Abstract

Purpose: To quantify normal corneal transparency by anterior segment optical coherence tomography (AS-OCT) by measuring the average pixel intensity. To analyze the variation in the average pixel intensity in mild and severe grades of corneal opacities.

Methods: This is an observational, cross-sectional study of 38 eyes from 19 patients with mild or severe grades of corneal opacities greater than 3 mm and a normal contralateral cornea. AS-OCT was performed centered on the opacity with a 3 mm cruciate protocol. A similar image is taken of the contralateral clear cornea in the same quadrant. The average pixel intensity was calculated in a standardized manner using MATLAB software.

Result: The average pixel intensity of the normal cornea was 99.6 ± 10.9 [standard deviation (SD)]. The average pixel intensity of the mild and severe corneal opacities was 115.5 ± 9.1 and 141.1 ± 10.3, respectively. The differences were statistically significant.

Conclusions: AS-OCT images can be used to quantify corneal transparency. Average pixel intensity is a measure that varies significantly with varying corneal opacification.

Keywords: Corneal transparency; Anterior segment optical coherence tomography; Mild and severe grades of corneal opacities; Pixel intensity

Introduction

Optical coherence tomography (OCT) is a tool which is commonly used to assess the retina and choroid. It is based on the principle of low coherence interferometry and is capable of taking high resolution, cross-sectional images of the retina. An anterior attachment to the OCT machine allows imaging of the anterior segment, and this is referred to as anterior segment OCT (AS-OCT). The transparent corneal dome can be assessed by different imaging modalities. The AS-OCT creates cross-sectional images of the cornea and anterior segment. It is a standard diagnostic modality of imaging the cornea and anterior segment. Corneal transparency can be assessed qualitatively by slit-lamp photography, and opacities can be graded into Nebula, Macula and Leucoma depending on the density of the opacity and the clarity of the iris details seen through the opacity. Opacities in the cornea have been graded by qualitative scales. The lack of quantification greatly limits the clinical ability to notice subtle changes in corneal transparency, and can induce potential errors of documentation because of inter-observer variability. In research, qualitative scales struggle with issues of standardization and the inability to apply statistics to the data collected. Corneal transparency ex vivo has been qualitatively assessed...
by passing a defined beam of light through the tissue and
detecting how much is transmitted without absorption or
scattering. The commonly used techniques to measure corneal
transparency \textit{ex vivo}, quantitatively are tungsten light-based or
laser-based bench-top optical systems.

One of the early attempts to measure light scatter \textit{in vivo}
was based on the use of an optical fiber, Scheimpflug
photography, video pachometry using a slit-lamp, confocal
microscopy and OCT.\textsuperscript{9} Various techniques have been used for
segmentation of three important layers of the cornea in normal
eyes using AS-OCT.\textsuperscript{10}

We designed an innovative method of quantifying corneal
transparency. The standardized AS-OCT photographs were
processed by image analysis, and the average pixel intensity
was calculated. In this pilot, cross-sectional study we analyzed
the distribution of average pixel intensity in clinically normal
corneas and compared the values in patients with mild and
severe grades of corneal opacities.

\textbf{Methods}

The institutional review board approved the study (IRB Min.
No: 9786). Informed consent was obtained from all participants.
The study was undertaken from January 2016 to June 2016. A
cross-sectional observational study design was used to acquire
data. Consecutive patients over 18 years of age that presented to
the outpatient clinic of the department of ophthalmology who
fitted the inclusion criteria after a comprehensive eye exami-
nation were chosen. Consecutive patients that had mild or severe
grades of corneal opacity of more than 3 mm in diameter with a
clear contralateral cornea were recruited. The clinical grade and
inclusion criteria were assessed by two independent observers

\end{figure}
before the subject was included in the study. Since there is no study prior to this that has used the AS-OCT as a quantification tool in humans, an arbitrary sample size of 20 was chosen to pilot the concept of the study.

A line segment (vertical and horizontal) AS-OCT (DRI OCT, Swept source, Triton plus, Topcon) scan using a 3 mm cruciate protocol was used to take an image of the cornea centered on the opacity \((n = 19)\). A similar protocol was used to take an image of the contralateral clear cornea \((n = 19)\) in the same corresponding quadrant.

Both the case and control images were of \(1024 \times 900\) pixels in resolution and saved in the portable network graphics (png) format. This format saves image data with no loss of information. These images were then imported, processed, and analyzed using MATLAB software. Only the pixels in the corneal region of the image were considered for analysis, and the background pixels were excluded. This was done by using thresholding and dilation image processing techniques.\(^{11,12}\)

By thresholding, pixels inside the corneal boundary were made equal to 1 (white) whereas all the background pixels were made 0 (black). However, the same pixels inside the boundary may still be black. Therefore, dilation was applied to remove these black spots and produce a white corneal area. This, when multiplied to the original image, selects only the pixels inside the boundary and makes the background 0. The number of non zero pixels is now equal to the pixels in the corneal area. The process is shown in Fig. 1. The average pixel intensity for normal, mild, and severe grades of corneal opacities was calculated (Fig. 2).

An Excel (Microsoft Corp., Redmond, WA, USA) spreadsheet was used to collect the data, which was then transferred to statistical package for social studies (SPSS 22; IBM Corp., Armonk, NY, USA). Independent \(t\) test was performed to compare the mean and standard deviations for normal, mild, and severe grades corneal opacities.

### Results

The baseline parameters of all controls showed no statistically significant difference with respect to meridian, age, or sex (Table 1). The average pixel intensity of normal corneas was \(99.58 \pm 21.8\) [standard deviation (SD)] (Table 2). There was a statistically significant difference in average pixel intensity between control \((98.2)\) and mild \((115.4)\) corneas \((P < 0.001)\) (Tables 3 and 4). The significance persisted between control \((100.8)\) and severe \((141.1)\) corneas \((P < 0.001)\). There was a significant difference between mild \((115.4)\) and severe \((141.1)\) corneas \((P < 0.001)\).

Discussion

The study highlights an added utility of the AS-OCT as a quantification tool for corneal transparency. Normative data was derived from the normal control corneas. The distribution of normal followed a Gaussian distribution as would be expected in most biological parameters.

This can be used as a guideline for other clinical studies involving corneal opacification and as a possible clinical tool to monitor corneal scarring.

To prove further the validity of the test, we have shown how a change in the clinical grade of the opacity as assessed by clinical examination, the current gold standard, produces a statistically significant difference in average pixel intensity with worsening corneal opacification. Corneal opacification has been graded clinically by subjective methods into mild and severe scarring. These are prone to bias, subjectivism and are unamenable to statistical analysis in a research setting. The results of this analysis shows that AS-OCT with image analysis is a reliable measure to quantify corneal transparency in vivo.

The study describes the standardized procedure of image acquisition and analysis that needs to be followed for acquiring accurate information.

The study lends proof of principle evidence to estimate corneal opacification on a nominal scale. A follow-up study with a larger sample size is underway to prove this principle in a larger population including leucoma scars.

AS-OCT imaging of the cornea along with image analysis can be used to quantify corneal transparency. Average pixel intensity for the normal cornea is 99.58 ± 10.9 (SD). The average pixel intensity varied significantly with increasing clinical grades of corneal opacification (115.4 and 141.1 for mild and severe, respectively).

The limitations of the study include the small sample size, no correlation with any specific aetiological diagnosis, analysis of only two directional scans for a given image, and the lack of comparisons with any other instruments that can measure corneal transparency.
