The emergence and dissemination of multi-drug resistant pathogens is a global concern. Moreover, even greater levels of resistance are conferred on bacteria when in the form of biofilms (i.e., complex, sessile communities of bacteria embedded in an organic polymer matrix). For decades, antimicrobial peptides have been hailed as a potential solution to the paucity of novel antibiotics, either as natural inhibitors that can be used alone or in formulations with synergistically acting antibiotics. Here, we evaluate the potential of the antimicrobial peptide nisin to increase the efficacy of the antibiotics polymyxin and colistin, with a particular focus on their application to prevent biofilm formation of Pseudomonas aeruginosa. The results reveal that the concentrations of polymyxins that are required to effectively inhibit biofilm formation can be dramatically reduced when combined with nisin, thereby enhancing efficacy, and ultimately, restoring sensitivity. Such combination therapy may yield added benefits by virtue of reducing polymyxin toxicity through the administration of significantly lower levels of polymyxin antibiotics.

Keywords: biofilm, colistin, polymyxin, nisin, lantibiotic, P. aeruginosa, bacteriocin, antibiotics

INTRODUCTION

The increasing spread of antibiotic resistance in Gram-negative bacteria, particularly in Pseudomonas aeruginosa, Acinetobacter baumannii and Klebsiella pneumoniae, represents a major global medical challenge (Bergen et al., 2012). Mortality, morbidity, and health care costs are substantially increased as a result of infections caused by these pathogens (Boucher et al., 2009). The situation is exacerbated by the lack of progress with respect to the clinical development of new antibiotics for Gram-negative bacteria over the last few decades (Carlet et al., 2012). These factors have led to a revival in the use of polymyxins to treat recalcitrant infections that are resistant to most or all other currently available antibiotics. In clinical settings, colistin (i.e., polymyxin E) and polymyxin B were initially used to treat numerous infections caused by Gram-negative bacteria, including sepsis, wound infections, urinary tract infection, pneumonia, and catheter-based infections (Landman et al., 2008). Polymyxins exert their antimicrobial action via direct interaction with the lipid A component of the lipopolysaccharide (LPS), resulting in the increased permeability of the bacterial cell membrane (Velkov et al., 2010). Although introduced in the 1950s, colistin and polymyxin B were abandoned in the 1970s due to reports of serious toxic effects, mainly to the kidney and nervous system (Velkov et al., 2013). However, the rapid increase in resistance to all other antibiotics necessitated their re-evaluation and in the 1980s...
colistin was reintroduced to control infection or colonization by *P. aeruginosa* in patients with cystic fibrosis (CF) (Nation and Li, 2009). Despite their relatively recent reintroduction in clinical practice, microbial resistance is already an issue of significance, with reports of the existence of plasmid-borne polymyxin resistance determinants (Liu et al., 2016) potentiating the rapid spread of resistance to these last-line antibiotics. Furthermore, antibiotic therapy by these, and other antibiotics, is hindered by the innate antibiotic resistance of bacteria present in biofilms (complex, sessile communities of bacteria embedded in an organic polymer matrix), making novel anti-biofilm strategies highly desirable (Marcinkiewicz et al., 2013). Approaches to overcome these issues, including drug discovery programs for the development of new polymyxin derivatives that are safer and more efficacious, have met with little success (Velkov et al., 2016). An alternative option is the use of polymyxins in combination with other antimicrobial agents including peptide inhibitors. Indeed, such strategies for peptide-antibiotic combinations to address issues related to prevent and eradicate bacterial biofilms formed by multidrug-resistant bacteria show great promise (Reffuveille et al., 2014; de la Fuente-Núñez and Hancock, 2015). In keeping with this line of enquiry, there has been a particular focus on assessing and enhancing the benefits of applying lantibiotics in clinical settings (Cotter et al., 2013; Field et al., 2015a). Lantibiotics are ribosomally synthesized peptides that are distinguished by the presence of unusual amino acids including lanthionine and/or methyllanthionine (Breukink and de Kruijff, 1999; Bierbaum and Sahl, 2009), and have become the focus of much biomedical and pharmaceutical research due to their high potency in *vitro*, numerous modes of action and capacity to destroy target cells rapidly (Cotter et al., 2005; Cavaera et al., 2015). The most thoroughly investigated lantibiotic is nisin, a 34 amino acid polycyclic peptide that exhibits antibacterial activity against a wide range of clinical and food-borne pathogens that is widely used as a natural biopreservative (Delves-Broughton et al., 1996; Deegan et al., 2006). It has frequently been suggested that the efficacy of nisin could be further improved through combination with other antimicrobials or membrane-active substances (Cavaera et al., 2015; Field et al., 2015b). Indeed, several studies have demonstrated synergistic relationships between conventional antibiotics and nisin. The majority of these studies have involved Gram-positive bacteria such as staphylococci, including methicillin-resistant forms (Piper et al., 2009; Dosler and Gerceker, 2011; Okuda et al., 2013), enterococci (Tong et al., 2014), including vancomycin-resistant enterococci (Brumfitt et al., 2002), and streptococci (Lebel et al., 2013). Nisin-antibiotic combinations have also been shown to be effective against Gram-positive bacterial biofilms (Okuda et al., 2013; Field et al., 2015c). Recent combinatorial nisin-antibiotic investigations have been directed against Gram-negative bacteria. For example, nisin displayed synergistic activity with the antibiotics penicillin, streptomycin, chloramphenicol and rifampicin against *P. fluorescens* (Naghmouchi et al., 2012), and with colistin against *Salmonella choleraesuis, P. aeruginosa, Yersinia enterocolitica, and Escherichia coli* (Naghmouchi et al., 2013). Similarly, nisin-ceftiraxone and nisin-cefotaxime were found to be highly synergistic when applied against clinical isolates of *S. enterica* serovar Typhimurium, as evident by checkerboard and time-kill assays (Rishi et al., 2014). While synergistic *in vitro* activities of antibiotics and antimicrobial cationic peptides in combination against biofilms of *P. aeruginosa* have been demonstrated (Dosler and Karaaslan, 2014), the effects of the prototypical lantibiotic nisin and antibiotic combinations on biofilm formation of Gram-negative bacteria has not been investigated. Here we assess the impact of combining nisin with a variety of clinical antibiotics and establish that nisin exhibits enhanced inhibitory activity in combination with either polymyxin B or colistin. Furthermore, we reveal that the combinations are more effective at inhibiting *P. aeruginosa* biofilm formation compared to when either antimicrobial is used alone. Importantly, the results provide data on effective synergistic concentrations that may allow for the effective clinical use of significantly lower levels of the nephrotoxic antibiotics colistin and polymyxin B.

**MATERIALS AND METHODS**

**Bacterial Strains and Growth Conditions**

*Lactococcus lactis* NZ9700 was grown in M17 broth supplemented with 0.5% glucose (GM17) or GM17 agar at 30°C. *E. coli, K. pneumoniae* and *Pseudomonas* strains were grown in Luria–Bertani (LB) broth [5 g L⁻¹ yeast extract (Oxoid), 10 g L⁻¹ tryptone (Oxoid) and 10 g L⁻¹ NaCl (Merck)], incubated overnight at 37°C and shaken at 170 rpm.

**Minimum Inhibitory Concentration Assays**

Minimum inhibitory concentration (MIC) determinations were carried out in triplicate in 96 well microtiter plates as described previously (Field et al., 2010, 2012). Briefly, target strains were grown overnight in the appropriate conditions and medium, subcultured into fresh broth and allowed to grow to an OD₆₀₀ of ~0.5, diluted to a final concentration of 10⁵ cfu ml⁻¹ in a volume of 0.2 ml. Chloramphenicol, penicillin G, erythromycin, colistin, and polymyxin B (Sigma) were resuspended in LB media to a stock concentration of 128 or 256 µg/ml. The antibiotics were adjusted to 16, 32, 64, or 128 µg/ml starting concentration and twofold serial dilutions of each compound were made in 96 well plates for a total of 12 dilutions. Purified nisin was adjusted to a 100 µM (when using *E. coli, K. pneumoniae, and Pseudomonas putida* as a target) or 200 µM (*P. aeruginosa*) starting concentration and twofold serial dilutions of each peptide were carried out. The target strain was then added and after incubation for 16 h at 37°C and the MIC was read as the lowest peptide concentration causing inhibition of visible growth.

**Nisin Purification**

Nisin was purified according to previously described protocols (Field et al., 2010; Healy et al., 2013). The purified nisin peptide was subjected to MALDI-ToF Mass Spectrometric analysis to confirm purity before use.
Growth Curve Experiments

For growth experiments, overnight cultures were transferred (10^7 cfu ml^{-1} in a volume of 1.0 ml) into LB supplemented with the relevant concentration of nisin A and antibiotic/peptide combinations, and subsequently 0.2 ml was transferred to 96 well microtiter plates (Sarstedt). Cell growth was measured spectrophotometrically over 24 or 48-h periods by using a SpectraMax M3 spectrophotometer (Molecular Devices, Sunnyvale, CA, USA).

Biofilm Formation

Static microtiter plate assays based on a previous study (Kelly et al., 2012), but with modifications to optimize the assay. Briefly, a 1:100 dilution was performed by adding 2 µl of log phase cells (10^7 CFU ml^{-1} of each culture) to 198 µl of LB in wells of a sterile 96-well microtiter plate (Sarstedt, Leicester, UK), giving a starting inoculum of 10^5 CFU ml^{-1}; 200 µl of LB was added to a set of wells as a negative control. All wells were seeded in triplicate. Microtiter plates were then incubated at 37°C for 24 h to allow biofilm formation to occur and Washing (PBS) and staining of wells (0.05% crystal violet) was carried out as described previously (Field et al., 2015c).

Inhibition of Biofilm Formation

Antibiotics (colistin or polymyxin) were added to the microtiter plate wells at 1/2, 1/2×, 1/10×, and nisin peptide at 1/3× or 1/10× and combinations thereof the relevant MIC as previously determined. Log phase cells were added to give a starting inoculum of 10^5 CFU ml^{-1}; all wells were seeded in triplicate. The plate was incubated for 24 h, at 37°C and cell growth measured using a SpectraMax M3 spectrophotometer (Molecular Devices, Sunnyvale, CA, USA). The plates were removed and washing (PBS) and staining of wells (0.05% crystal violet) was carried out as described previously (Field et al., 2015c). Absorbance was measured at 595 nm using a microtiter plate reader (Molecular Devices Spectramax M3, Sunnyvale, CA, USA). Data obtained in triplicate were calculated and expressed as the mean ± standard deviations.

RESULTS

Bacterial Susceptibility to Antimicrobial Compounds

Minimum inhibitory concentration with purified nisin A peptide, as well as a range of antibiotics including penicillin, erythromycin, chloramphenicol, colistin, and polymyxin B, were carried out to establish suitable concentrations for combinatorial studies with nisin against the Gram-negative targets E. coli K12 MG1655, K. pneumoniae NCIMB 13218, P. putida CA-3, and P. aeruginosa PA-01. Activity against the target strains required a relatively high concentration of nisin (50–200 µg/ml). These values were in agreement with data obtained by Naghmouchi et al. (2013) against a panel of Gram-negative strains and, yet again, highlights the relative resistance of Gram-negative bacteria to nisin compared to Gram-positive strains, with some examples of the latter having MICs in the nanomolar (nM) range. E. coli, Klebsiella and Pseudomonas strains were relatively resistant to erythromycin and penicillin but, with the exception of K. pneumoniae NCIMB 13218, were sensitive to chloramphenicol. MICs for colistin and polymyxin B against E. coli K12 MG1655 were in close agreement with previously established figures against strains of E. coli (Corvec et al., 2013). Similarly, colistin and polymyxin B exhibited almost identical activity (Gales et al., 2011) against K. pneumoniae NCIMB 13218 and the Pseudomonas strains and were within previously established ranges (MIC, 2 µg/ml) (Gales et al., 2001).

Growth Curve-Based Comparisons of the Activity of Nisin A and Antibiotic Combinations

Having established the MIC values for nisin A and a range of antibiotics against the representative Gram-negative strains, growth curves were performed in order to reveal the impact of sub-lethal concentrations of nisin A and antibiotics (alone and in combination) on bacterial growth. The final concentration of nisin or antibiotic used for each organism was a fraction of the previously determined MIC value (i.e., 1/2×, 1/3×, 1/4×, etc.) and combinations thereof. It was decided that penicillin and chloramphenicol should be included for combinatorial analysis given previous reports of synergism between these antibiotics and nisin A against strains of Pseudomonas (Naghmouchi et al., 2013). When nisin + penicillin, nisin + erythromycin or nisin + chloramphenicol combinations were employed against E. coli K12 MG1655, K. pneumoniae NCIMB 13218, P. putida CA-3, and P. aeruginosa PA-01, little to no synergistic effects were observed at the sub-inhibitory concentrations used (data not shown). However, pronounced inhibitory effects were observed when colistin or polymyxin B was combined with nisin, compared to the untreated control or when each of the antimicrobials was used alone (Figure 1). In the case of E. coli K12 MG1655, a combination of 1/8× MIC (0.05 µg/ml) colistin or polymyxin and 1/5× MIC (10 µg/ml) nisin A resulted in complete inhibition of growth (Figures 1A,B). Similarly, no growth of K. pneumoniae was observed when 1/2× MIC (0.75 µg/ml) of either colistin or polymyxin was used in combination with 1/3× MIC (16.66 µg/ml) nisin A (Figures 1C,D). Nisin at 1/3× MIC (16.66 µg/ml) had little impact of the growth of P. putida CA-3 when compared to the untreated control (Figure 1F), but no growth was observed over the 36 h period when combined with colistin or polymyxin at 1/4× MIC (0.1 µg/ml and 0.2 µg/ml, respectively). Finally, in the case of P. aeruginosa PA-01, polymyxin and colistin at 1/2× MIC in combination with 1/3× MIC nisin was sufficient to completely inhibit growth (Figures 1G,H).

Inhibition of Biofilm Formation with Purified Nisin A and Antibiotic Combinations

Prior to carrying out combinatorial experiments against biofilms, the biofilm-forming capabilities of the target strains was assessed and all demonstrated the ability to form biofilms as determined...
using 96 well flat-bottomed polystyrene plates and staining with crystal violet (data not shown). We employed the same methodology to study the ability of nisin A and colistin or polymyxin B in combination with nisin, a similar biofilm density was observed compared to the untreated control. However, it was established that combinations of nisin at 1/4 MIC in combination with 1/2 MIC or as little as 1/5 MIC polymyxin B or colistin were able to completely inhibit biofilm formation (**p < 0.001) of P. aeruginosa PA-01 due to the inhibition of growth of the bacteria (Figures 2B,D). Finally, no significant difference in biofilm density was apparent compared to the untreated control for all other combination of nisin and colistin or polymyxin B.

**DISCUSSION**

Infections caused by multi-drug resistant bacteria constitute the leading cause of serious healthcare-associated infections and are responsible for extended periods of hospital stay, severe illness, mortality, and increased economic burden. The polymyxins now play a critical role in the antibiotic arsenal, as they are one of few, and occasionally the sole, antimicrobial agent maintaining efficacy against multi-drug resistant Gram-negative pathogens that frequently cause life threatening infections in the most vulnerable of patient populations. Critically, there are clinical reports confirming that Gram-negative bacteria have developed resistance even to polymyxins (Falagas et al., 2008; Di Pilato et al., 2016), underpinning the necessity for strategies to reduce the effective dose needed for these antibiotics to help prevent or delay the further spread of resistance. The ability of these organisms to form biofilms must also be taken into consideration given the impermeable nature of many biofilms further contributes to resistance. Biofilm suppression can be achieved in three ways, namely: (i) inhibition of the initial planktonic population, (ii) prevention of the initial adhesion of cells to the surface, and (iii) removal of the established biofilm. Because biofilm-associated bacteria are not affected by therapeutically relevant concentrations of antimicrobial agents, anti-biofilm therapies have generally focused on the inhibition of biofilm formation (Dosler and Karaaslan, 2014). Field et al., 2016), underpinning the necessity for strategies to reduce the effective dose needed for these antibiotics to help prevent or delay the further spread of resistance. The ability of these organisms to form biofilms must also be taken into consideration given the impermeable nature of many biofilms further contributes to resistance. Biofilm suppression can be achieved in three ways, namely: (i) inhibition of the initial planktonic population, (ii) prevention of the initial adhesion of cells to the surface, and (iii) removal of the established biofilm. Because biofilm-associated bacteria are not affected by therapeutically relevant concentrations of antimicrobial agents, anti-biofilm therapies have generally focused on the inhibition of biofilm formation (Dosler and Karaaslan, 2014). Here, we set out to examine, for the first time, the ability of nisin, when used in conjunction with a selection of conventional antibiotics and its association with several chronic infectious diseases (Hall-Stoodley et al., 2004). For biofilm prevention studies, colistin, or polymyxin was employed at concentrations 1/2× MIC (10.78, 0.31, and 0.15 μg/ml, respectively) while nisin was used at 1/4× or 1/10× MIC (50 and 5 μg/ml), as well as combinations thereof. Growth was monitored spectrophotometrically (as Absorbance OD595) over 24-h, followed by staining and optical density readings at 595 nm (OD595). Notably, none of the antimicrobials inhibited biofilm formation when used alone (Figures 2B,D). Indeed, although colistin and polymyxin, when utilized at 1/2× MIC, exerted a significant delay in growth (as evident by the extended lag phase) compared to the untreated control (Figures 2A,C), only colistin caused a small reduction in biofilm mass (Figure 2D). When lower concentrations (1/10×) of the antibiotics were used, even in combination with nisin, a similar biofilm density was observed to that of the untreated control. However, it was established that combinations of nisin at 1/4× MIC in combination with 1/4× or as little as 1/5× MIC polymyxin B or colistin were able to completely inhibit biofilm formation (**p < 0.001) of P. aeruginosa PA-01 due to the inhibition of growth of the bacteria (Figures 2B,D). Finally, no significant difference in biofilm density was apparent compared to the untreated control for all other combination of nisin and colistin or polymyxin B.
antibiotics, to control a range of Gram-negative bacteria with the ultimate aim of identifying superior anti-biofilm combinations. Indeed, following MIC determinations and growth curve analysis in the presence of nisin and selected antibiotic combinations, substantial enhanced inhibitory relationships were only observed for nisin in combination with colistin or polymyxin B. The results reveal that sub-inhibitory levels (1/5×MIC and 1/4×MIC for colistin and nisin, respectively) can effectively prevent biofilm formation through total inhibition of growth. Notably, nisin alone had no effect on growth at any of the concentrations utilized. The poor activity of nisin and other lantibiotics toward Gram-negative bacteria is ascribed to the outer membrane (OM) of the Gram-negative cell wall which acts as a physical barrier, impeding the access of the peptides to the cytoplasmic membrane (Nikaido and Vaara, 1985). Indeed, previous studies have confirmed the enhanced efficacy of bioengineered nisin derivatives against Gram-negative bacteria in which the OM no longer functions as an impenetrable barrier following treatment with Polymyxin B nonapeptide (PMBN; Field et al., 2012). The potential benefits associated with identifying antibiotics that function synergistically with nisin are manifold. While antibiotic resistance has become a major obstacle, significant resistance to nisin outside of the laboratory has yet to be reported despite its widespread use as a food preservative (Breukink and de Kruijff, 1999) and thus the use of nisin-antibiotic combinations may prevent/overcome the emergence of resistance. Indeed, such approaches appear particularly promising for combinations of antimicrobials that target different sites. Additionally, combination therapy may permit the dose of the individual antimicrobials to be reduced and consequently counteract the development of drug-resistance in bacteria. Furthermore, the opportunity also exists to combine nisin and colistin/polymyxin with other antibiofilm agents including quorum sensing (QS) inhibitors such as polyphenolic compounds (baicalin hydrate, epigallocatechin) or enzymes for signal molecule destruction that affect biofilms.
via non-microbialic mechanisms, but instead target specific molecular pathways that regulate biofilm formation (Brackman and Coenye, 2015). For example, Human HDP LL-37 and the bovine neutrophil peptide indolicidin have previously been shown to prevent P. aeruginosa PAO1 biofilm formation at sub-inhibitory concentrations by downregulating the genes essential for cell attachment and biofilm formation (Overhage et al., 2008). Similarly, the antibiotics azithromycin and ceftazidime demonstrated inhibitory effects against P. aeruginosa biofilm through the downregulation of a range of QS-regulated virulence factors and adhesion activities (Skindersoe et al., 2008).

CONCLUSION AND PERSPECTIVES

The incidence of multi-drug resistant bacteria continues unabated despite the best efforts of antimicrobial stewardship and stringent infection control practices in hospitals. In addition to the urgent demand for newer antibiotics, imaginative, and judicious approaches are required to protect the efficacy of the current last resort compounds. The data presented here demonstrates the potential for nisin and conventional antibiotic combinations to act as potent antimicrobial and anti-biofilm agents against Gram-negative pathogens including P. aeruginosa. The enhanced activities of combinations of nisin A with both colistin and polymyxin B observed here for the first time to prevent P. aeruginosa biofilm formation has significant implications for their future use as novel therapeutics in the treatment of multi-drug resistant bacteria. Furthermore, these data reinforce the idea that bacteriocins can form a novel strategy to prevent adhesion and to control biofilm formation by clinically relevant pathogens and ultimately may facilitate the use of lower concentrations of polymyxin antibiotics in situations where the levels currently exercised are of concern to a toxicity standpoint.

AUTHOR CONTRIBUTIONS

DF and NS contributed equally to the manuscript. Conceived and designed the experiments: DF, PC, CH, and RR. Performed the experiments: NS and DF. Analyzed the data: DF, NS, PC, and CH.
