Summary We tested the ability of hormones and growth factors to enhance the colony formation in soft agarose of breast carcinoma using two human breast carcinoma cell lines, MCF-7 and MDA-MB231. MCF-7 could clone in a basal medium supplemented only by insulin, transferrin, prostaglandin F2α, and fibronectin. Combining oestradiol, dexamethasone, insulin, transferrin, and triiodothyronine with a basal medium supplemented with 5% (v/v) foetal bovine serum (FBS) increased colony forming efficiency (CFE) two-to-three fold over the best obtained in serum supplemented medium without hormones. While optimal CFE was seen in the hormonally supplemented medium plus 5% FBS, clonal anchorage independent growth could also be obtained without serum for both cell lines by substituting 0.5–1% (v/v) bovine serum albumin (BSA) for FBS. Although CFE was enhanced with the addition of hormones, they did not substantially alter the in vitro chemosensitivity patterns of the cell lines to 8 cytotoxic drugs. Hormonally-supplemented medium with 5% FBS increased the CFE of a small number of fresh specimens of human breast cancer compared with medium supplemented with serum alone. The systematic study of requirements for the in vitro growth of human breast cancer may improve drug sensitivity testing by increasing our ability to grow this neoplasm in culture.

Although excellent palliation of patients with metastatic breast cancer can be achieved with existing therapies, the majority of patients will still succumb to their disease. Therefore, new drugs and new treatment strategies must be found. One promising recent approach is the use of clonogenic assays to predict chemosensitivity in the individual patient (Salmon et al., 1978; Courtenay et al., 1978; Carney et al., 1980; Von Hoff et al., 1981). However, the success of the commonly used in vitro assays requires the ability to clone human tumours in semi-solid medium with a colony forming efficiency (CFE) sufficiently high to permit accurate analysis. At the present time, with standard culture techniques, the CFE of most fresh tumour specimens, including breast carcinoma, varies from 0.001–0.3%, permitting in vitro drug testing in only 20–35% of all specimens (Carney et al., 1981a; Bertoncello et al., 1982; Pavelic et al., 1980; Rupniak & Hill, 1980; Sandbach et al., 1982).

One approach to improve the anchorage independent, clonal growth of human tumours is to systematically analyze the nutritional requirements of a cell line of a particular type, as has been done for Raji lymphoma cells (Ayres, 1982). We have found that cell lines established from human neoplasms such as the various histological types of lung cancer tend to retain certain characteristics of the parent tumour including nutritional requirements and drug sensitivity profiles (Carney et al., 1981b, 1982, 1983a). For breast cancer, the established cell line MCF-7 has been used as a model for many hormonal and nutritional studies, as well as for development of in vitro chemosensitivity testing (Soule et al., 1973; Elson et al., 1982).

Because hormones are known to influence the growth of breast carcinoma in vitro (Klevjer-Anderson & Buehring, 1980), we decided to undertake a study to improve the growth of human breast carcinoma in agarose by adding hormones to basal medium. Since hormones, particularly oestradiol, may alter the chemosensitivity patterns of these cells to cytotoxic agents, we also evaluated the influence of hormone addition on chemosensitivity. Using previously described serum-free media which support the growth of human mammary carcinoma cell lines in liquid culture (Allegr & Lippman, 1978; Barnes & Sato, 1979), a 2–3 fold increase in the CFE in agarose of two breast carcinoma lines with different estrogen receptor status was obtained. CFE w-s also higher in the hormonally-supplemented medium for a small number of fresh breast cancer specimens.

Despite the increase in CFE, in vitro chemosensitivity of the cell lines to a variety of drugs was similar in hormone supplemented and non-supplemented medium.

Materials and methods

Cell lines

The human breast carcinoma lines MCF-7 (Soule et al., 1973) and MDA-MB231 (Cailleau et al., 1974) were kindly provided by Dr. M. Lippman, National Cancer Institute, Bethesda, Maryland, and were free of mycoplasma contamination (Microbiological Associates, Bethesda, Maryland). MCF-7 was established from a patient previously treated with radiation and hormone therapy, and has receptors for oestrogens, glucocorticoids, and insulin (Horwitz et al., 1978). MDA-MB231 was established from a patient previously treated with chemotherapy, and these cells have receptors for glucocorticoids and insulin but not for oestrogens (Horwitz et al., 1978). The two cell lines were routinely maintained in Falcon plastic flasks (75 sq. cm.) at 37°C in 5% CO₂, 95% air, in Dulbecco’s minimum essential medium (DMEM) supplemented with 10% foetal bovine serum (FBS) without antibiotics. Cells were passaged weekly for MCF-7 and twice weekly for MDA-MB231 by trypsinisation.

Culture media

The hormone supplemented media tested are listed in Table I. Medium A, designed by Allegro & Lippman (1978) to support the growth of the breast cell line ZR-75-1, contains insulin, transferrin, dexamethasone, triiodothyronine, and 17β oestradiol. Medium B, designed by Barnes & Sato (1979), supports the growth of MCF-7 in liquid cultures as a floating cell line. This medium was slightly modified for these experiments and contains insulin, transferrin, prostaglandin F₂, and fibronectin.

The medium in common use for the human tumour stem cell assay (HTSCA medium) (Soehnlen et al., 1981) was slightly modified to exclude DEAE dextran and mercaptoethanol from the overlay and splenic conditioned medium from the underlayer. In addition, agarose was used in place of agar in both layers.

DMEM, F12, McCos 5A, and CMRL 1066 media, FBS, horse serum, trypsin-EDTA (0.5 g trypsin and 0.2 g EDTA per litre in Hanks balanced salt solution without Ca²⁺ and Mg²⁺), L-glutamine, asparagine, L-serine, L-ascorbic acid, and penicillin-streptomycin solution (penicillin 10000 U ml⁻¹, streptomycin 10000 mcg ml⁻¹) were obtained from GIBCO Laboratories, Grand Island, New York. Human transferrin, L-triiodothyronine, bovine insulin, 17β oestradiol, dexamethasone, prostaglandin F₂, sodium pyruvate, and calcium chloride were obtained from Sigma Chemicals, St. Louis, MO. Tryptic soy broth was obtained from DIFCO, Detroit, MI. Bovine albumin fraction V was obtained from Miles Laboratory, Inc., Elkhart, Indiana.

Soft agarose cloning experiments

Cells cultured in serum supplemented medium were harvested in log phase growth with trypsin-EDTA, washed twice in DMEM, and a single cell suspension obtained by trituration; if clumps persisted, single cells were obtained by passage through 18–25 gauge needles. Cells were then counted by haemocytometer and 10⁴ viable cells (by trypsin blue exclusion) were suspended in the medium being tested with 1% (v/v) penicillin-streptomycin solution and 0.3% (v/v) agarose (Seakem, Rockland, Maine) at 40°C. One ml of the mixture was plated in triplicate in a 35 mm plastic petri dish containing a base layer of 0.5% agarose in culture medium (v/v) that had hardened. Cultures were incubated at 37°C in a humidified atmosphere of 10% CO₂, 90% air. The plates were initially examined with an inverted phase microscope to confirm that only single cells had been plated. Colonies (>50 cells) were counted 12 to 15 days after plating and the CFE determined. Each cloning experiment reported here was performed 3 times, and the results given are the means of these 3 values. For clinical specimens (effusions), viable mononuclear cells were isolated by density centrifugation using Ficoll-Hyphaque (Boyum, 1968; Katz & Lukeman, 1980). We
obtained a single cell suspension by passage through 18–25 gauge needles, and then plated 10⁵ viable mononuclear cells per dish.

In vitro chemosensitivity

The in vitro sensitivities of the cell lines to eight cytotoxic agents were determined as previously described (Salmon et al., 1978; Von Hoff et al., 1981). Cells (10⁴) were incubated for 1 h in DMEM at 37°C with 3 different drug concentrations: clinically achievable peak plasma concentration, and 10% and 1% of this concentration. After incubation, the cells were washed twice in DMEM and plated as described above. Sensitivity was defined as a 70% reduction of colony number after 1 h exposure to 10% peak plasma concentration, or 0.3 µg ml⁻¹ for methotrexate, 0.06 µg ml⁻¹ for adriamycin, 0.1 µg ml⁻¹ for vincristine, 0.5 µg ml⁻¹ for vinblastine, 6 µg ml⁻¹ for 5-fluorouracil, 0.25 µg ml⁻¹ for mephalan, 0.2 µg ml⁻¹ for cisplatinum, and 0.1 µg ml⁻¹ for mitomycin C (Alberts & Chen, 1981).

Results

Soft agarose cloning

The CFE of the two cell lines in different media is shown in Tables II and III. The optimal concentration of FBS when used as the only supplement to the basal medium (DMEM) was 10% (Table II). In DMEM + 10% FBS, CFE was 4.9% for MCF-7 and 4.0% for MDA-MB231.

Neither cell line could clone in serum-free medium A alone, but MCF-7 did clone in serum-free medium B although CFE was low at 0.3%. MDA-MB231 could not clone in either serum-free medium without further supplementation (Table II).

The optimal concentration of FBS when used to further enrich hormone-supplemented medium (A or B) was 5% (Table II). In medium A + 5% FBS, CFE was 8.6% for MCF-7 and 10.8% for MDA-MB231. This represents a 2-fold increase for MCF-7 and a 3-fold increase for MDA-MB231 over the optimal CFE obtained without hormonal supplementation. Even the addition of 1% FBS enhanced colony formation, particularly with medium B. Adding more than 5% FBS to the defined media led to decreased CFE, falling to <0.5% with 40% FBS.

Some colony formation was obtained with both cell lines in modified HTSCA medium, but CFE was only 0.15% for MCF-7 and 0.1% for MDA-MB231 (Table II). We see that the CFE of MCF-7 and MDA-MB231 in modified HTSCA medium was much less than that obtained with the optimal combination of hormonal supplementation and small volumes of foetal calf serum.

We next tested the ability of bovine serum albumin fraction V (BSA) to substitute for FBS (Table III). CFE for MCF-7 was 7.9% in medium A + 1% BSA and was 3.5% for MDA-MB231 in medium A + 1% BSA. Thus, hormonally-supplemented medium plus an optimal concentration of BSA gave a higher CFE for MCF-7 and a similar CFE for MDA-MB231 compared to DMEM + 10% FBS without hormonal supplementation.

Having demonstrated that high CFE of the breast cancer cell lines was obtained in medium A or medium B supplemented with 5% FBS, we next tested the ability of these combinations to support the soft agarose colony formation of three fresh specimens of human breast carcinoma, compared to modified HTSCA medium and to DMEM + 10% FBS. Results are shown in Table IV. Medium A + 5% FBS was clearly superior to the 3 other conditions tested with these fresh specimens. Cytology of the colonies of the different samples showed typical adenocarcinoma morphology.

### Table II Colony forming efficiency* of MCF-7 and MDA-MB231 in different media supplemented with fetal bovine serum (FBS)

| Growth conditions | MCF-7 | MDA-MB231 |
|-------------------|-------|-----------|
| DMEM + FBS (%)    | <0.01 | <0.01     |
| 1                 | <0.01 | <0.01     |
| 5                 | 4.7±1.7 | 3.7±1.5  |
| 10                | 4.9±1.1 | 4.0±0.8  |
| 20                | 4.4±1.4 | 2.7±0.7  |
| 40                | 0.5±0.3 | 0.6±0.1  |

Values given are the mean number of colonies of >50 cells obtained after plating 10^5 viable nucleated cells in triplicate.

In vitro chemosensitivity studies

After exposure to drug for 1 h as described in Materials and methods, cells were plated in either DMEM + 10% FBS, or in defined medium (A or B) + 5% FBS. Colony survival for the 2 cell lines after exposure to 5 fluorouracil, vincristine, and adriamycin differ in the different media are shown in Figure 1. No substantial difference was observed between the results of the drug testing in the different media for these three drugs. Both cell lines were also resistant in vitro in all 3 conditions to 1 h exposure at 10% of peak achievable plasma level of melphalan, mitomycin C, vinblastine, cis-platinum, and methotrexate.

Discussion

In this study, we have demonstrated that the in vitro soft agarose cloning of established cell lines of human breast carcinoma can be substantially increased by the addition of hormones including 17β oestradiol to the culture medium, without altering the drug sensitivity of the cell lines to cytotoxic agents including adriamycin, melphalan, methotrexate, vincristine, vinblastine, cis-platinum, and mitomycin C.

Our work was based in part on principles of serum-free cell culture (Barnes & Sato, 1980a, 1980b). In liquid culture, hormonally-supplemented, serum-free media may have certain advantages over conventional serum-supplemented medium including increased selectivity for the growth of tumour cells in fresh specimens (Carney et al., 1981b) and avoidance of competitive or inhibitory effects of various undefined hormones contained in...
serum. However, soft agarose cloning is markedly inferior in serum-free medium with these breast cancer cell lines, suggesting that some factors present in FBS or BSA are necessary for optimal soft agarose cloning of the cell lines. Lymphoid cells also clone poorly in serum-free medium without BSA, and it has recently been suggested that the function of the BSA may be to serve as a free radical scavenger, preventing hydrogen peroxide toxicity (Darfler & Insel, 1983).

The ability of MCF-7 to clone at all in defined medium without FBS or BSA is significant. It suggests that this cell line is able to produce factors needed for its own anchorage independent growth. Production of autocrine growth factors may be an explanation for the reduced serum requirement for certain transformed cells (Kaplan et al., 1982). We have demonstrated autocrine growth factor production by human small cell lung cancer cell lines (Carney et al., 1983b). Only small volumes of FBS or BSA were needed to achieve peak CFE of the cell lines when added to the defined media; higher concentrations decreased colony formation, suggesting that FBS or BSA also contain factors inhibitory to cell cloning. We found that the optimal concentration of animal serum for cloning, 5% was substantially lower than that used in other in vitro clonogenic assays. The poor CFE of 0.15% that we obtained for MCF-7 with modified HTSCA medium, which includes 15% animal serum, is quite similar to the cloning efficiency of 0.066% reported for MCF-7 from the University of Arizona with another version of HTSCA medium (Pathak et al., 1982).

Serum-free media have been developed for many of the common forms of human neoplasia, based on analysis of the growth factor requirements for these tumours in liquid culture (Simms et al., 1980; Barnes et al., 1981). It is conceivable that the optimal cloning medium for each tumour type may be provided by combining such defined media with small amounts of animal serum to provide the as yet unknown factors needed for anchorage independent growth. McClure (1983) has reported that anchorage independent growth of SV-40 transformed fibroblasts can be markedly enhanced by adding specific serum components such as fibronectin or platelet derived growth factor to a simple basal serum-free medium.

While the number of specimens was small, our work with three fresh pleural fluids does suggest a possible advantage in the use of the hormonally-supplemented media we devised by analyzing the nutritional requirements of human tumour cell lines. Further analysis of these nutritional requirements may permit us to determine which of the individual factors in medium A and medium B are most responsible for the stimulation of growth we observed. The lack of alteration in the in vitro chemosensitivity in the two cell lines in hormonally-supplemented medium suggests that these cloning media will not artifactually alter drug testing data obtained with fresh specimens, although this remains to be tested.

The use of in vitro clonogenic assays is undergoing a major reassessment (Lieber & Kovach, 1982; Selby et al., 1983). There are many technical problems with such assays, including the difficulty of obtaining true single cell suspensions (Agrez et al., 1982), but there are data to suggest that culture conditions such as oxygen tension play an important role in the growth of malignant cells in semi-solid medium (Courtney et al., 1978; Tveit et al., 1981). The identification of the specific growth requirements of individual tumour types may enhance our ability to obtain sufficient numbers of colonies from clinical specimens for routine in vitro drug testing. In addition, the ability to clone cell lines in serum-free medium may assist in our understanding of hormonal regulation of tumours, including possible autocrine regulatory mechanisms in human breast cancer.
