ABSTRACT

HD 142990 (V 913 Sco; B5 V) is a He-weak star with a strong surface magnetic field and a short rotation period ($P_{\text{rot}} \sim 1$ d). While it is clearly a rapid rotator, recent determinations of $P_{\text{rot}}$ are in formal disagreement. In this paper we collect magnetic and photometric data with a combined 40-year baseline in order to re-evaluate $P_{\text{rot}}$ and examine its stability. Both period analysis of individual datasets and $O-C$ analysis of the photometric data demonstrate that $P_{\text{rot}}$ has decreased over the past 30 years, violating expectations from magnetospheric braking models, but consistent with behaviour reported for 2 other hot, rapidly rotating magnetic stars, CU Vir and HD 37776. The available magnetic and photometric time series for HD 142990 can be coherently phased assuming a spin-up rate $\dot{P}$ of approximately $-0.6$ s/yr, although there is some indication that $\dot{P}$ may have slowed in recent years, possibly indicating an irregular or cyclic rotational evolution.

Key words: stars: individual: HD142990 – stars: early-type – stars: magnetic fields – stars: massive – stars: rotation

1 INTRODUCTION

Of order 10% of OBA stars possess detectable surface magnetic fields (e.g. Grunhut et al. 2017; Sikora et al. 2019a) which are generally topologically simple (approximately dipolar; Bohlender et al. 1987; Shultz et al. 2013; Sikora et al. 2019b), strong (with a surface strength at the magnetic pole above 300 G; Aurière et al. 2007; Sikora et al. 2019b), and demonstrate no detectable intrinsic evolution over observational timescales (e.g. Shultz et al. 2018) but gradual weakening over evolutionary timescales (e.g. Landstreet et al. 2007, 2008; Fossati et al. 2014). These properties have led to their characterization as ‘fossil’ magnetic fields (e.g. Braithwaite & Spruit 2004; Neiner et al. 2012), i.e. magnetic flux generated at an earlier evolutionary stage and preserved via persistent magneto-hydrostatic equilibria. The fossil fields of massive stars are thus fundamentally different from the magnetic fields of cool stars, which are maintained by contemporaneous dynamos.

Magnetic hot stars can be observationally distinguished from their non-magnetic kin by several phenomena which are empirically known to co-occur with the presence of a magnetic field. The best-known diagnostics, valid for stars later than about B1, are atmospheric chemical peculiarities: significant photospheric over- or under-abundances of He, Fe, Si, as well as rare-earth elements (e.g. Shulyak et al. 2010; Bailey & Landstreet 2013; Kochukhov et al. 2014; Yakunin et al. 2014; Shultz et al. 2015; Kochukhov et al. 2017; Sikora et al. 2019b). These are believed to arise due to radiative diffusion in atmospheres stabilized by strong magnetic fields (e.g. Michaud 1970; Michaud et al. 1981; Alecian 2012). These chemical peculiarities typically exhibit nonuniformities of up to several dex across the stellar surface, leading to photometric and spectroscopic variability modeled according to the star’s rotation (e.g. Krtiška et al. 2004, 2015). This variability is strictly periodic, allowing rotational periods to be easily determined from the spectroscopic and/or photometric variations of magnetic Chemically Peculiar (mCP) stars.

Another distinguishing feature is that magnetic hot stars are, as a population, more slowly rotating than non-magnetic stars (e.g. Shultz et al. 2018). This is consistent with the expectation that angular momentum is efficiently lost through the magnetically confined stellar wind (Weber & Davis 1967; ud-Doula et al. 2009). Period evolution has been directly measured for three magnetic hot stars: $\sigma$ Ori E, CU Vir, and HD 37776. All are stars with relatively short rotational periods, of the order of one day, for which
extensive and well-sampled datasets spanning decades are available. A spindown rate qualitatively compatible with predictions from magnetospheric braking was reported by Pedersen & Thomsen (1977); Bohlender et al. (1993); Høg et al. (2000); van Leeuwen (2001); Manfroid et al. (1995); Sterken et al. (1995); Hills et al. (2012); Bowman et al. (2018); Shultz et al. (2018). Spin-up was also reported by Mikulášek et al. (2011) for the magnetic B2 star HD 37776, a suspicion later confirmed by Mikulášek (2016) with additional observations.

The most recent magnetic measurements of HD 142990 were performed between 2011 and 2017 using ESPaDOnS spectropolarimetry obtained by the Magnetism in Massive Stars (MiMeS) large program at the Canada-France-Hawaii Telescope (Wade et al. 2016), together with several observations obtained by PI programs. The analysis of these data was described by Shultz et al. (2018). In addition to the modern data, we also compiled the photopolarimetric magnetic measurements reported by Borra et al. (1983) and Bohlender et al. (1993). These data were also analyzed by Shultz et al. (2018), however several of the measurements of Borra et al. were overlooked in that analysis. The combined magnetic dataset spans 1978 to 2017, but mostly samples the beginning and end of this time-frame.

The spectropolarimetric $B_\ell$ measurements used here were performed using H lines, since these measurements should be unaffected by distortions introduced by surface chemical abundance inhomogeneities (Shultz et al. 2018). The photopolarimetric data were also obtained using H lines, in particular the wings of H$\gamma$. The different measurement systems can in principle introduce systematic discrepancies between datasets. In practice, however, agreement between high-resolution H line ($B_\ell$) measurements and photopolarimetric ($B_\ell$) measurements is quite good, thus any such differences must be less than the intrinsic scatter in the latter (e.g. Oksala et al. 2012; Shultz et al. 2018).

Several photometric time series are also available, spanning the time frame from 1978 to 2014, but with more favourable sampling than the magnetic data. We acquired the ground-based Strömgren photometry reported by Pedersen & Thomsen (1977), from the mCPod photometric database (Mikulášek et al. 2007). We also obtained Strömgren photometry from the catalogues published by Manfroid et al. (1993) and Sterken et al. (1995) via VizieR. These data were originally analyzed by Catalano & Leone (1996), together with their own data which, unfortunately, are not publicly available. We downloaded Hipparcos photometry (Perryman et al. 1997) from VizieR. We obtained the Kepler light curve from the Mikulski Archive for Space Telescopes (MAST). As there are numerous Kepler reductions available, we selected the best light curve by eye by phasing the data with the rotation period determined by Bowman et al. (2018), choosing the light curve file k2sff0203814494-c02_1c and the corrected flux in aperture 9.

We use data obtained by the Solar Mass Ejection Imager, SMEI (Jackson et al. 2004). The data have been reprocessed by Jackson (priv. comm.) and are available on request. The new processing identifies which of the three cameras each individual datapoint was observed with. This allows for much better background and trend corrections, since these are individual to each camera. The computational methods for this are described by Rivinius et al. (2016). In detail the dataset was split into three per-camera subsets. In each set, the variability is strongly dominated by annual and daily signals. To remove them, first the variabili-

### Table 1. Summary of available datasets. Columns indicate the name of the dataset; the type of data, either P(hotometric) or M(agnetic); the year (or mean year) of the dataset’s acquisition; the timespan of dataset; and the original work in which is was published*. Note that the STEREO data are not publicly available, but are included here for completeness.

| Dataset          | Type      | Year | Timespan | $N_{\text{obs}}$ | Reference |
|------------------|-----------|------|----------|------------------|-----------|
| Strömgren        | P         | 1976 | 8 d      | 12 a             |           |
| Photopolarimetric| M         | 1980 | 4.1 yr   | 14 b             |           |
| Photopolarimetric| M         | 1988 | 0.26 d   | 4 c              |           |
| Tycho            | P         | 1991 | 2.1 yr   | 147 d            |           |
| Hipparcos        | P         | 1991 | 3.0 yr   | 111 e            |           |
| Strömgren        | P         | 1991 | 4 d      | 18 f             |           |

| SMEI             | P         | 2007 | 8.6 yr   | 18851 h          |           |
| STEREO           | P         | 2007 | 4.3 yr   | 6000 i           |           |
| K2               | P         | 2014 | 77 d     | 3293 j           |           |
| ESPaDOnS         | M         | 2015 | 5.9 yr   | 15 k             |           |

*Reference key: a: Pedersen & Thomsen (1977); b: Borra et al. (1983); c: Bohlender et al. (1993); d: Høg et al. (2000); e: van Leeuwen (2001); f: Manfroid et al. (1995); g: Sterken et al. (1995); h: Hills et al. (2012); j: Bowman et al. (2018); k: Shultz et al. (2018).
ity in the vicinity, meaning within typically 3\%, of 1 cycle/yr and the first nine harmonics were removed. In the next step the same was done for 1 cycle/d and its first four harmonics, but only removing signals within narrower windows of ±0.2\%. The resulting dataset was visually clipped for strong outliers, and the frequency removal procedure was repeated.

The final datasets can then either be re-merged to analyse all cameras together, or further split to allow an analysis per camera and season, for example. It turns out that the data quality delivered by one camera degraded much more strongly over the years than that of the others, so data from this camera was included in the analysis only for the first few mission years.

We also explored the photometric time series acquired by the All Sky Automated Survey Supernovae (ASAS-SN; Kochanek et al. 2017; Javasinghe et al. 2018) and by the Super-Wide Angle Search for Planets (SuperWASP Butters et al. 2010). However, even after detrending and outlier-rejection, the precision of these datasets is insufficient to detect HD 142990’s photometric variability (Andrzej Pigulski, priv. comm.).

3 RESULTS

3.1 Previous period determinations

Periods collected from the literature are summarized in Table 2.

The most recent rotational period of HD 142990 was determined by Bowman et al. (2018), who used Kepler 2 (K2) photometry to determine $P_{rot} = 0.97892(2)$ d. This period is close to, but not formally compatible with, $P_{rot} = 0.97892(2) d$ determined by Bowman et al. (2018), who used Kepler 2. Period analysis was performed using standard Lomb-Scargle statistics (Lomb 1976; Scargle 1982), utilizing both the IDL program PERIOD04 and the PERIOD04 package Lena\& Bregenz (2003). The uncertainties were determined in the same manner as by Shultz et al. (2018), i.e. according to the analytic method described by Bloomfield (1976).

Examing the ESPaDOnS data in isolation yields $P_{rot} = 0.97887(6)$ d, consistent within uncertainty with the K2 period (Bowman et al. 2018). The period determined from all available magnetic data (i.e. including the previously overlooked $B_p$ measurements of Borra et al. 1983) is $0.979855(5)$ d. The photometric and magnetic data are shown phased with this period in the middle panel of Fig. 1. Phasing ($B_p$) with this period and fitting the ESPaDOnS data with a second-order sinusoid yields a reduced $\chi^2 = 5$, i.e. a poor fit. This period also does not provide a coherent phasing of the majority of the photometric dataset. Notably, the variation in the phase-binned SMEI data almost completely disappears, likely because observations are being binned as though they were at the same phase when, in fact, they are not.

We can also combine all available photometric data (shifted to the mean magnitude of each dataset, as in Fig. 1), which yields $P_{rot} = 0.978891793(6)$. This makes the assumption that there are no large, systematic differences in light curve morphology between different bandpasses (this is explored in greater detail in §3.3). The left panel of Fig. 1 shows the datasets phased with this period. It achieves a reasonable phasing of the K2 and SMEI data, but a poor phasing of the other photometric datasets, and while it phases the ESPaDOnS data well, it does not coherently phase the modern and historical ($B_p$) data.

If the period is changing, the accuracy of the Catalano & Leone (1996) result is questionable as the dataset they used spans approximately 15 years. However, our own analysis of the Sterken et al. (1995) photometry used by Catalano & Leone, which has a much more restricted time-frame (about 2 years), finds $P_{rot} = 0.97902(5)$, which is compatible with the Catalano & Leone period.

We analyzed the Hipparcos data together with the Tycho BV data, with the weighted mean period for the three datasets yielding $P_{rot} = 0.97901(4)$ d, compatible with the Dubath et al. (2011) result. This is also compatible with the

3.2 Period analysis

We now turn to a re-examination of the period analysis of the individual datasets; the results are summarized in Table 2. Period analysis was performed using standard Lomb-Scargle statistics (Lomb 1976; Scargle 1982), utilizing both the IDL program PERIOD04 and the PERIOD04 package Lena\& Bregenz (2003). The uncertainties were determined in the same manner as by Shultz et al. (2018), i.e. according to the analytic method described by Bloomfield (1976).

Examining the ESPaDOnS data in isolation yields $P_{rot} = 0.97887(6)$ d, consistent within uncertainty with the K2 period (Bowman et al. 2018). The period determined from all available magnetic data (i.e. including the previously overlooked $B_p$ measurements of Borra et al. 1983) is $0.979855(5)$ d. The photometric and magnetic data are shown phased with this period in the middle panel of Fig. 1. Phasing ($B_p$) with this period and fitting the ESPaDOnS data with a second-order sinusoid yields a reduced $\chi^2 = 5$, i.e. a poor fit. This period also does not provide a coherent phasing of the majority of the photometric dataset. Notably, the variation in the phase-binned SMEI data almost completely disappears, likely because observations are being binned as though they were at the same phase when, in fact, they are not.

We can also combine all available photometric data (shifted to the mean magnitude of each dataset, as in Fig. 1), which yields $P_{rot} = 0.978891793(6)$. This makes the assumption that there are no large, systematic differences in light curve morphology between different bandpasses (this is explored in greater detail in §3.3). The left panel of Fig. 1 shows the datasets phased with this period. It achieves a reasonable phasing of the K2 and SMEI data, but a poor phasing of the other photometric datasets, and while it phases the ESPaDOnS data well, it does not coherently phase the modern and historical ($B_p$) data.

If the period is changing, the accuracy of the Catalano & Leone (1996) result is questionable as the dataset they used spans approximately 15 years. However, our own analysis of the Sterken et al. (1995) photometry used by Catalano & Leone, which has a much more restricted time-frame (about 2 years), finds $P_{rot} = 0.97902(5)$, which is compatible with the Catalano & Leone period.

We analyzed the Hipparcos data together with the Tycho BV data, with the weighted mean period for the three datasets yielding $P_{rot} = 0.97901(4)$ d, compatible with the Dubath et al. (2011) result. This is also compatible with the

https://hesperia.gsfc.nasa.gov/sw/gg/idl/util/periodogram.pro
Figure 1. Photometric (top) and magnetic \(\langle B_z \rangle\) (bottom) measurements, phased with periods determined from (left to right) K2 photometry, all \(\langle B_z \rangle\) measurements, and all photometric measurements. \(\langle B_z \rangle\) measurements were obtained from ESPaDOnS by Shultz et al. (2018) and photopolarimetric data by Borra et al. (1983, BLT 83) and Bohlender et al. (1993, BLT93). The solid and dashed curves show respectively the best second-order harmonic fit to the ESPaDOnS \(\langle B_z \rangle\) data and the 1 \(\sigma\) fit uncertainty. Photometric data are from K2, SMEI, Hipparcos (\(H_p\)), and Strömgren \(y\) photometry published by Sterken et al. (1995, S95), Manfroid et al. (1995, M95), and Pedersen & Thomsen (1973, P77). For clarity the K2 and SMEI data have been binned by phase, using bin sizes of 0.01 cycles. The mean magnitude of each dataset was subtracted for display purposes.

Table 2. Summary of periods from the literature and determined in the present work. The table is organized in order of the year corresponding to the mean observation time of the dataset(s) used to determine \(P_{\text{rot}}\). The second column gives the mean HJD of the datasets used for each period. The fourth column gives the difference in \(P\) relative to the K2 period. The Dataset column indicates the data used to determine the periods, corresponding to the reference key in Table I. Origin corresponds to the work in which the period was published. Periods in boldface were adopted for analysis.

| Year | HJD - 2400000 (d) | \(P_{\text{rot}}\) (d) | \(\Delta P\) (s) | Dataset | Origin |
|------|------------------|------------------|---------------|---------|--------|
| 1976 | 42826            | 0.976(2)         | -252 ± 172    | a       | Pedersen & Thomsen (1977) |
| 1981 | 44948            | 0.98292(2)       | 345 ± 2       | b, c    | Bohlender et al. (1993)   |
| 1986 | 46774            | 0.97907(1)       | 13 ± 1        | a, f, g | Catalano & Leone (1996)   |
| 1991 | 48307            | 0.97904(4)       | 10 ± 4        | e       | Dubath et al. (2011)      |
| 1993 | 49155            | 0.97901(4)       | 8 ± 4         | d, e    | This work                 |
| 1995 | 49896            | 0.97902(5)       | 9 ± 4         | g       | This work                 |
| 1997 | 50259            | 0.978832(2)      | -7.6 ± 0.2    | b, c, k | Shultz et al. (2018)      |
| 2007 | 54245            | 0.97890(5)       | -1 ± 4        | h       | This work                 |
| 2007 | 54387            | 0.9789(1)        | -2 ± 8        | i       | Wraight et al. (2012)     |
| 2014 | 56933            | 0.97892(2)       | 0 ± 2         | j       | Bowman et al. (2018)      |
| 2015 | 57227            | 0.97887(6)       | -4 ± 5        | k       | This work                 |

We next turn to a re-examination of the period determined by Bohlender et al. (1993), which is incompatible with any of the other periods. This is a sparse dataset spanning a large time-frame (about a decade), and as a result the periodogram has numerous closely-spaced peaks that are likely to yield false positives. Limiting the period window to 3 times the range spanned by the Catalano & Leone (1996) and ESPaDOnS periods (which bracket the lower and upper extremes of the derived periods), the most significant peak is at 0.97910(4) d; this is within uncertainty of the Catalano & Leone period. A window of 3 times the range of the Catalano & Leone and ESPaDOnS periods was chosen so as to allow the possibility of large changes, whilst still restricting the window to a somewhat plausible range.

Our analysis of the new reduction of the SMEI light curve, obtained between 2003 and 2011, finds \(P_{\text{rot}} = 0.97890(5)\) d from the full dataset. The analysis follows the same methods described by Rivinius et al. (2016), but due to the relatively low data quality the wavelet analysis is hardly distinguishable from noise. The data were analysed in several subsets, by camera, by year, and over several years. All analyses gave identical results within uncertainty, although of course every one of these analyses provided larger errors than that obtained from the full dataset. Only the results for the analysis of the full data set are used here.

The results in Fig. 1 are not improved by phasing the available data using any of the alternative periods. No m-
3.3 Photometric bandpass dependence

The photometric datasets were obtained using different filters with a variety of passband widths and central wavelengths. The light curve variations of CP stars are a consequence of chemical spots, which do not affect all regions of the spectrum in exactly the same way; thus, there may be differences in the shapes of light curves obtained using different filters, which in some cases manifest as apparent phase shifts (e.g., Krtíčka et al. 2009, 2012). We used the Strömgren uvby photometry published by Sterken et al. (1995) to evaluate the degree to which HD 142990’s light curve morphology is affected by the choice of filter. Fig. 2 shows the photometric magnitudes and colour indices phased with the rotation period inferred from these data.

While there is some suggestion of a variation in $c_1$ with rotation phase, $m_1$ is almost constant. Variability in $c_1$ is likely due to changes in the vicinity of the Balmer jump, as reported for other stars by Krtíčka et al. (2009, 2012). The lack of variation in $m_1$ suggests almost no difference in the behaviour of $v$, $b$, and $y$. The top right panel of Fig. 2 shows $u$, $v$, and $b$ as functions of $y$, and verifies that while there are systematic differences between $u$ and $y$, $b$ and $y$ return almost identical results. We used harmonic fits of $2^{nd}$ degree to uvby (Fig. 2 left panel) to determine the phase of minimum light in each waveband, which is essentially constant for all 4 filters (Fig. 2 bottom right).

3.4 Period evolution

Fig. 3 shows the inferred change in period as a function of time, where we chose $\Delta P = 0$ as the K2 period. $\Delta P$ is given in Table 2, where the periods selected for analysis are indicated in boldface. With the exception of the Dubath et al. (2011) period (which is simply a duplicate of the value we determined ourselves from Hipparcos photometry), periods were rejected either because either the precision was too low (e.g. the period determined by Pedersen & Thomsen 1977), or the determinations were judged to be inaccurate, as explained above in §3.1 and §3.2. Inclusion of the Dubath et al. (2011) or Pedersen & Thomsen (1977) periods has no effect on results. Inclusion of the other periods, many of which are nominally highly precise, makes any pattern difficult to discern due to scatter of up to 100s of s as compared to the K2 period.
Figure 4. $O-C$ diagram for the photometric datasets of sufficient size to fully sample the phase diagram (K2, SMEI, Sterken et al. (1995) Strömgren $y$, and Hipparcos). Symbol size is proportional to the inverse of the mean phase-binned variance. The solid and dotted curves show a parabolic fit and the fit uncertainties.

Table 3. Summary of $O - C$ values for individual 4-year time bins. Year and HJD give the mean for each bin; Dataset gives the origin of the data corresponding to the reference key in Table 1; Variance gives the mean phase-binned variance; $N_{\text{obs}}$ gives the number of observations in each time bin.

| Year | HJD - 2400000 (d) | Dataset | $O - C$ (d) | Variance (mag) | $N_{\text{obs}}$ |
|------|-------------------|---------|-------------|----------------|-----------------|
| 1991 | 48307             | e       | -0.062      | 0.000024       | 111             |
| 1992 | 48809             | e       | -0.040      | 0.000007       | 8               |
| 1993 | 49160             | g       | 0.000       | 0.000067       | 142             |

All of the modern periods - those determined from datasets obtained since 2000 - are consistent with one another, and are about 20 seconds shorter than the periods determined in the 1980s and 90s (which are also consistent with one another). The period change between the 1980s and the 2010s is well-matched by a linear decrease of $-0.53 \pm 0.12$ s/yr (solid line in Fig. 3).

To verify that the period is changing in a coherent fashion, we constructed an $O - C$ (Observed minus Calculated) diagram (Fig. 3). Only those photometric datasets of sufficient size and quality to fully sample the phase diagram were used, i.e. the K2, SMEI, Hipparcos, and Sterken et al. (1995) Strömgren $y$ data. We phased the K2 data with the K2 period, binned the data by phase, and fit a second-order sinusoid. We then broke the remaining data into time segments, phase-binned the data in each time segment, and determined the phase shift relative to the K2 photometry that was required to minimize the reduced $\chi^2$ of the harmonic fit. In Fig. 4 we show results for 4-year time segments; the results do not change qualitatively for different time segment durations. Results are also tabulated in Table 3.

The parabolic shape of the $O - C$ curve is a clear indication of a changing period, since the phase shift between datasets that would be produced by a constant period would be a straight line. Obtaining $P$ from the quadratic coefficient of the parabolic fit to the $O - C$ diagram (e.g. Sterken 2005) yields $P = -0.58 \pm 0.01$ s/yr, which is compatible with the rate of period change inferred from the linear fit to $\Delta P$.

The phase $\phi$ of the variable ephemeris is given by

$$\phi(t) = \frac{t - T_N}{P_N} \mod 1,$$

where $t$ is in HJD, and $P_N$ and $T_N$ are the period and zero-point at cycle $N$:

$$P_N = P_0 + \dot{P}N,$$

$$T_N = T_0 + P_0N + \frac{\dot{P}N^2P_0}{2},$$

where $\dot{P}$ is in units of d/d, and $N$ is found by

$$N = \frac{2\Delta t}{2P_0 + \Delta P t},$$

with $\Delta t = t - T_0$, where it is assumed that $\dot{P}/P_0 \Delta t \ll 1$.

Fig. 5 shows the various datasets phased using Eqns. 1–4, using $P_0 = 0.97911(4)$ d, $T_0 = 2442820.93(3)$, and $\dot{P} = -0.58 \pm 0.01$ s/yr. In contrast to the various constant periods examined in Fig. 1 there are no obvious phase shifts between comparable datasets. These values and uncertainties were obtained by two methods. First, starting from the ES-
Period evolution of HD 142990

4 DISCUSSION & CONCLUSIONS

We have shown that 1) a constant period cannot coherently phase the available photometric and magnetic data; 2) photometric phase shifts that can be plausibly attributed to differences in the various bandpasses are much smaller than those obtained between the various photometric datasets using constant periods; 3) periods obtained independently from individual datasets show a coherent decrease over time; 4) the photometric $O - C$ diagram is also consistent with an accelerating rotation period; and finally 5) phasing the data with a rotational period that accelerates at $-0.58 \pm 0.02$ s/yr is able to coherently phase the data. It is worth emphasizing that the magnetic data, which was acquired over a 35-year period, is coherently phased by the variable ephemeris derived from the photometric, representing an unbiased test of the photometric $O - C$ results.

One possible, conventional, explanation for an apparently accelerating rotational period may be the light-time effect due to the orbit of a binary companion. However, none of the magnetic B-type stars in which this phenomenon has been detected, including the present star, are known to be in binary systems (Shatsky & Tokovinin 2002) conducted a NIR search for visual companions, and found no evidence of a companion in the case of HD 142990). The change in radial velocity $\Delta RV = c\Delta P / P$, where $c$ is speed of light (e.g. Pigulski & Boratyński 1992). Fig. 6 shows the least-squares deconvolution (LSD) profiles extracted from the ESPaDOnS dataset with a line mask using all metallic lines in the spectrum (for details see Shultz et al. 2018). No bulk RV variability is apparent. Measuring the RV is complicated by the spectroscopic variability introduced by chemical spots, which in addition to equivalent width changes also introduce RV variations coherent with the rotation phase due to changes in the star’s centre of gravity. As a result, only measurements performed on observations obtained close to the same rotation phase can be compared. The ESPaDOnS data contains two observations obtained close to phase 0.6, separated by about 3 years (one on 14/06/2014, the second on 14/05/2017, with a difference in phase of 0.02 cycles when phased using the variable ephemeris). Measuring the centres-of-gravity of the LSD profiles extracted from these observations yields a difference in RV of 1 km s$^{-1}$, comparable to the measurement uncertainty. The RV change expected over 3 years if $P$ is due to orbital motion is about 3 km s$^{-1}$, so this test must be considered inconclusive. However, a change of $-20$ s over the 30 years of observations should have led to $\Delta RV = 71$ km s$^{-1}$; it is unlikely that such a large change in RV would have been missed. The Pulkovo Compilation of Radial Velocities (Gontcharov 2006) give $RV = -12 \pm 3$ km s$^{-1}$, consistent with RVs measured from ESPaDOnS data (which have a mean and standard deviation of $-4$ and $5$ km s$^{-1}$), suggesting that the RV has been stable over a time span of at least a decade.

Another explanation may be that HD 142990 is still evolving towards the zero-age main sequence, and that rotational spin-up is a consequence of ongoing core-contraction. The star is a member of the Upper Sco OB association (de Zeeuw et al. 1999), which has an estimated age of $log (t/yr) = 6.7 \pm 0.1$ (Landstreet et al. 2007). Given the star’s mass (about 5 $M_\odot$; Landstreet et al. 2007), it is indeed very close to the ZAMS. The possibility that its core might still be contracting should be explored, once grids of evolutionary models for OB stars with surface fossil magnetic fields become available (e.g.?). Mikulášek et al. (2018) suggested that vertically stratified differential rotation, due to episodic magnetic coupling and decoupling of the upper and lower layers of the photosphere, may explain the phenomenon for CU Vir and HD 37776. In this scenario, when the upper and lower layers couple, angular momentum is transported to the upper layer, spinning it up; when they decouple, the outer layer sheds angular momentum via magnetic braking. An alternate mechanism was proposed by Krtička et al. (2011), who suggested torsional oscillations arising from magnetohydrodynamic waves. However, they noted that while this mechanism can explain the oscillatory period of CU Vir, it cannot explain the behaviour of HD 37776. It may be interesting to see if this hypothesis is plausible in the case of HD 142990.

Line profile variations are in principle a sensitive diagnostic of rotational phase (e.g. Kochukhov et al. 2017). Fig. 6 compares the phasing of the ESPaDOnS LSD profiles obtained by the variable ephemeris and the period inferred from ESPaDOnS data. Different rotational cycles are indicated with different colours. In most cases, observations with similar phases were obtained at similar times, and so are insensitive to period evolution. Observations obtained at different rotational cycles, but with similar computed phases, can be seen near phases 0.5 and 0.6. The former are almost identical in phase, but were obtained only 1 rotational cycle apart; unsurprisingly, Stokes $I$ and $V$ are almost indistinguishable. Near phase 0.6, the observations differ by about 0.02 cycles with the variable ephemeris and 0.05 cycles with the constant ephemeris, and are separated by 1065 d. Stokes $I$ and $V$ are both similar between these observations; however, the morphological change seems too fast with the variable ephemeris, while phasing the line profiles with the ESPaDOnS period seems to give a somewhat improved phasing of these two observations. The relatively small size
of the dataset and small number of observations overlapping in phase makes this qualitative test inconclusive, but suggestive.

While we have assumed a constant acceleration of the period, there is no reason to believe this must be the case. In fact, the other two stars in which rotational acceleration has been reported exhibit apparently cyclical changes in $P_{\text{rot}}$ and $\dot{P}$ (Mikulášek et al. 2011, 2017). The top panel of Fig. 3 shows a sinusoidal fit to $\Delta P$, where we arbitrarily assumed a 60-year periodicity (or about twice the current span of observations). Notably, while $P_{\text{rot}}$ has apparently changed by about 20 s between 1980 and 2010, between 2005 and 2015 the results are consistent with no change in period. A cyclic variation in $P$ could explain why the phasing of the ESPaDOnS data is improved by a constant ephemeris. Further photometric monitoring will be essential to distinguishing between these scenarios. If the suggestion by Lenc et al. (2018) that HD 142990 exhibits pulsed radio emission is confirmed, this phenomenon may also enable tight constraints on $\dot{P}$ (e.g. Mikulášek et al. 2011).

It is interesting to note that the measured period change of HD 142990, about 20 s, is similar to the lower limit of that of HD 37776 (although it is likely that the amplitude of HD 37776’s period change is much higher), and much greater than that of CU Vir (about 4 s). CU Vir is a more rapid rotator ($P_{\text{rot}} \sim 0.52$ d) than either HD 142990 or HD 37776 ($P_{\text{rot}} \sim 1.5$ d); likewise, HD 142990 is intermediate in mass between CU Vir (a late Bp star) and HD 37776 (a hot He-strong B2 star). CU Vir and HD 37776 have both been mapped via Zeeman Doppler Imaging; the former possesses a distorted dipolar magnetic field topology with a mean surface strength of about 4 kG (Kochukhov et al. 2014), while the latter has an extremely complex topology with a maximum local magnetic field modulus of around 30 kG (Kochukhov et al. 2011). As can be seen in Fig. 6, the phase curve is not yet sampled with sufficient density to perform Zeeman Doppler Imaging; however, HD 142990’s anharmonic $\langle B_z \rangle$ curve shows signs of departure from a purely dipolar magnetic field, so we can infer that its surface magnetic field is likely to be qualitatively similar to that of CU Vir in both topology and strength. HD 142990 is intermediate between CU Vir and HD 37776 in stellar and rotational properties, and likely similar to CU Vir in magnetic properties. Assuming a common mechanism, some or all of these
factors may explain why its period change is apparently intermediate in amplitude between CU Vir and HD 37776. The remarkable occurrence of rotational spin-up in 3 of the 4 stars (CU Vir, HD 37776, σ Ori E, and now HD 142990) for which period change has been directly measured suggests that this may well be a general phenomenon. σ Ori E – the only exception so far – should be monitored in the future for signs of rotational acceleration. If the phenomenon is indeed common, this suggests a new element in our understanding of the rotational evolution of magnetic, hot stars. Given that magnetic stars are known to be much more slowly rotating than non-magnetic stars as a population, magnetic braking must dominate over the long term. However, superimposed on this long-term trend may be an oscillatory pattern of spin-up and spin-down, driven by entirely different physics. This may complicate efforts to compare theoretical spin-down timescales to observations (since in this case multiple period oscillation cycles would need to be observed, each likely to be decades in length). On the other hand, the phenomenon may provide otherwise unobtainable insights into the internal structure and evolution of magnetic hot stars.

ACKNOWLEDGEMENTS

This work is based on observations obtained at the Canada-France-Hawaii Telescope (CFHT) which is operated by the National Research Council of Canada, the Institut National des Sciences de l’Univers of the Centre National de la Recherche Scientifique of France, and the University of Hawaii. This research has made use of the VizieR catalogue access tool, CDS, Strasbourg, France. The original description of the VizieR service was published in Ochsenbein et al. (2000). Some of the data presented in this paper were obtained from the Mikulski Archive for Space Telescopes (MAST). STScI is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS5-26555. This paper includes data collected by the Kepler mission. Funding for the Kepler mission is provided by the NASA Science Mission directorate. MS acknowledges support from the Annie Jump Cannon Fellowship, supported by the NASA Science Mission directorate.
