ \to i (m v_0)^{-1} \partial / \partial \phi, \partial / \partial \rho_+ \to i m v_0 \phi \), we cast Eq. (34) into the following form

\[
\left( \frac{\partial}{\partial t} + v_0 \phi \frac{\partial}{\partial \rho_-} - \frac{2}{\tau_{\text{tr}}} \frac{\partial^2}{\partial \rho_-^2} \right) g = 0. \tag{41}
\]

Remarkably, Eq. (41) has a meaning of the Boltzmann kinetic equation for the phase-space distribution function describing the motion in the transverse direction characterized by the coordinate \( \rho_- \), with \( v_0 \phi \) playing the role of the corresponding velocity. This clarify the meaning of \( \phi \) (and explains the notation): it is the angle the velocity vector makes with the \( \| \) axis. (We remind that we are considering ballistic time scales, so that \( \phi \ll 1 \))

The last term in (41) plays the role of a collision integral and describes a diffusion process for the velocity angle.

Solution of this equation is a Gaussian packet

\[
g(\phi, \rho_-) = \frac{\sqrt{3\pi}}{2 mv_0^2 \rho_-^2} \exp \left\{ \frac{3(v_0 - \rho_- / (v_0 \phi^2) - \rho_0^2)}{2} + \frac{\tau_{\text{tr}}}{2} \right\}.
\]

Transforming back to the variable \( \rho_+ \), we get

\[
g(\rho_+, \rho_-) = \frac{1}{\sqrt{\pi \Sigma_-}} \exp \left\{ \frac{-\rho_-^2}{\Sigma_-} - \frac{\rho_+^2}{\Sigma_+} + \frac{2 t}{\tau_{\text{tr}}} \frac{\rho_+ \rho_-}{\Sigma_+ \Sigma_-} \right\},
\]

where

\[
\Sigma_- (t) = \frac{2 v_0 t}{3 \sqrt{\tau_{\text{tr}}} \left( \frac{2 t}{\tau_{\text{tr}}} \right)^{1/2}},
\]

\[
\Sigma_+ (t) = \frac{2}{mv_0 \left( \frac{2 t}{\tau_{\text{tr}}} \right)^{1/2}}. \tag{42}
\]

For the phase-space distribution function \( g(\phi, \rho_-) \) the quantities \( \Sigma_- \) and \( \Sigma_+ \) play the role of widths of the distribution with respect to the coordinate \( \rho_- \) and the momentum \( mv_0 \phi \), respectively.

To simplify calculations, we will neglect the cross-correlations between \( \rho_+ \) and \( \rho_- \) (this will only influence a numerical prefactor in \( M(t) \), which is of minor importance here) and assume that \( g \) has the form

\[
g(\rho_+, \rho_-) = \frac{1}{\sqrt{\pi \Sigma_-}} \exp \left\{ \frac{-\rho_-^2}{\Sigma_-} - \frac{\rho_+^2}{\Sigma_+} \right\}. \tag{43}
\]

We will see that this form of \( g \) will preserve during the further evolution of the distribution.

The characteristic values of \( \rho_- \) are increasing proportionally to \( t / \sqrt{2} \). Eventually, the neglected third (quartic) term in Eq. (34) becomes comparable to the fourth one. Using the result (42) for the characteristic value \( \Sigma_- (t) \) of \( \rho_- \), it is easy to see that this happens at \( t = \tau_L \). At \( t > \tau_L \) the fourth term dominates, and equation (38) takes the form

\[
\left( \frac{\partial}{\partial t} - \frac{i}{m} \frac{\partial^2}{\partial \rho_+ \partial \rho_-} + \frac{m^2 v_0^2 \rho^2}{\tau^2} \right) g = 0. \tag{44}
\]
After the Fourier transformation from $\rho_+$ to $\phi$, the last term takes the form $-(m^2/\tau^2)\partial^2 g/\partial \phi^2$ and describes a diffusion process for the angle $\phi$ with the diffusion coefficient proportional to the coordinate $\rho_-$. This is exactly the kinetic equation for the disorder-averaged distribution function $g(\phi, \rho_-)$ of phase-space separations between two classical paths [19, 23]. It leads to an exponential increase of the width of the distribution function $g(\rho_-, \phi)$ with a rate given by the Lyapunov exponent $\sim \tau_L^{-1}$. Thus in this Lyapunov regime we have

$$\Sigma_- (t) \simeq v_0 \tau_L \left( \frac{\tau_L}{\tau_L} \right)^{1/2} \exp \left\{ c \frac{t}{\tau_L} \right\},$$

$$\Sigma_+ (t) \simeq \lambda_0 \left( \frac{\tau_L}{\tau_L} \right)^{1/2} \exp \left\{ -c \frac{t}{\tau_L} \right\},$$

(45)

where $c$ is a numerical coefficient of order unity.

Let us emphasize a highly non-trivial character of the emergence of a classical kinetic equation. Indeed, we consider a random potential for which each scattering act is of a quantum (diffractive) nature and can not be described classically. It is only after the disorder averaging that the classical kinetics is restored.

The Lyapunov regime breaks down when the width $\Sigma_-$ reaches the correlation length $d$, i.e. at $\tau_0^E = (\tau_L/c) \ln(\tau_L/\tau_0)$. This time plays a role analogous to the Ehrenfest time but only depends on classical parameters (if one assumes that the perturbation $\delta U$ is independent of $h$).

When $t > \tau_0^E$, so that $\rho_- \gg d$, we can use another asymptote of the “potential” $U(\rho_+, \rho_-)|_{\rho_- \gg d} = 2m^2v_0^2\rho_0^2/\tau_L$. This leads to an equation very similar to Eq. (40) but with $\tau_0$ replaced by $\tau_L$. Therefore, in analogy with (42), we have again a power-law dependence of the distribution widths,

$$\Sigma_- (t) \simeq v_0 t \left( \frac{t}{\tau_L} \right)^{1/2},$$

$$\Sigma_+ (t) \simeq \lambda_0 \left( \frac{\tau_L}{t} \right)^{1/2}.$$

(46)

For times larger than $\tau_0^E$, all the calculations can also be performed using the diagrammatic technique for ballistic systems. This is because four trajectories, which were coupled all together into a “4-diffusion” by disorder correlations in the Lyapunov regime, split now in two conventional ballistic-diffusions separated by a distance $\gg d$ [19, 23].

Having got the solution $g$ of the kinetic equation in all the regimes of interest, we can calculate the fidelity $M(t)$. Substituting (43) into Eq. (43), we get

$$M(T) \simeq \frac{\min(\Sigma_+(T), \sigma)}{\max(\Sigma_-(T), \sigma)}.$$  

(47)

Thus, two additional time scales may become significant when we consider the fidelity: $\tau_{\sigma+}$, which is defined by $\Sigma_+(\tau_{\sigma+}) = \sigma$, and $\tau_{\sigma-}$ defined by $\Sigma_-(\tau_{\sigma-}) = \sigma$. Position of these time scales with respect to main characteristic times ($\tau_L, \tau^E, \tau_{tr}$) depends on the width $\sigma$ of the initial state. As an example, we choose $d < \sigma < \ell_{tr}$. In this case $\Sigma_+ < \sigma$ for all times $t > \tau_{\sigma+}$, so that the scale $\tau_{\sigma+}$ does not arise, and $\tau^E < \tau_{\sigma-} < \tau_{tr}$. The order of all characteristic scales on the time axis is illustrated in Fig. [7].

We mention for completeness that there is one more characteristic time $\tau_{\sigma\parallel}$ located between $\tau_{\sigma-}$ and $\tau_{tr}$. At this time, the approximation (25) of straight motion in the coordinate $R_0$, loses its validity. This leads to an additional factor $\sigma / \max\{\sigma, \Sigma_{||}\}$ in the expression for $M(t)$, where

$$\Sigma_{||} \simeq vt \frac{t}{\tau_{tr}}$$

(48)

characterizes longitudinal fluctuations of $R_0$. There is thus an additional crossover inside the ballistic-diagrammatic regime, which takes place at a time $\tau_{\sigma\parallel}$ satisfying $\Sigma_{||}(\tau_{\sigma\parallel}) = \sigma$.

We are now prepared to summarize the results of this section and to give a list of all the regimes of behavior of the fidelity. We have found as much as 6 essentially different regimes (as illustrated in Fig. [7]), one of them (the ballistic diffusion) splits up into three subregimes with different power-law behavior. We list the regimes in the order they appear as the time increases:

1. Perfect echo regime, $t \ll \tau_s$.

At such short times the perturbation is essentially irrelevant, and $M(t) \simeq 1$.

2. Golden rule regime, $t < \tau_s \ln(\sigma/d)$.

Substituting Eq. (31) into (33) we get the exponential decay,

$$M(t) = e^{-2t/\tau_s}.$$  

(49)

3. Power-law “pre-Lyapunov inflation” regime, $\tau_s \ln(\sigma/d) < t < \tau_L$.

Substituting Eq. (42) into (47) we get

$$M(t) \sim \frac{d}{\sigma} \left( \frac{\tau_s}{t} \right)^{1/2}.$$  

(50)

This behavior of the fidelity is related to a power-law spreading of classical trajectories in this regime due to the “ballistic diffusion” in the perturbation potential $\delta U$. 

FIG. 7: Characteristic time scales separating various regimes of the behavior of $M(t)$. The regimes 2 (golden rule) and 4 (Lyapunov) correspond to an exponential decay of $M(t)$, the remaining regimes to a power-law decay (see text for details).
4. Lyapunov regime, \( \tau_L < t < \tau_L^* \).

Combining (43) and (47), we get an exponential decay of the Loschmidt echo determined by the classical Lyapunov exponent,

\[
M(t) \sim \frac{d}{\sigma} \left( \frac{\tau_s}{\tau_L} \right)^{1/2} e^{-ct/\tau_L}. \tag{51}
\]

5. “Ballistic diffusion” regime, \( \tau_L^* < t < \tau_{tr} \).

This regime characterized by a power-law behavior of the fidelity is further subdivided into three sub-regimes:

(a) \( \tau_L^* < t < \tau_{tr} \). Using (47), (46) and noticing that \( \Sigma^- \) is still smaller than \( \sigma \) in this time range, we find

\[
M(t) \sim \frac{1}{\rho_0 \sigma} \left( \frac{\tau_{tr}}{t} \right)^{1/2}. \tag{52}
\]

(b) \( \tau_{tr} < t < \tau_{tr}^* \). The only difference compared to the previous case is that now \( \Sigma^- > \sigma \), yielding

\[
M(t) \sim \frac{1}{\rho_{tr}} \left( \frac{\tau_{tr}}{t} \right)^2. \tag{53}
\]

(c) \( \tau_{tr}^* < t < \tau_{tr} \). In this regime fluctuations in the motion in the parallel direction also become important, see the text around Eq. (18), with the result

\[
M(t) \sim \frac{\sigma}{\rho_{tr}^2} \left( \frac{\tau_{tr}}{t} \right)^4. \tag{54}
\]

6. Conventional diffusion regime, \( t > \tau_{tr} \).

In this regime the nature of disorder (short-range vs. long-range) is irrelevant, and the result (19) derived in Sec. II is applicable,

\[
M(t) \sim \frac{\sigma}{\rho_{tr}^2} \frac{\tau_{tr}}{t}. \tag{55}
\]

We would like to remind that the ordering of relevant time scales in Fig. 8 depends on the microscopic parameters of the problem. We have considered the most interesting case \( \tilde{t}_s \ll \tilde{t}_L \) and \( d < \sigma < \tilde{t}_{tr} \), when all possible regimes are developed. For other choices of parameters, some of the regimes may disappear (see, in particular, the footnote [38]).

IV. CONCLUSIONS

In this paper, we have studied the Loschmidt echo (or, in a different terminology, the fidelity), which characterizes the sensitivity of a quantum system to an external perturbation, in a model with a weak quantum random potential. Using the diagrammatic approach, we have shown that at short times the fidelity decays exponentially with the rate \( 2/\tilde{r}_s \) set by the golden rule, while its long-time asymptotics is of power-law type and is determined by the diffusive nature of the dynamics on this time scale. For a sufficiently long-range disorder a time range emerges where the diagrammatics becomes inapplicable due to merging of two ballistic diffusons into a more complicated “4-diffuson”. To study the fidelity in this regime, we have applied a quasiclassical (path integral) approach. This allowed us to express the disorder-averaged fidelity in terms of a solution of a quasiclassical evolution equation, see Eqs. (33) and (34). On time scales larger than \( \tilde{r}_s \) this equation takes a form of the kinetic equation for the distribution function \( g(\phi, \rho_{tr}) \) of phase-space separations between two classical paths (one of which is subject to the perturbation). Solving the kinetic equation, we find several additional regimes of behavior of the Loschmidt echo, separating the short-time golden-rule decay from the long-time diffusive asymptotics. In particular, there arises a “Lyapunov regime”, where the fidelity decays exponentially with a rate governed by the classical Lyapunov exponent.

It is worth mentioning that our path-integral calculation of the fidelity is closely connected to the analysis of quantum interference effects in a long-range disorder performed in [19, 23]. In particular, after the Fourier transformation \( \rho_{tr} \rightarrow \phi \) our evolution equation (33) has the same form as the equation describing the “Hikami box” in [19] (after averaging over the smooth random potential). This is a remarkable agreement, since the methods used are essentially different: Aleiner and Larkin [19] work in a given realization of a random potential (which assumes that the potential is classical, i.e. the condition opposite to Eq. (2) is fulfilled), while we consider the case of a diffractive scattering [Eq. (2)] and perform all calculations for disorder-averaged quantities. There is, however, an important difference between the equations obtained. Specifically, in our case the last term of Eq. (33) (which is proportional to \( 1/\tilde{r}_{tr} \)) is due to the difference \( \delta U \) between the Hamiltonians for the forward and the backward propagation. On the other hand, the authors of Ref. [19] add “by hand” a term of exactly the same type (with a certain time \( \tau_q \) replacing our \( \tilde{r}_{tr} \)) for a problem without any perturbation \( \delta U \), arguing that it mimics a small-angle diffraction in the system. To our opinion, this justification is questionable (at least, for a system with a weak smooth disorder). Indeed, in this case all scattering processes determining the transport in the system are of diffractive type and are taken into account in our approach. There is thus no freedom to add an additional “diffractive” term to the kinetic equation. We thus believe that the Hikami box is described by an equation without such term (i.e. analogous to our equations (33), (34) in the absence of perturbation, \( \delta U, \tilde{r}_{tr}^{-1} = 0 \)) but with appropriate boundary conditions. While this will probably not affect the main results of Ref. [19] (depending only logarithmically on \( \tau_q \)), such a more consistent
treatment of the quasiclassical Hikami box [31] would be of conceptual importance for the theory of quantum interference effects in systems with large-scale inhomogeneities. We leave this issue as an open problem for the future research.

[23] In the opposite case $l_L \ll \bar{l}_s$ (which is the case if the perturbation is very weak, or if the potential is not sufficiently long-ranged), the Lyapunov regime does not exist, and the golden rule decay crosses over directly to a power-law ballistic-diffusion regime.
