Objectives: Functional dyspepsia is one of the most common functional gastrointestinal disorders. We aimed to investigate the relationship between obstructive sleep apnea (OSA) and functional dyspepsia in patients with the complaint of sleep-disordered breathing. Methods: We prospectively recruited patients who visited the institute for the evaluation of sleep-disordered breathing. All patients underwent overnight polysomnography and submitted their responses to sleep questionnaires. A validated Korean version of the Rome III criteria was used to estimate functional dyspepsia. Functional dyspepsia was classified into two subtypes of epigastric pain syndrome and postprandial distress syndrome. Results: Out of 130 subjects with sleep disturbances, a total of 79 patients (60 men, 19 women) were enrolled. The mean (±standard deviation) age was 46.9±13.4 years. Functional dyspepsia was diagnosed in 8 (10%) patients. Patients with functional dyspepsia showed significantly higher values of Stanford Sleepiness Scale, the proportion of N1 sleep, arousal index, and apnea-hypopnea index compared to patients without functional dyspepsia (p=0.018, p=0.021, p=0.041, and p=0.039, respectively). With respect to OSA severity, 12% of patients with moderate OSA and 22% patients with severe OSA had functional dyspepsia. Severe OSA was significantly associated with a higher proportion of postprandial distress syndrome (p=0.030). Conclusions: Our patients with snoring or OSA revealed that functional dyspepsia is associated with more severe daytime sleepiness and apnea-hypopnea index compared to those without functional dyspepsia. In addition, postprandial distress syndrome was a prevalent subtype of functional dyspepsia in patients with severe OSA.

Key Words: Sleep, Obstructive sleep apnea, Dyspepsia, Gastrointestinal disorder.

Introduction

Functional dyspepsia, a disorder of the upper gastrointestinal tract affecting 5–20% of the worldwide population, is one of the most common functional gastrointestinal disorders. Functional dyspepsia is generally assessed using the Rome III symptom-based diagnostic criteria published by the Rome foundation. These criteria have played an important role in the research and diagnosis of functional gastrointestinal disorders because of a current lack of diagnostic biological markers. Functional dyspepsia has been considered to provoke disturbances of gastric physiologic factors, such as slow gastric emptying, failure of the gastric fundus to relax after a meal, and gastric hypersensitivity with distention of the stomach. Psychological stress, infection, and inflammation could be candidates that cause functional dyspepsia; however, its pathomechanism remains unclear.

Obstructive sleep apnea (OSA) is characterized by complete or partial obstruction of the upper airway. Recurrent hypoxic or apneic episodes cause intermittent hypoxemia, hypercapnia, microarousals, and fragmented sleep. OSA has been associated with increased risk of hypertension, type 2 diabetes mellitus, and with various cardiovascular and cerebrovascular disease risk factors. Gastroesophageal reflux has been associated with OSA in the previous studies. It is also well known that sleep disturbances are linked to functional gastrointestinal disorders and altered intestinal sensitivity. A previous report showed that poor sleep quality is associated with functional gastrointestinal symptoms in the general population. Insufficient sleep duration with reduced sleep quality might be a causal factor that results in emotional, cognitive, and...
somatic effects. Altered sleep duration and impaired sleep quality are common night symptoms in patients with OSA.

In the current study, we aimed to investigate the prevalence of functional dyspepsia in patients with untreated OSA. Clinical and polysomnographic parameters correlated with functional dyspepsia were assessed in patients with the complaint of sleep disordered breathing.

Methods

Study participants

Individuals with complaints of snoring or sleep-disordered breathing were prospectively screened at the Boramae Medical Center of Seoul National University between January 2018 and June 2019. One hundred-thirty subjects with sleep disturbances were initially screened. Each patient had a detailed clinical interview and submitted responses to a sleep questionnaire. Thirty-four patients were excluded according to the following criteria (Fig. 1): 1) insomnia (n=9), 2) parasomnia (n=18), 3) excessive daytime sleepiness (n=2), and 4) restless leg syndrome or periodic limb movement disorder (n=5). Overnight polysomnography was applied to 96 patients with night symptoms, including snoring, shortness of breath, or witnessed apnea during sleep. Seventeen patients with a greater than 15 per hour of periodic limb movement during sleep index were excluded. Finally, a total of 79 patients were enrolled in this study. Approval for this study was obtained from the Institutional Review Board at the Boramae Medical Center of Seoul National University. Written informed consent for participation in this study was obtained from each patient or his/her legal representative.

Sleep questionnaires and polysomnography

Subjective daytime sleepiness was estimated by applying the Epworth Sleepiness Scale and the Stanford Sleepiness Scale. The Pittsburgh sleep quality index (PSQI) was used to estimate the sleep disturbances and quality during the last month wherein a total score of higher than 5 indicated poor sleep quality.

Patients were instructed not to ingest alcohol or caffeinated beverages and to sleep and wake up at their regular hours for one week before the study. Polysomnography data were recorded using the Twin-polysomnography software (Natus Neurology Incorporated, West Warwick, RI, USA), a 6-channel electroencephalogram, a 4-channel electrooculogram, an electromyogram, and an electrocardiogram. A thermistor, a nasal air pressure monitoring sensor, an oximeter, piezoelectric bands, and a body position sensor were also connected to the patient. Obstructive apnea was defined as an airflow reduction of 90% or more lasting at least 10 s. Hypopnea was defined as an airflow reduction of more than 30%, with concurrent reduction in oxyhemoglobin saturation by at least 3%, or arousals from sleep. OSA was graded according to the apnea-hypopnea index (AHI): AHI<5 (events/h) was considered simple snoring without sleep apnea, 5≤AHI<15 was considered mild OSA, 15≤AHI<30 was considered moderate OSA, and AHI≥30 was considered severe OSA.

Evaluation of functional dyspepsia

A validated Korean version of the Rome III criteria was used for the assessment of functional dyspepsia. Patients were diagnosed with functional dyspepsia if they had been experiencing one or more of the following symptoms for at least 3 months with symptom onset in at least the previous 6 months: bothersome postprandial fullness, early satiation, epigastric pain, and/or epigastric burning, with no evidence of structural disease. Functional dyspepsia was classified into epigastric pain syndrome and postprandial distress syndrome subtypes.

Statistical analysis

The participants in this study were divided into two groups based on the presence of functional dyspepsia. To compare the clinical and polysomnographic parameters between the groups, we used t-tests for continuous variables and χ² or Fisher’s exact tests for categorical variables in this analysis. All the continuous quantitative parameters are represented as mean ± standard deviation. In addition, our subjects were divided 3 groups according to the severity of OSA. Differences in variables among these subgroups were measured by χ² or Fisher’s exact tests with adjustments for multiple comparisons using a Bonferroni correction. Two-sided p-values less than 0.05 were considered statistically significant. Statistical analyses were performed using SPSS statistical software version 26 (IBM).
Results

The patients’ age and body mass index (BMI) were 46.9±13.4 years and 25.5±3.8 kg/m², respectively. Of the 79 patients, 19 (24%) were women. Eight (10%) with complaints of snoring or sleep apnea showed functional dyspepsia. Patients with functional dyspepsia showed a significant daytime sleepiness with higher scores of Stanford Sleepiness Scale \( (p=0.018) \). The PSQI score of patients with functional dyspepsia was 11.0±3.5, which was significantly higher than 8.1±3.0 of the PSQI in patients without functional dyspepsia \( (p=0.036) \). Among the polysomnographic parameters, the proportion of N1 sleep and rapid eye movement sleep latency were significantly increased in patients with functional dyspepsia \( (p=0.021 \) and \( p=0.044 \), respectively). Functional dyspepsia group showed a significantly higher values of arousal index and AHI compared to patients without functional dyspepsia \( (p=0.041 \) and \( p=0.039 \), respectively). The detailed clinical demographics and polysomnographic findings of each group are summarized in Table 1. Of the total 79 subjects, 66 (84%) patients were diagnosed as OSA with AHI≥5/h. The prevalence of functional dyspepsia in patients with OSA was 12%, which was higher than that in patients with simple snoring (0%), but this difference was not significant (Table 2). OSA group showed significantly higher age and increased BMI compared to simple snoring group \( (p=0.003 \) and \( p=0.038 \)). Regarding the severity of OSA, 12% of patients with moderate OSA and 22% patients with severe OSA had functional dyspepsia; in patients with mild OSA, 0% had

functional dyspepsia (Table 3). Although the prevalence of functional dyspepsia showed no significant difference among three OSA subgroups, severe OSA group was significantly associated with a higher proportion of postprandial distress syndrome compared to moderate OSA group in the subtype analyses of functional dyspepsia (p=0.030).

Discussion

This prospective observational study has demonstrated that patients with functional dyspepsia showed significantly higher AHI compared to the other group without functional dyspepsia. Seep quality was much more impaired in OSA patients with functional dyspepsia than those without functional dyspepsia. Patients with OSA (AHI≥5/h) revealed a higher proportion of functional dyspepsia in comparison with that in simple snoring group. Furthermore, severe degree of OSA might be associated with postprandial distress syndrome subtype of functional dyspepsia. To the best of our knowledge, this is the first report to demonstrate the association between sleep apnea and functional dyspepsia in patients with sleep-disordered breathing.

Sleep disturbance and gastrointestinal symptoms have been considered as independent predictors for impaired quality of life after adjusting for age, gender, and BMI in a previous population-based study, where it was reported that poor sleep was associated with increased odds for multiple upper and lower gastrointestinal symptoms. In another study of 212 patients from a gastrointestinal clinic, the PSQI and Insomnia Severity Index were the parameters used. Irritable bowel syndrome group had the highest frequency of poor sleep (72%) and clinical insomnia (51%) compared to those in the celiac disease, gastroesophageal reflux disease, inflammatory bowel disease, and healthy control groups; functional dyspepsia was not included in that study due to the small sample size. A recent study which considered the health checkup data of 2,674 participants showed that 36% had sleep disturbance, which was associated with higher prevalence of functional dyspepsia. However, most of previous studies were solely based on subjective diagnostic tools including questionnaires on sleep disturbance and functional dyspepsia.

In this study, overnight polysomnography, which is a standard and objective tool for the diagnosis of OSA, was applied to elucidate the relationship between OSA and functional dyspepsia. OSA patients comorbid with functional dyspepsia showed more severe statuses of sleep apnea and respiratory arousals during night than those without functional dyspepsia. In addition, OSA group revealed a higher proportion of functional dyspepsia than simple snoring group, but not significant. In the aspects of cardiovascular pathogenesis of OSA, systemic inflammatory process has been considered to play a central role. The repetitive cycles of short periods of hypoxia followed by rapid reoxygenation could activate inflammatory pathways. Interestingly, inflammation is also one of pathophysiological mechanisms in functional dyspepsia. We propose that inflammatory process might be a possible common pathophysiology for the enhanced association between OSA and functional dyspepsia. In our additional analyses for the subtypes of functional dyspepsia, postprandial distress syndrome was significantly associated with severe OSA in comparison with moderate OSA group. In the previous studies, the innate inflammation, which is characterized by an eosinophil infiltrate in the duodenum, has been considered to the inflamma-
tory phenotype of functional dyspepsia in patients with post-
prandial distress syndrome. 2, 25

Several limitations should be considered when interpreting the results of the current study. First, the number of positive samples for functional dyspepsia was very small, which made it difficult to identify the reliable outcomes of this study. Second, the small sample in each OSA group and multiple com-
parisons by OSA severity reduced the statistical power of the study. Finally, age and BMI had not been included as covari-
s in our analyses for the relationship between OSA and functional dyspepsia although older age and higher BMI are risk factors for OSA.

In conclusion, our patients with snoring or OSA showed that functional dyspepsia is associated with more severe daytime sleepiness and AHI compared to those without functional dys-
pepsia. Furthermore, postprandial distress syndrome was sig-
nificantly linked to severe OSA compared to moderate OSA. Following studies with larger sample sizes need to be performed to further elucidate the relationship between OSA and func-
tional dyspepsia.
