Abstract

I discuss several theoretical tools which are useful for analyzing perturbative and non-perturbative problems in quantum chromodynamics, including (a) the light-cone Fock expansion, (b) the effective charge $\alpha_V$, (c) conformal symmetry, and (d) commensurate scale relations. Light-cone Fock-state wavefunctions encode the properties of a hadron in terms of its fundamental quark and gluon degrees of freedom. Given the proton's light-cone wavefunctions, one can compute not only the quark and gluon distributions measured in deep inelastic lepton-proton scattering, but also the multi-parton correlations which control the distribution of particles in the proton fragmentation region and dynamical higher twist effects. Light-cone wavefunctions also provide a systematic framework for evaluating exclusive hadronic matrix elements, including timelike heavy hadron decay amplitudes and form factors. The $\alpha_V$ coupling, defined from the QCD heavy quark potential, provides a physical expansion parameter for perturbative QCD with an analytic dependence on the fermion masses which is now known to two-loop order. Conformal symmetry provides a template for QCD predictions, including relations between observables which are present even in a theory which is not scale invariant. Commensurate scale relations are perturbative QCD predictions based on conformal symmetry relating observable to observable at fixed relative scale. Such relations have no renormalization scale or scheme ambiguity.

1 Introduction

A primary goal of both high energy and nuclear physics is to unravel the structure and dynamics of nucleons and nuclei in terms of their fundamental quark and gluon degrees of freedom. Our present empirical knowledge of the quark and gluon distributions of the proton has revealed a remarkably complex substructure. It is helpful to categorize the parton distributions as “intrinsic” – pertaining to the composition of the target hadron, and “extrinsic”, reflecting the substructure of the individual quarks and gluons themselves. For example, the $\bar{u}(x)$ and $\bar{d}(x)$ antiquark distributions of the proton at $Q^2 \sim 10 \text{ GeV}^2$ to be quite different in shape and thus must reflect dynamics intrinsic to the proton’s structure. If the sea quarks were generated solely by perturbative QCD evolution via gluon splitting, the anti-quark distributions would be
isospin symmetric. Evidence for a difference between the $\bar{s}(x)$ and $s(x)$ distributions has also been claimed. \[2\] Gluons carry a significant fraction of the proton’s spin as well as its momentum. Since gluon exchange between valence quarks contributes to the $p - \Delta$ mass splitting, it follows that the gluon distributions must be cannot be solely accounted for by gluon bremsstrahlung from individual quarks, the process responsible for DGLAP evolutions of the structure functions. Similarly, in the case of heavy quarks, $s\bar{s}$, $c\bar{c}$, $b\bar{b}$, the diagrams in which the sea quarks are multiply connected to the valence quarks are intrinsic to the proton structure itself. Thus neither gluons nor sea quarks are solely generated by DGLAP evolution, and one cannot define a resolution scale $Q_0$ where the sea or gluon degrees of freedom can be neglected. There have also been surprises associated with the chirality distributions $\Delta q = q_{\uparrow} - q_{\downarrow}$ of the valence quarks which again show that a simple valence quark approximation to nucleon spin structure functions is far from the actual dynamical situation. For a recent discussion and references, see Ref. \[3\].

A traditional focus of QCD has been on hard inclusive processes and jet physics where perturbative methods and leading-twist factorization provide predictions up to next-to-next-to leading order (NNLO) with very good precision. More recently, the domain of reliable perturbative QCD predictions has been extended to much more complex phenomena, such as a fundamental understanding of the hard QCD BFKL pomeron in deep inelastic scattering at small $x_{bj}$ and hard diffractive processes, such as $\gamma^* p \rightarrow \rho^0 p$. In these lectures I will discuss applications of QCD where the non-perturbative composition of hadrons in terms of their quark and gluon degrees of freedom play a crucial role, for example the $x_{bj}$-dependence of structure functions measured in deep inelastic scattering, exclusive and semi-exclusive processes such as form factors, two-photon processes, elastic scattering at fixed $\theta_{cm}$, as well as the semi-leptonic decays of heavy hadrons. The analysis of QCD processes at the amplitude level is a challenging problem, mixing issues involving non-perturbative and perturbative dynamics. However, a number of tools are available:

1. The Light-Cone Fock expansion provides a frame-independent representation of a hadrons in terms of a set of wavefunctions \{\psi_{n/H}(x_i, \vec{k}_i, \lambda_i)\} describing its composition into relativistic quark and gluon constituents. The light-cone wavefunctions can be derived from the eigensolutions of the QCD Hamiltonian defined at fixed light-cone time $\tau = t + z/c$. Structure functions are obtained from the sum over absolute squares of the light-cone wavefunctions. Spacelike form factors and semi-leptonic decay amplitudes can be written as exact identities in terms of the convolution of the
light-cone wavefunctions.

2. Factorization theorems for hard exclusive, semi-exclusive, and diffractive processes allow a rigorous separation of soft non-perturbative dynamics of the bound state hadrons from the hard dynamics of the perturbatively-calculable quark-gluon scattering amplitude $T_H^{(A)}$. The key non-perturbative input is the gauge and frame independent hadron distribution amplitude defined as the integral over transverse momenta of the valence (lowest particle number) Fock wavefunction; e.g. for the pion
\[
\phi_{\pi}(x_i, Q) \equiv \int d^2k_{\perp} \psi_{\pi/\pi}^{(Q)}(x_i, \vec{k}_{\perp i}, \lambda)
\]
where the global cutoff $\Lambda$ is identified with the resolution $Q$. The distribution amplitude controls leading-twist exclusive amplitudes at high momentum transfer, and it can be related to the gauge-invariant Bethe-Salpeter wavefunction at equal light-cone time $\tau = x^+$. Thus hard exclusive hadronic amplitudes such as quarkonium decay, heavy hadron decay, and scattering amplitudes where the hadrons are scattered with momentum transfer can be factorized as the convolution of the light-cone Fock state wavefunctions with quark-gluon matrix elements
\[
M_{\text{Hadron}} = \prod_H \sum_n \int d^2k_{\perp} \prod_i dx_i \delta \left(1 - \sum_i x_i\right) \delta \left(\sum_i \vec{k}_{\perp i}\right) \times \psi_{n/H}^{(A)}(x_i, \vec{k}_{\perp i}, \lambda_i) T_H^{(A)}.
\]
Here $T_H^{(A)}$ is the underlying quark-gluon subprocess scattering amplitude, where the incident or final hadrons are replaced by quarks and gluons with momenta $x_i p^+$, $x_i \vec{p}_{\perp} + \vec{k}_{\perp i}$ and invariant mass above the separation scale $M^2_n > \Lambda^2$.

3. The logarithmic evolution of hadron distribution amplitudes $\phi_H(x_i, Q)$ can be derived from the perturbatively-computable tail of the valence light-cone wavefunction in the high transverse momentum regime.

4. Conformal symmetry provides a template for QCD predictions, leading to relations between observables which are present even in a theory which is not scale invariant. Thus an important guide in QCD analyses is to identify the underlying conformal relations of QCD which are manifest if we drop quark masses and effects due to the running of the QCD couplings. In fact, if QCD has an infrared fixed point (vanishing of the Gell Mann-Low function at low momenta), the theory will closely resemble a scale-free conformally symmetric theory in many applications.

5. Commensurate scale relations are perturbative QCD predictions which relate observable to observable at fixed relative scale, such as the "generalized Crewther
relation”, which connects the Bjorken and Gross-Llewellyn Smith deep inelastic scattering sum rules to measurements of the $\text{e}^+\text{e}^-$ annihilation cross section. The relations have no renormalization scale or scheme ambiguity. The coefficients in the perturbative series for commensurate scale relations are identical to those of conformal QCD; thus no infrared renormalons are present. All non-conformal effects are absorbed by fixing the ratio of the respective momentum transfer and energy scales. In the case of fixed-point theories, commensurate scale relations relate both the ratio of couplings and the ratio of scales as the fixed point is approached.

5. $\alpha_V$ Scheme. A natural scheme for defining the QCD coupling in exclusive and other processes is the $\alpha_V$ scheme defined from heavy quark interactions. All vacuum polarization corrections due to fermion pairs are then automatically and analytically incorporated into the Gell Mann-Low function, thus avoiding the problem of explicitly computing and resumming quark mass corrections related to the running of the coupling.

6. The Abelian Correspondence Principle. One can consider QCD predictions as analytic functions of the number of colors $N_C$ and flavors $N_F$. In particular, one can show at all orders of perturbation theory that PQCD predictions reduce to those of an Abelian theory at $N_C \to 0$ with $\hat{\alpha} = C_F \alpha_s$ and $\hat{N}_F = N_F / T C_F$ held fixed. There is thus a deep connection between QCD processes and their corresponding QED analogs.

2 The Light-Cone Fock Expansion in QCD

In a relativistic collision, an incident hadron projectile presents itself as an ensemble of coherent states containing various numbers of quark and gluon quanta. Thus when a laser beam crosses a proton at fixed “light-cone” time $\tau = t + z/c = x^0 + x^z$, it encounters a baryonic state with a given number of quarks, anti-quarks, and gluons in flight with $n_q - n_{\bar{q}} = 3$. The natural formalism for describing these hadronic components in QCD is the light-cone Fock representation obtained by quantizing the theory at fixed $\tau$. For example, the proton state has the Fock expansion

$$| p \rangle = \sum_n \langle n | p \rangle | n \rangle$$

$$= \psi_{3q/p}^{(A)}(x_i, \vec{k}_{\perp i}, \lambda_i) | uud \rangle$$

$$+ \psi_{3qg/p}^{(A)}(x_i, \vec{k}_{\perp i}, \lambda_i) | uudg \rangle + \cdots$$

(3)
representing the expansion of the exact QCD eigenstate on a non-interacting quark and gluon basis. The probability amplitude for each such \( n \)-particle state of on-mass shell quarks and gluons in a hadron is given by a light-cone Fock state wavefunction \( \psi_{n/H}(x_i, \vec{k}_{\perp i}, \lambda_i) \), where the constituents have longitudinal light-cone momentum fractions

\[
x_i = \frac{k_i^+}{p^+} = \frac{k_0^+ + k_z^+}{p^0 + p^z}, \quad \sum_{i=1}^n x_i = 1,
\]

relative transverse momentum

\[
\vec{k}_{\perp i}, \quad \sum_{i=1}^n \vec{k}_{\perp i} = \vec{0}_\perp,
\]

and helicities \( \lambda_i \). The effective lifetime of each configuration in the laboratory frame is \( \frac{2P_{\text{lab}}}{M^2_n - M^2_p} \) where

\[
M^2_n = \sum_{i=1}^n \frac{k_i^2 + m^2}{x} < \Lambda^2
\]

is the off-shell invariant mass and \( \Lambda \) is a global ultraviolet regulator. The form of \( \psi^{(\Lambda)}_{n/H}(x_i, \vec{k}_{\perp i}, \lambda_i) \) is invariant under longitudinal boosts; \( i.e. \), the light-cone wavefunctions expressed in the relative coordinates \( x_i \) and \( k_{\perp i} \) are independent of the total momentum \( P^+, \vec{P}_\perp \) of the hadron.

The interactions of the proton reflects an average over the interactions of its fluctuating states. For example, a valence state with small impact separation, and thus a small color dipole moment, would be expected to interact weakly in a hadronic or nuclear target reflecting its color transparency. The nucleus thus filters differentially different hadron components.[6, 7] The ensemble \( \{\psi_{n/H}\} \) of such light-cone Fock wavefunctions is a key concept for hadronic physics, providing a conceptual basis for representing physical hadrons (and also nuclei) in terms of their fundamental quark and gluon degrees of freedom. Given the \( \psi^{(\Lambda)}_{n/H} \), we can construct any spacelike electromagnetic or electroweak form factor from the diagonal overlap of the LC wavefunctions.[8] Similarly, the matrix elements of the currents that define quark and gluon structure functions can be computed from the integrated squares of the LC wavefunctions.[4, 9]

In general the LC ultraviolet regulators provide a factorization scheme for elastic and inelastic scattering, separating the hard dynamical contributions with invariant mass squared \( \mathcal{M}^2 > \Lambda^2 \) from the soft physics with \( \mathcal{M}^2 \leq \Lambda^2 \) which is incorporated in the nonperturbative LC wavefunctions. (Similarly, the DGLAP evolution of quark and gluon distributions can be derived by computing the variation of the Fock expansion with respect to \( \Lambda^2 \).[4])
The light-cone Fock formalism is derived in the following way: one first constructs the light-cone time evolution operator \( P^- = P^0 - P^z \) and the invariant mass operator \( H_{LC} = P^- P^+ - P^2_\perp \) in light-cone gauge \( A^+ = 0 \) from the QCD Lagrangian. The total longitudinal momentum \( P^+ = P^0 + P^z \) and transverse momenta \( \vec{P}_\perp \) are conserved, \( i.e. \) are independent of the interactions. The matrix elements of \( H_{LC} \) on the complete orthonormal basis \( \{|n\rangle\} \) of the free theory \( H_{LC}^0 = H_{LC}(g = 0) \) can then be constructed. The matrix elements \( \langle n | H_{LC} | m \rangle \) connect Fock states differing by 0, 1, or 2 quark or gluon quanta, and they include the instantaneous quark and gluon contributions imposed by eliminating dependent degrees of freedom in light-cone gauge.

It is thus important to not only compute the spectrum of hadrons and gluonic states, but also to determine the wavefunction of each QCD bound state in terms of its fundamental quark and gluon degrees of freedom. If we could obtain such nonperturbative solutions of QCD, then we could compute the quark and gluon structure functions and distribution amplitudes which control hard-scattering inclusive and exclusive reactions as well as calculate the matrix elements of currents which underlie electroweak form factors and the weak decay amplitudes of the light and heavy hadrons. The light-cone wavefunctions also determine the multi-parton correlations which control the distribution of particles in the proton fragmentation region as well as dynamical higher twist effects. Thus one can analyze not only the deep inelastic structure functions but also the fragmentation of the spectator system. Knowledge of hadron wavefunctions would also open a window to a deeper understanding of the physics of QCD at the amplitude level, illuminating exotic effects of the theory such as color transparency, intrinsic heavy quark effects, hidden color, diffractive processes, and the QCD van der Waals interactions.

Solving a quantum field theory such as QCD is clearly not easy. However, highly nontrivial, one-space one-time relativistic quantum field theories which mimic many of the features of QCD, have already been completely solved using light-cone Hamiltonian methods.\[^{[5]}\] Virtually any \((1+1)\) quantum field theory can be solved using the method of Discretized Light-Cone-Quantization (DLCQ) \[^{[10, 11]}\] where the matrix elements \( \langle n | H_{LC}^A | m \rangle \), are made discrete in momentum space by imposing periodic or anti-periodic boundary conditions in \( x^- = x^0 - x^z \) and \( \vec{x}_\perp \). Upon diagonalization of \( H_{LC} \), the eigenvalues provide the invariant mass of the bound states and eigenstates of the continuum. In DLCQ, the Hamiltonian \( H_{LC} \), which can be constructed from the Lagrangian using light-cone time quantization, is completely diagonalized, in analogy to Heisenberg’s solution of the eigenvalue problem in quantum mechan-
ics. The quantum field theory problem is rendered discrete by imposing periodic or anti-periodic boundary conditions. The eigenvalues and eigensolutions of collinear QCD then give the complete spectrum of hadrons, nuclei, and gluonium and their respective light-cone wavefunctions. A beautiful example is “collinear” QCD: a variant of $QCD(3 + 1)$ defined by dropping all of interaction terms in $H_{LC}^{QCD}$ involving transverse momenta.\[12\] Even though this theory is effectively two-dimensional, the transversely-polarized degrees of freedom of the gluon field are retained as two scalar fields. Antonuccio and Dalley \[13\] have used DLCQ to solve this theory. The diagonalization of $H_{LC}$ provides not only the complete bound and continuum spectrum of the collinear theory, including the gluonium states, but it also yields the complete ensemble of light-cone Fock state wavefunctions needed to construct quark and gluon structure functions for each bound state. Although the collinear theory is a drastic approximation to physical $QCD(3 + 1)$, the phenomenology of its DLCQ solutions demonstrate general gauge theory features, such as the peaking of the wavefunctions at minimal invariant mass, color coherence and the helicity retention of leading partons in the polarized structure functions at $x \to 1$. The solutions of the quantum field theory can be obtained for arbitrary coupling strength, flavors, and colors.

In practice it is essential to introduce an ultraviolet regulator in order to limit the total range of $\langle n \mid H_{LC} \mid m \rangle$, such as the “global” cutoff in the invariant mass of the free Fock state. One can also introduce a “local” cutoff to limit the change in invariant mass $|\mathcal{M}_n^2 - \mathcal{M}_m^2| < \Lambda_{local}^2$ which provides spectator-independent regularization of the sub-divergences associated with mass and coupling renormalization. Recently, Hiller, McCartor, and I have shown\[14\] that the Pauli-Villars method has advantages for regulating light-cone quantized Hamiltonian theory. We show that Pauli-Villars fields satisfying three spectral conditions will regulate the interactions in the ultraviolet, while at same time avoiding spectator-dependent renormalization and preserving chiral symmetry. Although gauge theories are usually quantized on the light-cone in light-cone gauge $A^+ = 0$, it is also possible and interesting to quantize the theory in Feynman gauge\[15\]. Covariant gauges are advantageous since they preserve the rotational symmetry of the gauge interactions.

The natural renormalization scheme for the QCD coupling is $\alpha_V(Q)$, the effective charge defined from the scattering of two infinitely-heavy quark test charges. This is discussed in more detail below. The renormalization scale can then be determined from the virtuality of the exchanged momentum, as in the BLM and commensurate scale methods.\[16, 17, 18, 19\] Similar effective charges have been proposed by
In principle, we could also construct the wavefunctions of QCD(3+1) starting with collinear QCD(1+1) solutions by systematic perturbation theory in $\Delta H$, where $\Delta H$ contains the terms which produce particles at non-zero $k_\perp$, including the terms linear and quadratic in the transverse momenta $\vec{k}_\perp$ which are neglected in the Hamilton $H_0$ of collinear QCD. We can write the exact eigensolution of the full Hamiltonian as

$$\psi_{(3+1)} = \psi_{(1+1)} + \frac{1}{M^2 - H + i\epsilon} \Delta H \psi_{(1+1)},$$

where

$$\frac{1}{M^2 - H + i\epsilon} = \frac{1}{M^2 - H_0 + i\epsilon} + \frac{1}{M^2 - H + i\epsilon} \Delta H \frac{1}{M^2 - H_0 + i\epsilon}$$

can be represented as the continued iteration of the Lippmann Schwinger resolvant. Note that the matrix $(M^2 - H_0)^{-1}$ is known to any desired precision from the DLCQ solution of collinear QCD.

3 Electroweak Matrix Elements and Light-Cone Wavefunctions

Dae Sung Hwang and I have recently shown that exclusive semileptonic $B$-decay amplitudes, such as $B \to A\ell$ can be evaluated exactly in the light-cone formalism. These timelike decay matrix elements require the computation of the diagonal matrix element $n \to n$ where parton number is conserved, and the off-diagonal $n+1 \to n-1$ convolution where the current operator annihilates a $qq'$ pair in the initial $B$ wavefunction. See Fig. 1. This term is a consequence of the fact that the time-like decay $q^2 = (p_\ell + p_\nu)^2 > 0$ requires a positive light-cone momentum fraction $q^+ > 0$. Conversely for space-like currents, one can choose $q^+ = 0$, as in the Drell-Yan-West representation of the space-like electromagnetic form factors. However, as can be seen from the explicit analysis of the form factor in a perturbation model, the off-diagonal convolution can yield a nonzero $q^+/q^+$ limiting form as $q^+ \to 0$. This extra term appears specifically in the case of “bad” currents such as $J^-$ in which the coupling to $q\bar{q}$ fluctuations in the light-cone wavefunctions are favored. In effect, the $q^+ \to 0$ limit generates $\delta(x)$ contributions as residues of the $n+1 \to n-1$ contributions.
Figure 1: Exact representation of electroweak decays and time-like form factors in the light-cone Fock representation.

The necessity for such “zero mode” $\delta(x)$ terms has been noted by Chang, Root and Yan, Burkardt, and Ji and Choi.

The off-diagonal $n + 1 \rightarrow n - 1$ contributions give a new perspective for the physics of $B$-decays. A semileptonic decay involves not only matrix elements where a quark changes flavor, but also a contribution where the leptonic pair is created from the annihilation of a $q\bar{q}$ pair within the Fock states of the initial $B$ wavefunction. The semileptonic decay thus can occur from the annihilation of a nonvalence quark-antiquark pair in the initial hadron. This feature will carry over to exclusive hadronic $B$-decays, such as $B^0 \rightarrow \pi^- D^+$. In this case the pion can be produced from the coalescence of a $d\bar{u}$ pair emerging from the initial higher particle number Fock wavefunction of the $B$. The $D$ meson is then formed from the remaining quarks after the internal exchange of a $W$ boson.

In principle, a precise evaluation of the hadronic matrix elements needed for $B$-
decays and other exclusive electroweak decay amplitudes requires knowledge of all of the light-cone Fock wavefunctions of the initial and final state hadrons. In the case of model gauge theories such as QCD(1+1) [26] or collinear QCD [13] in one-space and one-time dimensions, the complete evaluation of the light-cone wavefunction is possible for each baryon or meson bound-state using the DLCQ method. It would be interesting to use such solutions as a model for physical $B$-decays.

The existence of an exact formalism for electroweak matrix elements gives a basis for systematic approximations and a control over neglected terms. For example, one can analyze exclusive semileptonic $B$-decays which involve hard internal momentum transfer using a perturbative QCD formalism patterned after the analysis of form factors at large momentum transfer. [4] The hard-scattering analysis proceeds by writing each hadronic wavefunction as a sum of soft and hard contributions

$$\psi_n = \psi_n^{\text{soft}}(M_n^2 < \Lambda^2) + \psi_n^{\text{hard}}(M_n^2 > \Lambda^2),$$

(7)

where $M_n^2$ is the invariant mass of the partons in the $n$-particle Fock state and $\Lambda$ is the separation scale. The high internal momentum contributions to the wavefunction $\psi_n^{\text{hard}}$ can be calculated systematically from QCD perturbation theory by iterating the gluon exchange kernel. The contributions from high momentum transfer exchange to the $B$-decay amplitude can then be written as a convolution of a hard scattering quark-gluon scattering amplitude $T_H$ with the distribution amplitudes $\phi(x_i, \Lambda)$, the valence wavefunctions obtained by integrating the constituent momenta up to the separation scale $M_n < \Lambda < Q$. This is the basis for the perturbative hard scattering analyses. [27, 28, 29, 30] In the exact analysis, one can identify the hard PQCD contribution as well as the soft contribution from the convolution of the light-cone wavefunctions. Furthermore, the hard scattering contribution can be systematically improved. For example, off-shell effects can be retained in the evaluation of $T_H$ by utilizing the exact light-cone energy denominators.

Given the solution for the hadronic wavefunctions $\psi_n^{(\Lambda)}$ with $M_n^2 < \Lambda^2$, one can construct the wavefunction in the hard regime with $M_n^2 > \Lambda^2$ using projection operator techniques. [4] The construction can be done perturbatively in QCD since only high invariant mass, far off-shell matrix elements are involved. One can use this method to derive the physical properties of the LC wavefunctions and their matrix elements at high invariant mass. Since $M_n^2 = \sum_{i=1}^{n} \left( \frac{k_i^2 + m_i^2}{x} \right)$, this method also allows the derivation of the asymptotic behavior of light-cone wavefunctions at large $k_{\perp}$, which in turn leads to predictions for the fall-off of form factors and other exclusive matrix
elements at large momentum transfer, such as the quark counting rules for predicting the nominal power-law fall-off of two-body scattering amplitudes at fixed $\theta_{cm}$. The phenomenological successes of these rules can be understood within QCD if the coupling $\alpha_{V}(Q)$ freezes in a range of relatively small momentum transfer.

4 Other Applications of Light-Cone Quantization to QCD Phenomenology

Diffractive vector meson photoproduction. The light-cone Fock wavefunction representation of hadronic amplitudes allows a simple eikonal analysis of diffractive high energy processes, such as $\gamma^{*}(Q^{2})p \rightarrow \rho p$, in terms of the virtual photon and the vector meson Fock state light-cone wavefunctions convoluted with the $gp \rightarrow gp$ near-forward matrix element. One can easily show that only small transverse size $b_{\perp} \sim 1/Q$ of the vector meson distribution amplitude is involved. The hadronic interactions are minimal, and thus the $\gamma^{*}(Q^{2})N \rightarrow \rho N$ reaction can occur coherently throughout a nuclear target in reactions without absorption or shadowing. The $\gamma^{*}A \rightarrow VA$ process thus is a laboratory for testing QCD color transparency. This is discussed further in the next section.

Regge behavior of structure functions. The light-cone wavefunctions $\psi_{n/H}$ of a hadron are not independent of each other, but rather are coupled via the equations of motion. Antonuccio, Dalley and I have used the constraint of finite “mechanical” kinetic energy to derive “ladder relations” which interrelate the light-cone wavefunctions of states differing by one or two gluons. We then use these relations to derive the Regge behavior of both the polarized and unpolarized structure functions at $x \rightarrow 0$, extending Mueller’s derivation of the BFKL hard QCD pomeron from the properties of heavy quarkonium light-cone wavefunctions at large $N_{C}$ QCD.

Structure functions at large $x_{bj}$. The behavior of structure functions where one quark has the entire momentum requires the knowledge of LC wavefunctions with $x \rightarrow 1$ for the struck quark and $x \rightarrow 0$ for the spectators. This is a highly off-shell configuration, and thus one can rigorously derive quark-counting and helicity-retention rules for the power-law behavior of the polarized and unpolarized quark and gluon distributions in the $x \rightarrow 1$ endpoint domain. It is interesting to note that the evolution of structure functions is minimal in this domain because the struck quark is highly virtual as $x \rightarrow 1$; i.e. the starting point $Q_{0}^{2}$ for evolution cannot be held fixed,
but must be larger than a scale of order \((m^2 + k_\perp^2)/(1-x)\). [4, 8, 33]

Intrinsic gluon and heavy quarks. The main features of the heavy sea quark-pair contributions of the Fock state expansion of light hadrons can also be derived from perturbative QCD, since \(\mathcal{M}_n^2\) grows with \(m_Q^2\). One identifies two contributions to the heavy quark sea, the “extrinsic” contributions which correspond to ordinary gluon splitting, and the “intrinsic” sea which is multi-connected via gluons to the valence quarks. The intrinsic sea is thus sensitive to the hadronic bound state structure. [36]

The maximal contribution of the intrinsic heavy quark occurs at \(x_Q \approx m_\perp/Q / \sum_i m_\perp\); i.e. at large \(x_Q\), since this minimizes the invariant mass \(\mathcal{M}_n^2\). The measurements of the charm structure function by the EMC experiment are consistent with intrinsic charm at large \(x\) in the nucleon with a probability of order 0.6 \pm 0.3\%. [37] Similarly, one can distinguish intrinsic gluons which are associated with multi-quark interactions and extrinsic gluon contributions associated with quark substructure. [38] One can also use this framework to isolate the physics of the anomaly contribution to the Ellis-Jaffe sum rule.

Materialization of far-off-shell configurations. In a high energy hadronic collisions, the highly-virtual states of a hadron can be materialized into physical hadrons simply by the soft interaction of any of the constituents. [39] Thus a proton state with intrinsic charm \(|uudc\rangle\) can be materialized, producing a \(J/\psi\) at large \(x_F\), by the interaction of a light-quark in the target. The production occurs on the front-surface of a target nucleus, implying an \(A^{2/3}\) \(J/\psi\) production cross section at large \(x_F\), which is consistent with experiment, such as Fermilab experiments E772 and E866.

Rearrangement mechanism in heavy quarkonium decay. It is usually assumed that a heavy quarkonium state such as the \(J/\psi\) always decays to light hadrons via the annihilation of its heavy quark constituents to gluons. However, as Karliner and I [40] have recently shown, the transition \(J/\psi \rightarrow \rho\pi\) can also occur by the rearrangement of the \(\rho\pi\) from the \(J/\psi\) into the \(|q\bar{q}\rho\pi\rangle\) intrinsic charm Fock state of the \(\rho\) or \(\pi\). On the other hand, the overlap rearrangement integral in the decay \(\psi' \rightarrow \rho\pi\) will be suppressed since the intrinsic charm Fock state radial wavefunction of the light hadrons will evidently not have nodes in its radial wavefunction. This observation gives a natural explanation of the long-standing puzzle why the \(J/\psi\) decays prominently to two-body pseudoscalar-vector final states, whereas the \(\psi'\) does not.

Asymmetry of intrinsic heavy quark sea. The higher Fock state of the proton \(|uuds\rangle\) should resemble a \(|K\Lambda\rangle\) intermediate state, since this minimizes its invari-
ant mass $M$. In such a state, the strange quark has a higher mean momentum fraction $x$ than the $\bar{s}$.\cite{11,12,13} Similarly, the helicity intrinsic strange quark in this configuration will be anti-aligned with the helicity of the nucleon.\cite{11,43} This $Q \leftrightarrow \bar{Q}$ asymmetry is a striking feature of the intrinsic heavy-quark sea.

**Comover phenomena.** Light-cone wavefunctions describe not only the partons that interact in a hard subprocess but also the associated partons freed from the projectile. The projectile partons which are comoving (i.e., which have similar rapidity) with final state quarks and gluons can interact strongly producing (a) leading particle effects, such as those seen in open charm hadroproduction; (b) suppression of quarkonium\cite{14} in favor of open heavy hadron production, as seen in the E772 experiment; (c) changes in color configurations and selection rules in quarkonium hadroproduction, as has been emphasized by Hoyer and Peigne.\cite{45} All of these effects violate the usual ideas of factorization for inclusive reactions. Further, more than one parton from the projectile can enter the hard subprocess, producing dynamical higher twist contributions, as seen for example in Drell-Yan experiments.\cite{46,47}

**Jet hadronization in light-cone QCD.** One of the goals of nonperturbative analysis in QCD is to compute jet hadronization from first principles. The DLCQ solutions provide a possible method to accomplish this. By inverting the DLCQ solutions, we can write the “bare” quark state of the free theory as $|q_0\rangle = \sum |n\rangle \langle n| q_0\rangle$ where now $\{ |n\rangle\}$ are the exact DLCQ eigenstates of $H_{LC}$, and $\langle n| q_0\rangle$ are the DLCQ projections of the eigensolutions. The expansion in automatically infrared and ultraviolet regulated if we impose global cutoffs on the DLCQ basis: $\lambda^2 < \Delta M_n^2 < \Lambda^2$ where $\Delta M_n^2 = M_n^2 - (\sum M_i)^2$. It would be interesting to study jet hadronization at the amplitude level for the existing DLCQ solutions to QCD (1+1) and collinear QCD.

**Hidden Color.** The deuteron form factor at high $Q^2$ is sensitive to wavefunction configurations where all six quarks overlap within an impact separation $b_{\perp i} \leq \mathcal{O}(1/Q)$; the leading power-law fall off predicted by QCD is $F_d(Q^2) = f(\alpha_s(Q^2))/Q^5$, where, asymptotically, $f(\alpha_s(Q^2)) \propto \alpha_s(Q^2)^{5+2\gamma}$.\cite{18} The derivation of the evolution equation for the deuteron distribution amplitude and its leading anomalous dimension $\gamma$ is given in Ref.\cite{19} In general, the six-quark wavefunction of a deuteron is a mixture of five different color-singlet states. The dominant color configuration at large distances corresponds to the usual proton-neutron bound state. However at small impact space separation, all five Fock color-singlet components eventually acquire equal weight, i.e., the deuteron wavefunction evolves to 80% “hidden color.” The relatively large normalization of the deuteron form factor observed at large $Q^2$ points to sizable
hidden color contributions.\[31\]

**Spin-Spin Correlations in Nucleon-Nucleon Scattering and the Charm Threshold.** One of the most striking anomalies in elastic proton-proton scattering is the large spin correlation $A_{NN}$ observed at large angles.$[51]$ At $\sqrt{s} \simeq 5$ GeV, the rate for scattering with incident proton spins parallel and normal to the scattering plane is four times larger than that for scattering with anti-parallel polarization. This strong polarization correlation can be attributed to the onset of charm production in the intermediate state at this energy.$[52]$ The intermediate state $|uuduud\bar{c}\rangle$ has odd intrinsic parity and couples to the $J = S = 1$ initial state, thus strongly enhancing scattering when the incident projectile and target protons have their spins parallel and normal to the scattering plane. The charm threshold can also explain the anomalous change in color transparency observed at the same energy in quasi-elastic $pp$ scattering. A crucial test is the observation of open charm production near threshold with a cross section of order of $1\mu b$.

## 5 Hard Exclusive Reactions

Exclusive hard-scattering reactions and hard diffractive reactions are now giving a valuable window into the structure and dynamics of hadronic amplitudes. Recent measurements of the photon-to-pion transition form factor at CLEO,$[53]$ the diffractive dissociation of pions into jets at Fermilab,$[54]$ diffractive vector meson leptoproduction at Fermilab and HERA, and the new program of experiments on exclusive proton and deuteron processes at Jefferson Laboratory are now yielding fundamental information on hadronic wavefunctions, particularly the distribution amplitude of mesons. Such information is also critical for interpreting exclusive heavy hadron decays and the matrix elements and amplitudes entering $CP$-violating processes at the $B$ factories.

There has been much progress analyzing exclusive and diffractive reactions at large momentum transfer from first principles in QCD. Rigorous statements can be made on the basis of asymptotic freedom and factorization theorems which separate the underlying hard quark and gluon subprocess amplitude from the nonperturbative physics incorporated into the process-independent hadron distribution amplitudes $\phi_H(x_i, Q).[4]$ The valence light-cone wavefunctions integrated over $k^2_\perp < Q^2$. An important new application is the recent analysis of hard exclusive $B$ decays by Beneke, *et al.*$[55]$ Key features of such analyses are: (a) evolution equations for distribu-
tion amplitudes which incorporate the operator product expansion, renormalization
group invariance, and conformal symmetry; \cite{4, 56, 57, 58, 59, 60} (b) hadron helicity
conservation which follows from the underlying chiral structure of QCD; \cite{61} (c)
color transparency, which eliminates corrections to hard exclusive amplitudes from
initial and final state interactions at leading power and reflects the underlying gauge
theoretic basis for the strong interactions; \cite{32, 62} and (d) hidden color degrees of
freedom in nuclear wavefunctions, which reflects the color structure of hadron and
nuclear wavefunctions. \cite{49} There have also been recent advances eliminating renor-
malization scale ambiguities in hard-scattering amplitudes via commensurate scale
relations \cite{63, 64, 65} which connect the couplings entering exclusive amplitudes to the
$\alpha_V$ coupling which controls the QCD heavy quark potential. \cite{66} The postulate that
the QCD coupling has an infrared fixed-point can explain the applicability of confor-
mal scaling and dimensional counting rules to physical QCD processes. \cite{67, 68, 66} The
field of analyzable exclusive processes has recently been expanded to a new range of
QCD processes, such as electroweak decay amplitudes, highly virtual diffractive pro-
cesses such as $\gamma^* p \rightarrow \rho p$ \cite{31, 69} and semi-exclusive processes such as $\gamma^* p \rightarrow \pi^+ X$
\cite{70, 71, 72} where the $\pi^+$ is produced in isolation at large $p_T$.

The natural renormalization scheme for the QCD coupling in hard exclusive pro-
cesses is $\alpha_V(Q)$, the effective charge defined from the scattering of two infinitely-heavy
quark test charges. The renormalization scale can then be determined from the vir-
tuality of the exchanged momentum of the gluons, as in the BLM and commensurate
scale methods. \cite{16, 63, 64, 65}

The main features of exclusive processes to leading power in the transferred mo-
mента are:

(1) The leading power fall-off is given by dimensional counting rules for the hard-
scattering amplitude: $T_H \sim 1/Q^{n-1}$, where $n$ is the total number of fields (quarks,
leptons, or gauge fields) participating in the hard scattering. \cite{77, 68} Thus the reaction
is dominated by subprocesses and Fock states involving the minimum number of
interacting fields. The hadronic amplitude follows this fall-off modulo logarithmic
corrections from the running of the QCD coupling, and the evolution of the hadron
distribution amplitudes. In some cases, such as large angle $pp \rightarrow pp$ scattering,
pinch contributions from multiple hard-scattering processes must also be included. \cite{73}

The general success of dimensional counting rules implies that the effective coupling
$\alpha_V(Q^*)$ controlling the gluon exchange propagators in $T_H$ are frozen in the infrared,
\emph{i.e.}, have an infrared fixed point, since the effective momentum transfers $Q^*$ exchanged
by the gluons are often a small fraction of the overall momentum transfer.\[66\] The pinch contributions are suppressed by a factor decreasing faster than a fixed power.\[67\]

(2) The leading power dependence is given by hard-scattering amplitudes $T_H$ which conserve quark helicity.\[61, 74\] Since the convolution of $T_H$ with the light-cone wavefunctions projects out states with $L_z = 0$, the leading hadron amplitudes conserve hadron helicity; \textit{i.e.}, the sum of initial and final hadron helicities are conserved.

(3) Since the convolution of the hard scattering amplitude $T_H$ with the light-cone wavefunctions projects out the valence states with small impact parameter, the essential part of the hadron wavefunction entering a hard exclusive amplitude has a small color dipole moment. This leads to the absence of initial or final state interactions among the scattering hadrons as well as the color transparency of quasi-elastic interactions in a nuclear target.\[32, 62\] For example, the amplitude for diffractive vector meson photoproduction $\gamma^*(Q^2)p \rightarrow pp$, can be written as convolution of the virtual photon and the vector meson Fock state light-cone wavefunctions the $gp \rightarrow gp$ near-forward matrix element.\[31\] One can easily show that only small transverse size $b_\perp \sim 1/Q$ of the vector meson distribution amplitude is involved. The sum over the interactions of the exchanged gluons tend to cancel reflecting its small color dipole moment. Since the hadronic interactions are minimal, the $\gamma^*(Q^2)N \rightarrow \rho N$ reaction at large $Q^2$ can occur coherently throughout a nuclear target in reactions without absorption or final state interactions. The $\gamma^* A \rightarrow VA$ process thus provides a natural framework for testing QCD color transparency. Evidence for color transparency in such reactions has been found by Fermilab experiment E665.\[75\]

Diffractive multi-jet production in heavy nuclei provides a novel way to measure the shape of the LC Fock state wavefunctions and test color transparency. For example, consider the reaction \[6, 7, 76\] $\pi A \rightarrow \text{Jet}_1 + \text{Jet}_2 + A'$ at high energy where the nucleus $A'$ is left intact in its ground state. The transverse momenta of the jets have to balance so that $\vec{k}_{\perp 1} + \vec{k}_{\perp 2} = \vec{q}_\perp < R^{-1}_A$, and the light-cone longitudinal momentum fractions have to add to $x_1 + x_2 \sim 1$ so that $\Delta p_L < R^{-1}_A$. The process can then occur coherently in the nucleus. Because of color transparency, \textit{i.e.}, the cancelation of color interactions in a small-size color-singlet hadron, the valence wavefunction of the pion with small impact separation will penetrate the nucleus with minimal interactions, diffracting into jet pairs.\[4\] The $x_1 = x$, $x_2 = 1-x$ dependence of the di-jet distributions will thus reflect the shape of the pion distribution amplitude; the $\vec{k}_{\perp 1} - \vec{k}_{\perp 2}$ relative transverse momenta of the jets also gives key information on the underlying shape of the valence pion wavefunction.\[7, 76\] The QCD analysis can be confirmed.
by the observation that the diffractive nuclear amplitude extrapolated to $t = 0$ is linear in nuclear number $A$, as predicted by QCD color transparency. The integrated diffractive rate should scale as $A^2/R_A^2 \sim A^{4/3}$. A diffractive dissociation experiment of this type, E791, is now in progress at Fermilab using 500 GeV incident pions on nuclear targets. The preliminary results from E791 appear to be consistent with color transparency. The momentum fraction distribution of the jets is consistent with a valence light-cone wavefunction of the pion consistent with the shape of the asymptotic distribution amplitude, $\phi_{\pi}^{\text{asympt}}(x) = \sqrt{3} f_\pi x (1 - x)$. As discussed below, data from CLEO for the $\gamma\gamma^* \to \pi^0$ transition form factor also favor a form for the pion distribution amplitude close to the asymptotic solution to the perturbative QCD evolution equation. It will also be interesting to study diffractive tri-jet production using proton beams $pA \to \text{Jet}_1 + \text{Jet}_2 + \text{Jet}_3 + A'$ to determine the fundamental shape of the 3-quark structure of the valence light-cone wavefunction of the nucleon at small transverse separation. One interesting possibility is that the distribution amplitude of the $\Delta(1232)$ for $J_z = 1/2, 3/2$ is close to the asymptotic form $x_1 x_2 x_3$, but that the proton distribution amplitude is more complex. This would explain why the $p \to \Delta$ transition form factor appears to fall faster at large $Q^2$ than the elastic $p \to p$ and the other $p \to N^*$ transition form factors. Conversely, one can use incident real and virtual photons: $\gamma^* A \to \text{Jet}_1 + \text{Jet}_2 + A'$ to confirm the shape of the calculable light-cone wavefunction for transversely-polarized and longitudinally-polarized virtual photons. Such experiments will open up a direct window on the amplitude structure of hadrons at short distances.

There are a large number of measured exclusive reactions in which the empirical power law fall-off predicted by dimensional counting and PQCD appears to be accurate over a large range of momentum transfer. These include processes such as the proton form factor, time-like meson pair production in $e^+ e^-$ and $\gamma\gamma$ annihilation, large-angle scattering processes such as pion photoproduction $\gamma p \to \pi^0 p$, and nuclear processes such as the deuteron form factor at large momentum transfer and deuteron photodisintegration. A spectacular example is the recent measurements at CESR of the photon to pion transition form factor in the reaction $e\gamma \to e\pi^0$. As predicted by leading twist QCD $Q^2 F_{\gamma\pi^0}(Q^2)$ is essentially constant for $1 \text{ GeV}^2 < Q^2 < 10 \text{ GeV}^2$. Further, the normalization is consistent with QCD at NLO if one assumes that the pion distribution amplitude takes on the form $\phi_{\pi}^{\text{asympt}}(x) = \sqrt{3} f_\pi x (1 - x)$ which is the asymptotic solution to the evolution equation for the pion distribution amplitude.
The measured deuteron form factor and the deuteron photodisintegration cross section appear to follow the leading-twist QCD predictions at large momentum transfers in the few GeV region.\cite{82, 83} The normalization of the measured deuteron form factor is large compared to model calculations \cite{50} assuming that the deuteron’s six-quark wavefunction can be represented at short distances with the color structure of two color singlet baryons. This provides indirect evidence for the presence of hidden color components as required by PQCD.\cite{49}

If the pion distribution amplitude is close to its asymptotic form, then one can predict the normalization of exclusive amplitudes such as the spacelike pion form factor $Q^2 F_\pi(Q^2)$. Next-to-leading order predictions are now becoming available which incorporate higher order corrections to the pion distribution amplitude as well as the hard scattering amplitude.\cite{58, 84, 85} However, the normalization of the PQCD prediction for the pion form factor depends directly on the value of the effective coupling $\alpha_V(Q^*)$ at momenta $Q^{*2} \approx Q^2/20$. Assuming $\alpha_V(Q^*) \approx 0.4$, the QCD LO prediction appears to be smaller by approximately a factor of 2 compared to the presently available data extracted from the original pion electroproduction experiments from CEA.\cite{86} A definitive comparison will require a careful extrapolation to the pion pole and extraction of the longitudinally polarized photon contribution of the $ep \rightarrow \pi^+ n$ data.

An important debate has centered on whether processes such as the pion and proton form factors and elastic Compton scattering $\gamma p \rightarrow \gamma p$ might be dominated by higher twist mechanisms until very large momentum transfers.\cite{87, 88, 89} For example, if one assumes that the light-cone wavefunction of the pion has the form $\psi_{\text{soft}}(x, k_\perp) = A \exp(-b k_\perp^2 x (1-x))$, then the Feynman endpoint contribution to the overlap integral at small $k_\perp$ and $x \approx 1$ will dominate the form factor compared to the hard-scattering contribution until very large $Q^2$. However, the above form of $\psi_{\text{soft}}(x, k_\perp)$ has no suppression at $k_\perp = 0$ for any $x$; i.e., the wavefunction in the hadron rest frame does not fall-off at all for $k_\perp = 0$ and $k_z \rightarrow -\infty$. Thus such wavefunctions do not represent well soft QCD contributions. Furthermore, endpoint contributions will be suppressed by the QCD Sudakov form factor, reflecting the fact that a near-on-shell quark must radiate if it absorbs large momentum. If the endpoint contribution dominates proton Compton scattering, then both photons will interact on the same quark line in a local fashion and the amplitude is real, in strong contrast to the QCD predictions which have a complex phase structure. The perturbative QCD predictions\cite{90} for the Compton amplitude phase can be tested in virtual Compton scattering by interference
It should be noted that there is no apparent endpoint contribution which could explain the success of dimensional counting in large angle pion photoproduction.

It is interesting to compare the corresponding calculations of form factors of bound states in QED. The soft wavefunction is the Schrödinger-Coulomb solution \( \psi_{1s}(\vec{k}) \propto (1 + \vec{p}^2/(\alpha m_{\text{red}})^2)^{-2} \), and the full wavefunction, which incorporates transversely polarized photon exchange, only differs by a factor \( (1 + \vec{p}^2/m_{\text{red}}^2) \). Thus the leading twist dominance of form factors in QED occurs at relativistic scales \( Q^2 > m_{\text{red}}^2 \). Furthermore, there are no extra relative factors of \( \alpha \) in the hard-scattering contribution. If the QCD coupling \( \alpha_V \) has an infrared fixed point, then the fall-off of the valence wavefunctions of hadrons will have analogous power-law forms, consistent with the Abelian correspondence principle. If power-law wavefunctions are indeed applicable to the soft domain of QCD then, the transition to leading-twist power law behavior will occur in the nominal hard perturbative QCD domain where \( Q^2 \gg \langle k_{\perp}^2 \rangle, m_q^2 \).

6 Semi-Exclusive Processes: New Probes of Hadron Structure

A new class of hard “semi-exclusive” processes of the form \( A + B \to C + Y \), have been proposed as new probes of QCD.\(^7\)\(^2\)\,\(^7\)\(^0\)\,\(^7\)\(^1\). These processes are characterized by a large momentum transfer \( t = (p_A - p_C)^2 \) and a large rapidity gap between the final state particle \( C \) and the inclusive system \( Y \). Here \( A, B \) and \( C \) can be hadrons or (real or virtual) photons. The cross sections for such processes factorize in terms of the distribution amplitudes of \( A \) and \( C \) and the parton distributions in the target \( B \). Because of this factorization semi-exclusive reactions provide a novel array of generalized currents, which not only give insight into the dynamics of hard scattering QCD processes, but also allow experimental access to new combinations of the universal quark and gluon distributions.

QCD scattering amplitude for deeply virtual exclusive processes like Compton scattering \( \gamma^* p \to \gamma p \) and meson production \( \gamma^* p \to Mp \) factorizes into a hard subprocess and soft universal hadronic matrix elements.\(^7\)\(^4\)\,\(^6\)\(^9\)\,\(^3\)\(^1\). For example, consider exclusive meson electroproduction such as \( ep \to e\pi^+ n \) (Fig. 3). Here one takes (as in DIS) the Bjorken limit of large photon virtuality, with \( x_B = Q^2/(2m_p\nu) \) fixed,
Figure 2: (a): Factorization of $\gamma^* p \rightarrow \pi^+ n$ into a skewed parton distribution (SPD), a hard scattering $H$ and the pion distribution amplitude $\phi_\pi$. (b): Semi-exclusive process $\gamma^{(*)} p \rightarrow \pi^+ Y$. The $d$-quark produced in the hard scattering $H$ hadronizes independently of the spectator partons in the proton. (c): Diagram for the cross section of a generic semi-exclusive process. It involves a hard scattering $H$, distribution amplitudes $\phi_A$ and $\phi_C$ and a parton distribution (PD) in the target $B$.

while the momentum transfer $t = (p_p - p_n)^2$ remains small. These processes involve ‘skewed’ parton distributions, which are generalizations of the usual parton distributions measured in DIS. The skewed distribution in Fig. 2a describes the emission of a $u$-quark from the proton target together with the formation of the final neutron from the $d$-quark and the proton remnants. As the subenergy $\hat{s}$ of the scattering process $\gamma^* u \rightarrow \pi^+ d$ is not fixed, the amplitude involves an integral over the $u$-quark momentum fraction $x$.

An essential condition for the factorization of the deeply virtual meson production amplitude of Fig. 2a is the existence of a large rapidity gap between the produced meson and the neutron. This factorization remains valid if the neutron is replaced with a hadronic system $Y$ of invariant mass $M_Y^2 \ll W^2$, where $W$ is the c.m. energy
of the $\gamma^*p$ process. For $M^2_Y \gg m^2_{\gamma^*}$ the momentum $k'$ of the $d$-quark in Fig. 2b is large with respect to the proton remnants, and hence it forms a jet. This jet hadronizes independently of the other particles in the final state if it is not in the direction of the meson, i.e., if the meson has a large transverse momentum $q'_\perp = \Delta_\perp$ with respect to the photon direction in the $\gamma^*p$ c.m. Then the cross section for an inclusive system $Y$ can be calculated as in DIS, by treating the $d$-quark as a final state particle.

The large $\Delta_\perp$ furthermore allows only transversally compact configurations of the projectile $A$ to couple to the hard subprocess $H$ of Fig. 2b, as it does in exclusive processes. Hence the above discussion applies not only to incoming virtual photons at large $Q^2$, but also to real photons ($Q^2 = 0$) and in fact to any hadron projectile.

Let us then consider the general process $A + B \to C + Y$, where $B$ and $C$ are hadrons or real photons, while the projectile $A$ can also be a virtual photon. In the semi-exclusive kinematic limit $\Lambda^2_{QCD}, M^2_B, M^2_C \ll M^2_Y, \Delta^2_\perp \ll W^2$ we have a large rapidity gap $|y_C - y_d| = \log \frac{W^2}{M^2_Y}$ between $C$ and the parton $d$ produced in the hard scattering (see Fig. 2b). The cross section then factorizes into the form

$$\frac{d\sigma}{dt \, dx_S}(A + B \to C + Y) = \sum_b f_{b/B}(x_S, \mu^2) \frac{d\sigma}{dt}(Ab \to Cd),$$

where $t = (q - q')^2$ and $f_{b/B}(x_S, \mu^2)$ denotes the distribution of quarks, antiquarks and gluons $b$ in the target $B$. The momentum fraction $x_S$ of the struck parton $b$ is fixed by kinematics to the value $x_S = \frac{-t}{M^2_Y - t}$ and the factorization scale $\mu^2$ is characteristic of the hard subprocess $Ab \to Cd$.

It is conceptually helpful to regard the hard scattering amplitude $H$ in Fig. 2b as a generalized current of momentum $q - q' = p_A - p_C$, which interacts with the target parton $b$. For $A = \gamma^*$ we obtain a close analogy to standard DIS when particle $C$ is removed. With $q' \to 0$ we thus find $-t \to Q^2$, $M^2_Y \to W^2$, and see that $x_S$ goes over into $x_B = Q^2/(W^2 + Q^2)$. The possibility to control the value of $q'$ (and hence the momentum fraction $x_S$ of the struck parton) as well as the quantum numbers of particles $A$ and $C$ should make semi-exclusive processes a versatile tool for studying hadron structure. The cross section further depends on the distribution amplitudes $\phi_A, \phi_C$ (c.f. Fig. 2c), allowing new ways of measuring these quantities.
7 Conformal Symmetry as a Template

Testing quantum chromodynamics to high precision is not easy. Even in processes involving high momentum transfer, perturbative QCD predictions are complicated by questions of the convergence of the series, particularly by the presence of “renormalon” terms which grow as \( n! \), reflecting the uncertainty in the analytic form of the QCD coupling at low scales. Virtually all QCD processes are complicated by the presence of dynamical higher twist effects, including power-law suppressed contributions due to multi-parton correlations, intrinsic transverse momentum, and finite quark masses. Many of these effects are inherently nonperturbative in nature and require knowledge of hadron wavefunction themselves. The problem of interpreting perturbative QCD predictions is further compounded by theoretical ambiguities due to the apparent freedom in the choice of renormalization schemes, renormalizations scales, and factorization procedures.

A central principle of renormalization theory is that predictions which relate physical observables to each other cannot depend on theoretical conventions. For example, one can use any renormalization scheme, such as the modified minimal subtraction dimensional regularization scheme, and any choice of renormalization scale \( \mu \) to compute perturbative series observables \( A \) and \( B \). However, all traces of the choices of the renormalization scheme and scale must disappear when we algebraically eliminate the \( \alpha_{\overline{MS}}(\mu) \) and directly relate \( A \) to \( B \). This is the principle underlying “commensurate scale relations” (CSR) \[17\], which are general leading-twist QCD predictions relating physical observables to each other. For example, the “generalized Crewther relation”, which is discussed in more detail below, provides a scheme-independent relation between the QCD corrections to the Bjorken (or Gross Llewellyn-Smith) sum rule for deep inelastic lepton-nucleon scattering, at a given momentum transfer \( Q \), to the radiative corrections to the annihilation cross section \( \sigma_{e^+e^-\rightarrow\text{hadrons}}(s) \), at a corresponding “commensurate” energy scale \( \sqrt{s} \). \[17, 95\] The specific relation between the physical scales \( Q \) and \( \sqrt{s} \) reflects the fact that the radiative corrections to each process have distinct quark mass thresholds.

Any perturbatively calculable physical quantity can be used to define an effective charge\[96, 97, 98\] by incorporating the entire radiative correction into its definition. For example, the \( e^+e^-\gamma^* \rightarrow \text{hadrons} \) annihilation to muon pair cross section ratio can be written

\[
R_{e^+e^-}(s) \equiv R_{e^+e^-}^0(s)[1 + \frac{\alpha_R(s)}{\pi}],
\]  

(9)
where $R_{e^+e^-}^{\alpha}$ is the prediction at Born level. Similarly, we can define the entire radiative correction to the Bjorken sum rule as the effective charge $\alpha_{g_1}(Q^2)$ where $Q$ is the corresponding momentum transfer:

$$\int_0^1 dx \left[ g_{1p}^{ep}(x, Q^2) - g_{1n}^{en}(x, Q^2) \right] \equiv \frac{1}{6} g_A \left| \frac{g_A}{g_V} \right| C_{Bj}(Q^2) = \frac{1}{6} g_A \left[ 1 - \frac{3}{4} C_F \frac{\alpha_{g_1}(Q^2)}{\pi} \right].$$

(10)

By convention, each effective charge is normalized to $\alpha_s$ in the weak coupling limit. One can define effective charges for virtually any quantity calculable in perturbative QCD; e.g. moments of structure functions, ratios of form factors, jet observables, and the effective potential between massive quarks. In the case of decay constants of the $Z$ or the $\tau$, the mass of the decaying system serves as the physical scale in the effective charge. In the case of multi-scale observables, such as the two-jet fraction in $e^+e^-$ annihilation, the multiple arguments of the effective coupling $\alpha_{2jet}(s, y)$ correspond to the overall available energy $s$ variables such as $y = \max_{ij}(p_i + p_j)^2/s$ representing the maximum jet mass fraction.

Commensurate scale relations take the general form

$$\alpha_A(Q_A) = C_{AB}[\alpha_B(Q_B)] .$$

(11)

The function $C_{AB}(\alpha_B)$ relates the observables $A$ and $B$ in the conformal limit; i.e., $C_{AB}$ gives the functional dependence between the effective charges which would be obtained if the theory had zero $\beta$ function. The conformal coefficients can be distinguished from the terms associated with the $\beta$ function at each order in perturbation theory from their color and flavor dependence, or by an expansion about a fixed point.

The ratio of commensurate scales is determined by the requirement that all terms involving the $\beta$ function are incorporated into the arguments of the running couplings, as in the original BLM procedure. Physically, the ratio of scales corresponds to the fact that the physical observables have different quark threshold and distinct sensitivities to fermion loops. More generally, the differing scales are in effect relations between mean values of the physical scales which appear in loop integrations. Commensurate scale relations are transitive; i.e., given the relation between effective charges for observables $A$ and $C$ and $C$ and $B$, the resulting between $A$ and $B$ is independent of $C$. In particular, transitivity implies $\Lambda_{AB} = \Lambda_{AC} \times \Lambda_{CB}$.

One can consider QCD predictions as functions of analytic variables of the number of colors $N_C$ and flavors $N_F$. For example, one can show at all orders of perturbation theory that PQCD predictions reduce to those of an Abelian theory at $N_C \to 0$ with

24
$$\hat{\alpha} = C_F \alpha_s$$ and $$\hat{N}_F = N_f/T C_F$$ held fixed. In particular, CSRs obey the “Abelian correspondence principle” in that they give the correct Abelian relations at $$N_c \to 0$$.

Similarly, commensurate scale relations obey the “conformal correspondence principle”: the CSRs reduce to correct conformal relations when $$N_C$$ and $$N_F$$ are tuned to produce zero $\beta$ function. Thus conformal symmetry provides a template for QCD predictions, providing relations between observables which are present even in theories which are not scale invariant. All effects of the nonzero beta function are encoded in the appropriate choice of relative scales $$\Lambda_{AB} = Q_A/Q_B$$.

The scale $$Q$$ which enters a given effective charge corresponds to a physical momentum scale. The total logarithmic derivative of each effective charge effective charge $$\alpha_A(Q)$$ with respect to its physical scale is given by the Gell Mann-Low equation:

$$\frac{d\alpha_A(Q, m)}{d \log Q} = \Psi_A(\alpha_A(Q, m), Q/m), \quad (12)$$

where the functional dependence of $$\Psi_A$$ is specific to its own effective charge. Here $$m$$ refers to the quark’s pole mass. The pole mass is universal in that it does not depend on the choice of effective charge. The Gell Mann-Low relation is reflexive in that $$\psi_A$$ depends on only on the coupling $$\alpha_A$$ at the same scale. It should be emphasized that the Gell Mann-Low equation deals with physical quantities and is independent of the renormalization procedure and choice of renormalization scale. A central feature of quantum chromodynamics is asymptotic freedom; i.e., the monotonic decrease of the QCD coupling $$\alpha_A(\mu^2)$$ at large spacelike scales. The empirical test of asymptotic freedom is the verification of the negative sign of the Gell Mann-Low function at large momentum transfer, which must be true for any effective charge.

In perturbation theory,

$$\Psi_A = -\psi_A^{(0)} \frac{\alpha_A^2}{\pi} - \psi_A^{(1)} \frac{\alpha_A^3}{\pi^2} - \psi_A^{(2)} \frac{\alpha_A^4}{\pi^3} + \cdots \quad (13)$$

At large scales $$Q^2 \gg m^2$$, the first two terms are universal and identical to the first two terms of the $\beta$ function $$\psi_A^{(0)} = \beta_0 = \frac{11}{3} N_C - \frac{2}{3} N_F$$, $$\psi^{(1)}_A = \beta_1$$, whereas $$\psi^{(n)}_A$$ for $$n \geq 2$$ is process dependent. The quark mass dependence of the $$\psi$$ function is analytic, and in the case of $$\alpha_V$$ scheme is known to two loops.

The commensurate scale relation between $$\alpha_A$$ and $$\alpha_B$$ implies an elegant relation between their conformal dependence $$C_{AB}$$ and their respective Gell Mann Low functions:

$$\psi_B = \frac{dC_{BA}}{d\alpha_A} \times \psi_A$$. \quad (14)
Thus given the result for $N_{F,V}(m/Q)$ in $\alpha_V$ scheme we can use the CSR to derive $N_{F,A}(m/Q)$ for any other effective charge, at least to two loops. The above relation also shows that if one effective charge has a fixed point $\psi_A[\alpha_A(Q_A^{FP})] = 0$, then all effective charges $B$ have a corresponding fixed point $\psi_B[\alpha_B(Q_B^{FP})] = 0$ at the corresponding commensurate scale and value of effective charge.

In quantum electrodynamics, the running coupling $\alpha_{QED}(Q^2)$, defined from the Coulomb scattering of two infinitely heavy test charges at the momentum transfer $t = -Q^2$, is taken as the standard observable. Is there a preferred effective charge which we should use to characterize the coupling strength in QCD? In the case of QCD, the heavy-quark potential $V(Q^2)$ is defined via a Wilson loop from the interaction energy of infinitely heavy quark and antiquark at momentum transfer $t = -Q^2$. The relation $V(Q^2) = -4\pi C_F \alpha_V(Q^2)/Q^2$ then defines the effective charge $\alpha_V(Q)$. As in the corresponding case of Abelian QED, the scale $Q$ of the coupling $\alpha_V(Q)$ is identified with the exchanged momentum. Thus there is never any ambiguity in the interpretation of the scale. All vacuum polarization corrections due to fermion pairs are incorporated in $\alpha_V$ through the usual vacuum polarization kernels which depend on the physical mass thresholds. Other observables could be used to define the standard QCD coupling, such as the effective charge defined from heavy quark radiation.[99]

Commensurate scale relations between $\alpha_V$ and the QCD radiative corrections to other observables have no scale or scheme ambiguity, even in multiple-scale problems such as multi-jet production. As is the case in QED, the momentum scale which appears as the argument of $\alpha_V$ reflect the mean virtuality of the exchanged gluons. Furthermore, we can write a commensurate scale relation between $\alpha_V$ and an analytic extension of the $\overline{\text{MS}}$ coupling, thus transferring all of the unambiguous scale-fixing and analytic properties of the physical $\alpha_V$ scheme to the $\overline{\text{MS}}$ coupling.

An elegant example is the relation between the rate for semi-leptonic $B$-decay and $\alpha_V$:

$$\Gamma(b \to X_u\ell\nu) = \frac{G_F^2 |V_{ub}|^2 M_b^2}{192\pi^3} \left[ 1 - 2.41 \frac{\alpha_V(0.16M_b)}{\pi} - 1.43 \frac{\alpha_V(0.16M_b)}{\pi} \right] \right]^2, \quad (15)$$

where $M_b$ is the scheme independent $b$-quark pole mass. The coefficient of $\alpha_{\overline{\text{MS}}}(\mu)$ in the usual expansion with $\mu = m_b$ is 26.8.

Some other examples of CSR’s at NLO:

$$\alpha_R(\sqrt{s}) = \alpha_{g_1}(0.5\sqrt{s}) - \frac{\alpha_{g_1}^2(0.5\sqrt{s})}{\pi} + \frac{\alpha_{g_1}^3(0.5\sqrt{s})}{\pi^2} \quad (16)$$
\[ \alpha_R(\sqrt{s}) = \alpha_V(1.8\sqrt{s}) + 2.08 \frac{\alpha_V^2(1.8\sqrt{s})}{\pi} - 7.16 \frac{\alpha_V^3(1.8\sqrt{s})}{\pi^2} \]  
(17)

\[ \alpha_r(\sqrt{s}) = \alpha_V(0.8\sqrt{s}) + 2.08 \frac{\alpha_V^2(0.8\sqrt{s})}{\pi} - 7.16 \frac{\alpha_V^3(0.8\sqrt{s})}{\pi^2} \]  
(18)

\[ \alpha_{gL}(\sqrt{s}) = \alpha_V(0.8Q) + 1.08 \frac{\alpha_V^2(0.8Q)}{\pi} - 10.5 \frac{\alpha_V^3(0.8Q)}{\pi^2} \]  
(19)

For numerical purposes in each case we have used \( N_F = 5 \) and \( \alpha_V = 0.1 \) to compute the NLO correction to the CSR scale.

Commensurate scale relations thus provide fundamental and precise scheme-independent tests of QCD, predicting how observables track not only in relative normalization, but also in their commensurate scale dependence.

8 The Generalized Crewther Relation

The generalized Crewther relation can be derived by calculating the QCD radiative corrections to the deep inelastic sum rules and \( R_{e^+e^-} \) in a convenient renormalization scheme such as the modified minimal subtraction scheme \( \overline{\text{MS}} \). One then algebraically eliminates \( \alpha_{\overline{\text{MS}}}(\mu) \). Finally, BLM scale-setting[16] is used to eliminate the \( \beta \)-function dependence of the coefficients. The form of the resulting relation between the observables thus matches the result which would have been obtained had QCD been a conformal theory with zero \( \beta \) function. The final result relating the observables is independent of the choice of intermediate \( \overline{\text{MS}} \) renormalization scheme.

More specifically, consider the Adler function[100] for the \( e^+e^- \) annihilation cross section

\[ D(Q^2) = -12\pi^2 Q^2 \frac{d}{dQ^2} \Pi(Q^2), \quad \Pi(Q^2) = -\frac{Q^2}{12\pi^2} \int_4^{\infty} \frac{R_{e^+e^-}(s) ds}{s(s+Q^2)}. \]  
(20)

The entire radiative correction to this function is defined as the effective charge \( \alpha_D(Q^2) \):

\[ D \left( Q^2/\mu^2, \alpha_s(\mu^2) \right) = D \left( 1, \alpha_s(Q^2) \right) \]  
(21)

\[ \equiv 3 \sum_f Q_f^2 \left[ 1 + \frac{3}{4} C_F \frac{\alpha_D(Q^2)}{\pi} \right] + \left( \sum_f Q_f \right)^2 C_L(Q^2) \]

\[ \equiv 3 \sum_f Q_f^2 C_D(Q^2) + \left( \sum_f Q_f \right)^2 C_L(Q^2), \]
where $C_F = \frac{N_C^2 - 1}{2N_C}$. The coefficient $C_L(Q^2)$ appears at the third order in perturbation theory and is related to the “light-by-light scattering type” diagrams. (Hereafter $\alpha_s$ will denote the $\overline{\text{MS}}$ scheme strong coupling constant.)

It is straightforward to algebraically relate $\alpha_g(Q^2)$ to $\alpha_D(Q^2)$ using the known expressions to three loops in the $\overline{\text{MS}}$ scheme. If one chooses the renormalization scale to resum all of the quark and gluon vacuum polarization corrections into $\alpha_D(Q^2)$, then the final result turns out to be remarkably simple (Ref. 95) ($\hat{\alpha} = 3/4 C_F \alpha / \pi$):

$$
\hat{\alpha}_g(Q) = \hat{\alpha}_D(Q) - \hat{\alpha}_D^2(Q) + \hat{\alpha}_D^3(Q) + \cdots, \tag{22}
$$

where

$$
\ln \left( \frac{Q^*}{Q} \right) = \frac{7}{2} - 4 \zeta(3) + \left( \frac{\alpha_D(Q)}{4\pi} \right) \left[ \left( \frac{11}{12} + \frac{56}{3} \zeta(3) - 16 \zeta^2(3) \right) \beta_0 \\
+ \frac{26}{9} C_A - \frac{8}{3} C_A \zeta(3) - \frac{145}{18} C_F - \frac{184}{3} C_F \zeta(3) + 80 C_F \zeta(5) \right]. \tag{23}
$$

where in QCD, $C_A = N_C = 3$ and $C_F = 4/3$. This relation shows how the coefficient functions for these two different processes are related to each other at their respective commensurate scales. We emphasize that the $\overline{\text{MS}}$ renormalization scheme is used only for calculational convenience; it serves simply as an intermediary between observables. The renormalization group ensures that the forms of the CSR relations in perturbative QCD are independent of the choice of an intermediate renormalization scheme.

The Crewther relation was originally derived assuming that the theory is conformally invariant; i.e., for zero $\beta$ function. In the physical case, where the QCD coupling runs, all non-conformal effects are resummed into the energy and momentum transfer scales of the effective couplings $\alpha_R$ and $\alpha_g$. The general relation between these two effective charges for non-conformal theory thus takes the form of a geometric series

$$
1 - \hat{\alpha}_g = [1 + \hat{\alpha}_D(Q^*)]^{-1}. \tag{24}
$$

We have dropped the small light-by-light scattering contributions. This is again a special advantage of relating observable to observable. The coefficients are independent of color and are the same in Abelian, non-Abelian, and conformal gauge theory. The non-Abelian structure of the theory is reflected in the expression for the scale $Q^*$.

Is experiment consistent with the generalized Crewther relation? Fits to the experimental measurements of the $R$-ratio above the thresholds for the production
of $c \bar{c}$ bound states provide the empirical constraint: $\alpha_R(\sqrt{s} = 5.0 \text{ GeV})/\pi \simeq 0.08 \pm 0.03$. The prediction for the effective coupling for the deep inelastic sum rules at the commensurate momentum transfer $Q$ is then $\alpha_{glS}(Q = 12.33 \pm 1.20 \text{ GeV})/\pi \simeq 0.074 \pm 0.026$. Measurements of the Gross-Llewellyn Smith sum rule have so far only been carried out at relatively small values of $Q^2$\[102, 103\]; however, one can use the results of the theoretical extrapolation\[104\] of the experimental data presented in\[103\]: $\alpha_{\text{extrap}}^{\text{GLS}}(Q = 12.25 \text{ GeV})/\pi \simeq 0.093 \pm 0.042$. This range overlaps with the prediction from the generalized Crewther relation. It is clearly important to have higher precision measurements to fully test this fundamental QCD prediction.

9 General Form of Commensurate Scale Relations

In general, commensurate scale relations connecting the effective charges for observables $A$ and $B$ have the form

$$\alpha_A(Q_A) = \alpha_B(Q_B) \left(1 + r_{A/B}^{(1)} \frac{\alpha_B(Q_B)}{\pi} + r_{A/B}^{(2)} \frac{\alpha_B(Q_B)^2}{\pi} + \cdots \right), \quad (25)$$

where the coefficients $r_{A/B}^n$ are identical to the coefficients obtained in a conformally invariant theory with $\beta_B(\alpha_B) = (d/d \ln Q^2)\alpha_B(Q^2) = 0$. The ratio of the scales $Q_A/Q_B$ is thus fixed by the requirement that the couplings sum all of the effects of the non-zero $\beta$ function. In practice the NLO and NNLO coefficients and relative scales can be identified from the flavor dependence of the perturbative series; i.e. by shifting scales such that the $N_F$-dependence associated with $\beta_0 = 11/3C_A - 4/3T_F N_F$ and $\beta_1 = -34/3C_A^2 + \frac{32}{3} C_A T_F N_F + 4 C_F T_F N_F$ does not appear in the coefficients. Here $C_A = N_C$, $C_F = (N_C^2 - 1)/2N_C$ and $T_F = 1/2$. The shift in scales which gives conformal coefficients in effect pre-sums the large and strongly divergent terms in the PQCD series which grow as $n!/(\beta_0 \alpha_s)^n$, i.e., the infrared renormalons associated with coupling-constant renormalization.\[106, 34, 107, 108\]

The renormalization scales $Q^*$ in the BLM method are physical in the sense that they reflect the mean virtuality of the gluon propagators. This scale-fixing procedure is consistent with scale fixing in QED, in agreement with in the Abelian limit, $N_C \rightarrow 0$.\[16, 93, 109, 110, 111\] The ratio of scales $\lambda_{A/B} = Q_A/Q_B$ guarantees that the observables $A$ and $B$ pass through new quark thresholds at the same physical scale. One can also show that the commensurate scales satisfy the transitivity rule.
\[ \lambda_{A/B} = \lambda_{A/C} \lambda_{C/B}, \] which ensures that predictions are independent of the choice of an intermediate renormalization scheme or intermediate observable \( C \).

In general, we can write the relation between any two effective charges at arbitrary scales \( \mu_A \) and \( \mu_B \) as a correction to the corresponding relation obtained in a conformally invariant theory:

\[
\alpha_A(\mu_A) = C_{AB}[\alpha_B(\mu_B)] + \beta_B[\alpha_B(\mu_B)]F_{AB}[\alpha_B(\mu_B)]
\] (26)

where

\[
C_{AB}[\alpha_B] = \alpha_B + \sum_{n=1}^{\infty} C_{AB}^{(n)} \alpha_B^n
\] (27)

is the functional relation when \( \beta_B[\alpha_B] = 0 \). In fact, if \( \alpha_B \) approaches a fixed point \( \overline{\alpha}_B \) where \( \beta_B[\overline{\alpha}_B] = 0 \), then \( \alpha_A \) tends to a fixed point given by

\[
\alpha_A \to \overline{\alpha}_A = C_{AB}[\overline{\alpha}_B].
\] (28)

The commensurate scale relation for observables \( A \) and \( B \) has a similar form, but in this case the relative scales are fixed such that the non-conformal term \( F_{AB} \) is zero. Thus the commensurate scale relation \( \alpha_A(Q_A) = C_{AB}[\alpha_B(Q_B)] \) at general commensurate scales is also the relation connecting the values of the fixed points for any two effective charges or schemes. Furthermore, as \( \beta \to 0 \), the ratio of commensurate scales \( Q_A^2/Q_B^2 \) becomes the ratio of fixed point scales \( \overline{Q}_A^2/\overline{Q}_B^2 \) as one approaches the fixed point regime.

### 10 Implementation of \( \alpha_V \) Scheme

The effective charge \( \alpha_V(Q) \) provides a physically-based alternative to the usual modified minimal subtraction (\( \overline{\text{MS}} \)) scheme. All vacuum polarization corrections due to fermion pairs are incorporated in \( \alpha_V \) through the usual vacuum polarization kernels which depend on the physical mass thresholds. When continued to time-like momenta, the coupling has the correct analytic dependence dictated by the production thresholds in the crossed channel. Since \( \alpha_V \) incorporates quark mass effects exactly, it avoids the problem of explicitly computing and resumming quark mass corrections which are related to the running of the coupling. Thus the effective number of flavors \( N_F(Q/m) \) is an analytic function of the scale \( Q \) and the quark masses \( m \). The effects of finite quark mass corrections on the running of the strong coupling were first considered by De Rújula and Georgi [112] within the momentum subtraction...
schemes (MOM) (see also Georgi and Politzer \[113\], Shirkov and collaborators \[114\], and Chýla \[115\]).

One important advantage of the physical charge approach is its inherent gauge invariance to all orders in perturbation theory. This feature is not manifest in massive \(\beta\)-functions defined in non-physical schemes such as the MOM schemes. A second, more practical, advantage is the automatic decoupling of heavy quarks according to the Appelquist-Carazzone theorem\[116\].

By employing the commensurate scale relations other physical observables can be expressed in terms of the analytic coupling \(\alpha_V\) without scale or scheme ambiguity. This way the quark mass threshold effects in the running of the coupling are taken into account by utilizing the mass dependence of the physical \(\alpha_V\) scheme. In effect, quark thresholds are treated analytically to all orders in \(m^2/Q^2\); i.e., the evolution of the physical \(\alpha_V\) coupling in the intermediate regions reflects the actual mass dependence of a physical effective charge and the analytic properties of particle production. Furthermore, the definiteness of the dependence in the quark masses automatically constrains the scale \(Q\) in the argument of the coupling. There is thus no scale ambiguity in perturbative expansions in \(\alpha_V\).

In the conventional \(\overline{\text{MS}}\) scheme, the coupling is independent of the quark masses since the quarks are treated as either massless or infinitely heavy with respect to the running of the coupling. Thus one formulates different effective theories depending on the effective number of quarks which is governed by the scale \(Q\); the massless \(\beta\)-function is used to describe the running in between the flavor thresholds. These different theories are then matched to each other by imposing matching conditions at the scale where the effective number of flavors is changed (normally the quark masses). The dependence on the matching scale can be made arbitrarily small by calculating the matching conditions to high enough order. For physical observables one can then include the effects of finite quark masses by making a higher-twist expansion in \(m^2/Q^2\) and \(Q^2/m^2\) for light and heavy quarks, respectively. These higher-twist contributions have to be calculated for each observables separately, so that in principle one requires an all-order resummation of the mass corrections to the effective Lagrangian to give correct results.

The specification of the coupling and renormalization scheme also depends on the definition of the quark mass. In contrast to QED where the on-shell mass provides a natural definition of lepton masses, an on-shell definition for quark masses is complicated by the confinement property of QCD. In this paper we will use the pole mass
\( m(p^2 = m^2) = m \) which has the advantage of being scheme and renormalization-scale invariant. Furthermore, when combined with the \( \alpha_V \) scheme, the pole mass gives predictions which are free of the leading renormalon ambiguity.

A technical complication of massive schemes is that one cannot easily obtain analytic solutions of renormalization group equations to the massive \( \beta \) function, and the Gell-Mann Low function is scheme-dependent even at lowest order.

In a recent paper we have presented a two-loop analytic extension of the \( \alpha_V \)-scheme based on the recent results of Ref. \[117\]. The mass effects are in principle treated exactly to two-loop order and are only limited in practice by the uncertainties from numerical integration. The desired features of gauge invariance and decoupling are manifest in the form of the two-loop Gell-Mann Low function, and we give a simple fitting-function which interpolates smoothly the exact two-loop results obtained by using the adoptive Monte Carlo integrator VEGAS\[118\]. Strong consistency checks of the results are performed by comparing the Abelian limit to the well known QED results in the on-shell scheme. In addition, the massless as well as the decoupling limit are reproduced exactly, and the two-loop Gell-Mann Low function is shown to be renormalization scale independent.

The results of our numerical calculation of \( N_{F,V}^{(1)} \) in the \( V \)-scheme for QCD and QED are shown in Fig. 3. The decoupling of heavy quarks becomes manifest at small \( Q/m \), and the massless limit is attained for large \( Q/m \). The QCD form actually becomes negative at moderate values of \( Q/m \), a novel feature of the anti-screening non-Abelian contributions. This property is also present in the (gauge dependent) MOM results. In contrast, in Abelian QED the two-loop contribution to the effective number of flavors becomes larger than 1 at intermediate values of \( Q/m \). We also display the one-loop contribution \( N_{F,V}^{(0)} \left( \frac{Q}{m} \right) \) which monotonically interpolates between the decoupling and massless limits. The solid curves displayed in Fig. 3 shows that the parameterizations which we used for fitting the numerical results are quite accurate.

The relation of \( \alpha_V(Q^2) \) to the conventional \( \overline{MS} \) coupling is now known to NNLO,\[119\] but for clarity in this section only the NLO relation will be used. The commensurate scale relation is given by\[120\]

\[
\alpha_{\overline{MS}}(Q) = \alpha_V(Q^* \ell) + 2 \frac{\alpha^2_V(Q^*)}{\pi},
\]

(29)

which is valid for \( Q^2 \gg m^2 \). The coefficients in the perturbation expansion have their
Figure 3: The numerical results for the gauge-invariant $N_{F,V}^{(1)}$ in QED (open circles) and QCD (triangles) with the best $\chi^2$ fits superimposed respectively. The dashed line shows the one-loop $N_{F,V}^{(0)}$ function. For comparison we also show the gauge dependent two-loop result obtained in MOM schemes (dash-dot) \cite{121,122}. At large $Q/m$ the theory becomes effectively massless, and both schemes agree as expected. The figure also illustrates the decoupling of heavy quarks at small $Q/m$.

conformal values, \textit{i.e.}, the same coefficients would occur even if the theory had been conformally invariant with $\beta = 0$. The commensurate scale is given by

$$Q^* = Q \exp \left[ \frac{5}{6} \right].$$  

The scale in the $\overline{MS}$ scheme is thus a factor $\sim 0.4$ smaller than the physical scale. The coefficient $2N_C/3$ in the NLO coefficient is a feature of the non-Abelian couplings of QCD; the same coefficient occurs even if the theory were conformally invariant with $\beta_0 = 0$.

Using the above QCD results, we can transform any NLO prediction given in $\overline{MS}$ scheme to a scale-fixed expansion in $\alpha_V(Q)$. We can also derive the connection

33
between the $\overline{MS}$ and $\alpha_V$ schemes for Abelian perturbation theory using the limit $N_C \to 0$ with $C_F \alpha_s$ and $N_F/C_F$ held fixed.\[2\]

The use of $\alpha_V$ and related physically defined effective charges such as $\alpha_p$ (to NLO the effective charge defined from the (1,1) plaquette, $\alpha_p$ is the same as $\alpha_V$) as expansion parameters has been found to be valuable in lattice gauge theory, greatly increasing the convergence of perturbative expansions relative to those using the bare lattice coupling.\[109\] Recent lattice calculations of the $\Upsilon$- spectrum\[123\] have been used with BLM scale-fixing to determine a NLO normalization of the static heavy quark potential: $\alpha_V^{(3)}(8.2\text{GeV}) = 0.196(3)$ where the effective number of light flavors is $n_f = 3$. The corresponding modified minimal subtraction coupling evolved to the $Z$ mass and five flavors is $\alpha_M^{(5)}(M_Z) = 0.1174(24)$. Thus a high precision value for $\alpha_V(Q^2)$ at a specific scale is available from lattice gauge theory. Predictions for other QCD observables can be directly referenced to this value without the scale or scheme ambiguities, thus greatly increasing the precision of QCD tests.

One can also use $\alpha_V$ to characterize the coupling which appears in the hard scattering contributions of exclusive process amplitudes at large momentum transfer, such as elastic hadronic form factors, the photon-to-pion transition form factor at large momentum transfer\[16, 19\] and exclusive weak decays of heavy hadrons.\[124\] Each gluon propagator with four-momentum $k^\mu$ in the hard-scattering quark-gluon scattering amplitude $T_H$ can be associated with the coupling $\alpha_V(k^2)$ since the gluon exchange propagators closely resembles the interactions encoded in the effective potential $V(Q^2)$. [In Abelian theory this is exact.] Commensurate scale relations can then be established which connect the hard-scattering subprocess amplitudes which control exclusive processes to other QCD observables.

We can anticipate that eventually nonperturbative methods such as lattice gauge theory or discretized light-cone quantization will provide a complete form for the heavy quark potential in QCD. It is reasonable to assume that $\alpha_V(Q)$ will not diverge at small space-like momenta. One possibility is that $\alpha_V$ stays relatively constant $\alpha_V(Q) \simeq 0.4$ at low momenta, consistent with fixed-point behavior. There is, in fact, empirical evidence for freezing of the $\alpha_V$ coupling from the observed systematic dimensional scaling behavior of exclusive reactions.\[13\] If this is in fact the case, then the range of QCD predictions can be extended to quite low momentum scales, a regime normally avoided because of the apparent singular structure of perturbative extrapolations.

There are a number of other advantages of the $V$-scheme:
1. Perturbative expansions in $\alpha_V$ with the scale set by the momentum transfer cannot have any $\beta$-function dependence in their coefficients since all running coupling effects are already summed into the definition of the potential. Since coefficients involving $\beta_0$ cannot occur in an expansions in $\alpha_V$, the divergent infrared renormalon series of the form $\alpha^n_V \beta^n_0 n!$ cannot occur. The general convergence properties of the scale $Q^*$ as an expansion in $\alpha_V$ is not known.\[34\]

2. The effective coupling $\alpha_V(Q^2)$ incorporates vacuum polarization contributions with finite fermion masses. When continued to time-like momenta, the coupling has the correct analytic dependence dictated by the production thresholds in the $t$ channel. Since $\alpha_V$ incorporates quark mass effects exactly, it avoids the problem of explicitly computing and resumming quark mass corrections.

3. The $\alpha_V$ coupling is the natural expansion parameter for processes involving non-relativistic momenta, such as heavy quark production at threshold where the Coulomb interactions, which are enhanced at low relative velocity $v$ as $\pi \alpha_V / v$, need to be re-summed.\[123\] \[126\] \[127\] The effective Hamiltonian for nonrelativistic QCD is thus most naturally written in $\alpha_V$ scheme. The threshold corrections to heavy quark production in $e^+e^-$ annihilation depend on $\alpha_V$ at specific scales $Q^*$. Two distinct ranges of scales arise as arguments of $\alpha_V$ near threshold: the relative momentum of the quarks governing the soft gluon exchange responsible for the Coulomb potential, and a high momentum scale, induced by hard gluon exchange, approximately equal to twice the quark mass for the corrections.\[126\] One thus can use threshold production to obtain a direct determination of $\alpha_V$ even at low scales. The corresponding QED results for $\tau$ pair production allow for a measurement of the magnetic moment of the $\tau$ and could be tested at a future $\tau$-charm factory.\[123\] \[126\]

We also note that computations in different sectors of the Standard Model have been traditionally carried out using different renormalization schemes. However, in a grand unified theory, the forces between all of the particles in the fundamental representation should become universal above the grand unification scale. Thus it is natural to use $\alpha_V$ as the effective charge for all sectors of a grand unified theory, rather than in a convention-dependent coupling such as $\alpha_{\overline{MS}}$.\[35\]
11 The Analytic Extension of the $\overline{MS}$ Scheme

The standard $\overline{MS}$ scheme is not an analytic function of the renormalization scale at heavy quark thresholds; in the running of the coupling the quarks are taken as massless, and at each quark threshold the value of $N_F$ which appears in the $\beta$ function is incremented. Thus Eq. (29) is technically only valid far above a heavy quark threshold. However, we can use this commensurate scale relation to define an extended $\overline{MS}$ scheme which is continuous and analytic at any scale. The new modified scheme inherits all of the good properties of the $\alpha_V$ scheme, including its correct analytic properties as a function of the quark masses and its unambiguous scale fixing.[120] Thus we define

$$\tilde{\alpha}_{\overline{MS}}(Q) = \alpha_V(Q^*) + \frac{2N_C}{3} \frac{\alpha^2_V(Q^{**})}{\pi} + \cdots,$$

(31)

for all scales $Q$. This equation not only provides an analytic extension of the $\overline{MS}$ and similar schemes, but it also ties down the renormalization scale to the physical masses of the quarks as they enter into the vacuum polarization contributions to $\alpha_V$.

The modified scheme $\tilde{\alpha}_{\overline{MS}}$ provides an analytic interpolation of conventional $\overline{MS}$ expressions by utilizing the mass dependence of the physical $\alpha_V$ scheme. In effect, quark thresholds are treated analytically to all orders in $m^2/Q^2$; i.e., the evolution of the analytically extended coupling in the intermediate regions reflects the actual mass dependence of a physical effective charge and the analytic properties of particle production. Just as in Abelian QED, the mass dependence of the effective potential and the analytically extended scheme $\tilde{\alpha}_{\overline{MS}}$ reflects the analyticity of the physical thresholds for particle production in the crossed channel. Furthermore, the definiteness of the dependence in the quark masses automatically constrains the renormalization scale. There is thus no scale ambiguity in perturbative expansions in $\alpha_V$ or $\tilde{\alpha}_{\overline{MS}}$.

In leading order the effective number of flavors in the modified scheme $\tilde{\alpha}_{\overline{MS}}$ is given to a very good approximation by the simple form[120]

$$\tilde{N}_{F,\overline{MS}}(m^2/Q^2) \approx \left(1 + \frac{5m^2}{Q^2 \exp\left(\frac{5}{3}\right)}\right)^{-1} \approx \left(1 + \frac{m^2}{Q^2}\right)^{-1}.$$

(32)

Thus the contribution from one flavor is $\approx 0.5$ when the scale $Q$ equals the quark mass $m_i$. The standard procedure of matching $\alpha_{\overline{MS}}(\mu)$ at the quark masses serves as a zeroth-order approximation to the continuous $N_F$.

Adding all flavors together gives the total $\tilde{N}_{F,\overline{MS}}(Q)$ which is shown in Fig. 4. For reference, the continuous $N_F$ is also compared with the conventional procedure

36
The continuous $\tilde{N}_{F,\overline{\text{MS}}}^{(0)}$ in the analytic extension of the $\overline{\text{MS}}$ scheme as a function of the physical scale $Q$. (For reference the continuous $N_F$ is also compared with the conventional procedure of taking $N_F$ to be a step-function at the quark-mass thresholds.)

The figure shows clearly that there are hardly any plateaus at all for the continuous $\tilde{N}_{F,\overline{\text{MS}}}^{(0)}(Q)$ in between the quark masses. Thus there is really no scale below 1 TeV where $\tilde{N}_{F,\overline{\text{MS}}}^{(0)}(Q)$ can be approximated by a constant; for all $Q$ below 1 TeV there is always one quark with mass $m_i$ such that $m_i^2 \ll Q^2$ or $Q^2 \gg m_i^2$ is not true. We also note that if one would use any other scale than the BLM-scale for $\tilde{N}_{F,\overline{\text{MS}}}^{(0)}(Q)$, the result would be to increase the difference between the analytic $N_F$ and the standard procedure of using the step-function at the quark-mass thresholds.

Figure 5 shows the relative difference between the two different solutions of the 1-loop renormalization group equation, i.e. $(\tilde{\alpha}_{\overline{\text{MS}}}(Q) - \alpha_{\overline{\text{MS}}}(Q))/\tilde{\alpha}_{\overline{\text{MS}}}(Q)$. The solutions have been obtained numerically starting from the world average $\alpha_{\overline{\text{MS}}}(M_Z) = 0.118$. The figure shows that taking the quark masses into account in the running leads to effects of the order of one percent which are most especially pronounced near thresholds.
Figure 5: The solid curve shows the relative difference between the solutions to the 1-loop renormalization group equation using continuous $N_F$, $\tilde{\alpha}_{\overline{\text{MS}}}(Q)$, and conventional discrete theta-function thresholds, $\alpha_{\overline{\text{MS}}}(Q)$. The dashed (dotted) curves shows the same quantity but using the scale $2Q$ ($Q/2$) in $\tilde{N}_{F,\overline{\text{MS}}}$. The solutions have been obtained numerically starting from the world average $[128] \alpha_{\overline{\text{MS}}}(M_Z) = 0.118$.

The extension of the $\overline{\text{MS}}$-scheme proposed here provides a coupling which is an analytic function of both the scale and the quark masses. The new modified coupling $\tilde{\alpha}_{\overline{\text{MS}}}(Q)$ inherits most of the good properties of the $\alpha_V$ scheme, including its correct analytic properties as a function of the quark masses and its unambiguous scale fixing $[120]$. However, the conformal coefficients in the commensurate scale relation between the $\alpha_V$ and $\overline{\text{MS}}$ schemes does not preserve one of the defining criterion of the potential expressed in the bare charge, namely the non-occurrence of color factors corresponding to an iteration of the potential. This is probably an effect of the breaking of conformal invariance by the $\overline{\text{MS}}$ scheme. The breaking of conformal symmetry has also been observed when dimensional regularization is used as a factorization scheme in both exclusive $[57, 129, 130]$ and inclusive $[131]$ reactions. Thus, it does not turn out to be possible to extend the modified scheme $\tilde{\alpha}_{\overline{\text{MS}}}$ beyond leading order without running into an intrinsic contradiction with conformal symmetry.
12 Application of Commensurate Scale Relations to the Hard QCD Pomeron

The observation of rapidly increasing structure functions in deep inelastic scattering at small-$x_{bj}$ and the observation of rapidly increasing diffractive processes such as $\gamma^*p \rightarrow \rho p$ at high energies at HERA is in agreement with the expectations of the BFKL QCD high-energy limit. The highest eigenvalue, $\omega_{max}$, of the leading order (LO) BFKL equation is related to the intercept of the Pomeron which in turn governs the high-energy asymptotics of the cross sections: $\sigma \sim s^{\alpha_I - 1} = s^{\omega_{max}}$. The BFKL Pomeron intercept in LO turns out to be rather large: $\alpha_I - 1 = \omega_{max} = 12 \ln 2 (\alpha_S/\pi) \simeq 0.55$ for $\alpha_S = 0.2$; hence, it is very important to know the next-to-leading order (NLO) corrections.

Recently the NLO corrections to the BFKL resummation of energy logarithms were calculated by employing the modified minimal subtraction scheme (MS) to regulate the ultraviolet divergences with arbitrary scale setting. The NLO corrections to the highest eigenvalue of the BFKL equation turn out to be negative and even larger than the LO contribution for $\alpha_s > 0.157$. It is thus important to analyze the NLO BFKL resummation of energy logarithms in physical renormalization schemes and apply the BLM-CSR method. In fact, as shown in a recent paper, the reliability of QCD predictions for the intercept of the BFKL Pomeron at NLO when evaluated using BLM scale setting within non-Abelian physical schemes, such as the momentum space subtraction (MOM) scheme or the $\Upsilon$-scheme based on $\Upsilon \rightarrow ggg$ decay, is significantly improved compared to the MS-scheme.

The renormalization scale ambiguity problem can be resolved if one can optimize the choice of scales and renormalization schemes according to some sensible criteria. In the BLM optimal scale setting, the renormalization scales are chosen such that all vacuum polarization effects from the QCD $\beta$-function are resummed into the running couplings. The coefficients of the perturbative series are thus identical to the perturbative coefficients of the corresponding conformally invariant theory with $\beta = 0$.

In the present case one can show that within the V-scheme (or the MS-scheme) the BLM procedure does not change significantly the value of the NLO coefficient $r(\nu)$. This can be understood since the V-scheme, as well as MS-scheme, are ad-
justed primarily to the case when in the LO there are dominant QED (Abelian) type contributions, whereas in the BFKL case there are important LO gluon-gluon (non-Abelian) interactions. Thus one can choose for the BFKL case the MOM-scheme [137, 138] or the Υ-scheme based on Υ → ggg decay.

Adopting BLM scale setting, the NLO BFKL eigenvalue in the MOM-scheme is

$$\omega_{BSM}^2(Q^2, \nu) = N_{\chi L}(\nu) \frac{\alpha_{BSM}(Q_{BSM}^2)}{\pi} \left[ 1 + r_{BSM}^2(\nu) \frac{\alpha_{BSM}(Q_{BSM}^2)}{\pi} \right], \quad (33)$$

$$r_{BSM}^2(\nu) = r_{BSM}^{conf}(\nu).$$

The $\beta$-dependent part of the $r_{BSM}^2(\nu)$ defines the corresponding BLM optimal scale

$$Q_{BSM}^2(\nu) = Q^2 \exp \left[ -\frac{4\alpha_{BSM}(\nu)}{\beta_0} \right] = Q^2 \exp \left[ \frac{1}{2} \chi L(\nu) - \frac{5}{2} + 2 \left( 1 + \frac{2}{3} \right) \right]. \quad (34)$$

At $\nu = 0$ we have $Q_{BSM}^2(0) = Q^2 (4 \exp[2(1 + 2I/3) - 5/3]) \simeq Q^2 127$. Note that $Q_{BSM}^2(\nu)$ contains a large factor, $\exp[-4\alpha_{BSM}(\nu)/\beta_0] = \exp[2(1 + 2I/3)] \simeq 168$, which reflects a large kinematic difference between MOM- and $\overline{\text{MS}}$- schemes [139, 16].

One of the striking features of this analysis is that the NLO value for the intercept of the BFKL Pomeron, improved by the BLM procedure, has a very weak dependence on the gluon virtuality $Q^2$. This agrees with the conventional Regge-theory where one expects an universal intercept of the Pomeron without any $Q^2$-dependence. The minor $Q^2$-dependence obtained, on one side, provides near insensitivity of the results to the precise value of $\Lambda$, and, on the other side, leads to approximate scale and conformal invariance. Thus one may use conformal symmetry [140, 141] for the continuation of the present results to the case $t \neq 0$.

The NLO corrections to the BFKL equation for the QCD Pomeron thus become controllable and meaningful provided one uses physical renormalization scales and schemes relevant to non-Abelian gauge theory. BLM optimal scale setting automatically sets the appropriate physical renormalization scale by absorbing the non-conformal $\beta$-dependent coefficients. The strong renormalization scheme dependence of the NLO corrections to BFKL resummation then largely disappears. This is in contrast to the unstable NLO results obtained in the conventional $\overline{\text{MS}}$-scheme with arbitrary choice of renormalization scale. A striking feature of the NLO BFKL Pomeron intercept in the BLM approach is its very weak $Q^2$-dependence, which provides approximate conformal invariance.
The new results presented here open new windows for applications of NLO BFKL resummation to high-energy phenomenology.

Recently the $L3$ collaboration at LEPL3 has presented new results for the virtual photon cross section $\sigma(\gamma^*(Q_A)\gamma^*(Q_b) \rightarrow \text{hadrons}$ using double tagged $e^+e^- \rightarrow e^+e^-$ hadrons. This process provides a remarkably clean possible test of the perturbative QCD pomeron since there are no initial hadrons. The calculation of $\sigma(\gamma^*\gamma^*)$ and is discussed in detail in references [142]. We note here some important features:

i) for large virtualities, $\sigma(\gamma^*\gamma^*)$ the longitudinal cross section $\sigma_{LL}$ dominates and scales like $1/Q^2$, where $Q^2 \sim \max\{Q^2_A, Q^2_B\}$. This is characteristic of the perturbative QCD prediction. Models based on Regge factorization (which work well in the soft-interaction regime dominating $\gamma\gamma$ scattering near the mass shell) would predict a higher power in $1/Q$.

ii) $\sigma(\gamma^*\gamma^*)$ is affected by logarithmic corrections in the energy $s$ to all orders in $\alpha_s$. As a result of the BFKL summation of these contributions, the cross section rises like a power in $s$, $\sigma \propto s^\lambda$. The Born approximation to this result (that is, the $\mathcal{O}(\alpha_s^2)$ contribution, corresponding to single gluon exchange gives a constant cross section, $\sigma_{\text{Born}} \propto s^0$. A fit to photon-photon sub-energy dependence measured by L3 at $\sqrt{s_{e^+e^-}} = 91$ GeV and $<Q^2_A> = <Q^2_B> = 3.5$ GeV$^2$ gives $\alpha_P - 1 = 0.28 \pm 0.05$. The L3 data at $\sqrt{s_{e^+e^-}} = 183$ GeV and $<Q^2_A> = <Q^2_B> = 14$ GeV$^2$, gives $\alpha_P - 1 = 0.40 \pm 0.07$ which shows a rise of the virtual photon cross section much stronger than single gluon or soft pomeron exchange, but it is compatible with the expectations from the NLO scale- and scheme-fixed BFKL predictions. It will be crucial to measure the $Q^2_A$ and $Q^2_B$ scaling and polarization dependence and compare with the detailed predictions of PQCD [142].

13 Summary on Commensurate Scale Relations

Commensurate scale relations have a number of attractive properties:

1. The ratio of physical scales $Q_A/Q_B$ which appears in commensurate scale relations reflects the relative position of physical thresholds, i.e. quark anti-quark pair production.

2. The functional dependence and perturbative expansion of the CSR are identical to those of a conformal scale-invariant theory where $\beta_A(\alpha_A) = 0$ and $\beta_B(\alpha_B) = 0$. 

41
3. In the case of theories approaching fixed-point behavior $\beta_A(\alpha_A) = 0$ and $\beta_B(\alpha_B) = 0$, the commensurate scale relation relates both the ratio of fixed point couplings $\alpha_A/\alpha_B$, and the ratio of scales as the fixed point is approached.

4. Commensurate scale relations satisfy the Abelian correspondence principle \[93\]; i.e. the non-Abelian gauge theory prediction reduces to Abelian theory for $N_C \to 0$ at fixed $C_F \alpha_s$ and fixed $N_F/C_F$.

5. The perturbative expansion of a commensurate scale relation has the same form as a conformal theory, and thus has no $n!$ renormalon growth arising from the $\beta$-function.\[143\] It is an interesting conjecture whether the perturbative expansion relating observables to observable are in fact free of all $n!$ growth. The generalized Crewther relation, where the commensurate relation’s perturbative expansion forms a geometric series to all orders, has convergent behavior.

Virtually any perturbative QCD prediction can be written in the form of a commensurate scale relation, thus eliminating any uncertainty due to renormalization scheme or scale dependence. Recently it has been shown\[144\] how the commensurate scale relation between the radiative corrections to $\tau$-lepton decay and $R_{e^+e^-}(s)$ can be generalized and empirically tested for arbitrary $\tau$ mass and nearly arbitrarily functional dependence of the $\tau$ weak decay matrix element.

An essential feature of the $\alpha_V(Q)$ scheme is the absence of any renormalization scale ambiguity, since $Q^2$ is, by definition, the square of the physical momentum transfer. The $\alpha_V$ scheme naturally takes into account quark mass thresholds, which is of particular phenomenological importance to QCD applications in the mass region close to threshold. As we have seen, commensurate scale relations provide an analytic extension of the conventional $\overline{\text{MS}}$ scheme in which many of the advantages of the $\alpha_V$ scheme are inherited by the $\tilde{\alpha}_{\overline{\text{MS}}}$ scheme, but only minimal changes have to be made. Given the commensurate scale relation connecting $\tilde{\alpha}_{\overline{\text{MS}}}$ to $\alpha_V$ expansions in $\tilde{\alpha}_{\overline{\text{MS}}}$ are effectively expansions in $\alpha_V$ to the given order in perturbation theory at a corresponding commensurate scale.

The calculation of $\psi_{\alpha_V}^{(1)}$, the two-loop term in the Gell-Mann Low function for the $\alpha_V$ scheme, with massive quarks gives for the first time a gauge invariant and renormalization scheme independent two-loop result for the effects of quarks masses in the running of the coupling. Renormalization scheme independence is achieved by using the pole mass definition for the “light” quarks which contribute to the scale
dependence of the static heavy quark potential. Thus the pole mass and the V-scheme are closely connected and have to be used in conjunction to give reasonable results.

It is interesting that the effective number of flavors in the two-loop coefficient of the Gell-Mann Low function in the $\alpha_V$ scheme, $N_{F,V}^{(1)}$, becomes negative for intermediate values of $Q/m$. This feature can be understood as anti-screening from the non-Abelian contributions and should be contrasted with the QED case where the effective number of flavors becomes larger than 1 for intermediate $Q/m$. For small $Q/m$ the heavy quarks decouple explicitly as expected in a physical scheme, and for large $Q/m$ the massless result is retained.

The analyticity of the $\alpha_V$ coupling can be utilized to obtain predictions for any perturbatively calculable observables including the finite quark mass effects associated with the running of the coupling. By employing the commensurate scale relation method, observables which have been calculated in the $\overline{\text{MS}}$ scheme can be related to the analytic V-scheme without any scale ambiguity. The commensurate scale relations provides the relation between the physical scales of two effective charges where they pass through a common flavor threshold. We also note the utility of the $\alpha_V$ effective charge in supersymmetric and grand unified theories, particularly since the unification of couplings and masses would be expected to occur in terms of physical quantities rather than parameters defined by theoretical convention.

As an example we have showed in Ref. [120] how to calculate the finite quark mass corrections connected with the running of the coupling for the non-singlet hadronic width of the Z-boson compared with the standard treatment in the $\overline{\text{MS}}$ scheme. The analytic treatment in the V-scheme gives a simple and straightforward way of incorporating these effects for any observable. This should be contrasted with the $\overline{\text{MS}}$ scheme where higher twist corrections due to finite quark mass threshold effects have to be calculated separately for each observable. The V-scheme is especially suitable for problems where the quark masses are important such as for threshold production of heavy quarks and the hadronic width of the $\tau$ lepton.

It has also been shown that the NLO corrections to the BFKL equation for the QCD Pomeron become controllable and meaningful provided one uses physical renormalization scales and schemes relevant to non-Abelian gauge theory. BLM optimal scale setting automatically sets the appropriate physical renormalization scale by absorbing the non-conformal $\beta$-dependent coefficients. The strong renormalization scheme dependence of the NLO corrections to BFKL resummation then largely disappears. This is in contrast to the unstable NLO results obtained in the conven-
tional $\overline{\text{MS}}$-scheme with arbitrary choice of renormalization scale. A striking feature of the NLO BFKL Pomeron intercept in the BLM/CSR approach is its very weak $Q^2$-dependence, which provides approximate conformal invariance. The new results presented here open new windows for applications of NLO BFKL resummation to high-energy phenomenology, particularly virtual photon-photon scattering.

Acknowledgments

Many of the results presented here are based on collaborations with a number of colleagues, including Victor Fadin, Gregory Gabadadze, Mandeep Gill, John Hiller, Dae Sung Hwang, Chueng Ji, Andrei Kataev, Victor Kim, Peter Lepage, Lev Lipatov, Hung Jung Lu, Gary McCartor, Michael Melles, Chris Pauli, Grigorii B. Pivovarov, and Johan Rathsman. I thank S. Dalley, Yitzhak Frishman, Einan Gardi, Georges Grunberg, Paul Hoyer, Marek Karliner, Carlos Merino, and Jose Pelaez for helpful conversations. The sections on commensurate scale relations are based on a review written in collaboration with Johan Rathsman. I also wish to thank Chueng Ji and Dong-Pil Min for their outstanding hospitality at the Asia Pacific Center for Theoretical Physics in Seoul.
