Increasing resistance of Pseudomonas aeruginosa (P. aeruginosa) to conventional treatments demands the search for novel therapeutic strategies. In this study, the antimicrobial activity of dehydroleucodine (DhL), a sesquiterpene lactone obtained from Artemisia (A.) douglasiana, was screened against several pathogenic virulence effectors of P. aeruginosa. In vitro, minimum inhibitory concentration of DhL was determined against P. aeruginosa strains PAO1, PA103, PA14, and multidrug resistant clinical strain, CDN118. Results showed that DhL was active against each strain where PAO1 and PA103 showed higher susceptibility (MIC 0.48 mg/mL) as compared to PA14 (MIC 0.96 mg/mL) and CDN118 (MIC 0.98 mg/mL). Also, when PAO1 strain was grown in the presence of DhL (MIC50, 0.12 mg/mL), a delay in the generation time was noticed along with significant inhibition of secretory protease and elastase activities, interruption in biofilm attachment phase in a stationary culture, and a significant decline in Type III effector ExoS. At MIC50, DhL treatment increased the sensitivity of P. aeruginosa towards potent antibiotics. Furthermore, treatment of P. aeruginosa with DhL prevented toxin-induced apoptosis in macrophages. These observations suggest that DhL activity was at the bacterial transcriptional level. Hence, antimicrobial activity of DhL may serve as leads in the development of new anti-Pseudomonas pharmaceuticals.

1. Introduction

Pseudomonas aeruginosa (P. aeruginosa) is a Gram-negative opportunistic pathogen with a high prominence of intrinsic antibiotic resistance [1]. Resistant strains of P. aeruginosa are commonly found as a secondary infection in immune-compromised patients with cystic fibrosis, COPD, AIDS, and cancer and even among diabetics [2–4], leaving serious blood stream infection with significant mortality and healthcare costs [5]. The success in establishing P. aeruginosa pathogenicity is largely due to formation of intractable biofilm and secretion of myriads of virulent factors including LasA protease, LasB elastase, pyocyanin, pyoverdin, Type III secretion (T3S) effectors, and alginate [6–9]. Unfortunately, selection of the most appropriate antibiotic is complicated due to the ability of P. aeruginosa to develop resistance to multiple classes of antibiotics.

P. aeruginosa can develop resistance to antibiotics because of the low permeability of its outer membrane, the constitutive expression of various efflux pumps [10], and the naturally occurring chromosomal AmpC β-lactamase, turning it resistant toward penicillin G, aminopenicillins, and first- and second-generation cephalosporin [11]. P. aeruginosa easily acquires additional resistance mechanisms, which leads to serious therapeutic problems [12]. Currently, antipseudomonas treatments include higher-than-usual doses of β-lactam, fluoroquinolones, and amino glycosides, which possess a high degree of toxicity and very low eradication rate [13]. The dearth of successful antibiotics to completely control P. aeruginosa infection makes it crucial to finding alternatives.
to currently available drugs. Since the pathogenicity of *P. aeruginosa* is regulated by several secretory-systems mediated cell-to-cell communications, inhibition of this system can cause attenuation of virulence and protect against infection [14, 15].

Artemisia, the largest diverse genera of Asteraceae family, possesses medicinally valuable essential oils and secondary metabolites [16, 17]. Many studies indicate antimicrobial activity in *Artemisia (A.)* spp. [18–20]. *A. douglasiana* is well documented as preventive folk medicine in Argentina [21]. Dehydroleucodine (DhL), a sesquiterpene lactone of the guaianolide group, is one of the principal active secondary metabolites in *A. douglasiana* [21]. DhL, first isolated from *Lidbeckia pectinata* [22], possesses cytoprotective activity [23] as well as antimicrobial activity against several pathogens [24–27].

In this study, we tested the antibacterial activity of DhL and against *P. aeruginosa* virulence. At first we evaluated the minimum inhibitory concentration (MIC) and its synergistic effect on other commercial antibiotics, and then we examined the antipseudomonal properties of this phytochemical in terms of arresting growth and attenuating virulent factors such as biofilm formation and secretion of Type III effectors, elastase A, and elastase B. We also assessed the capacity of this phytocompound to inhibit *P. aeruginosa* induced host cell toxicity.

2. Material and Methods

2.1. Reagents. Dehydroleucodine was extracted from *A. douglasiana* (Voucher specimen 2012-1018-F, Fairchild Tropical Botanical Garden, Miami, FL) as previously documented [21, 28]. DH-DhL was prepared as described previously [21]. All chemicals and reagents were purchased from Sigma-Aldrich (St. Louis, MO), unless otherwise indicated. Primary and secondary antibodies used in immunoblotting were purchased from Cell Signaling Technology Inc. (Danvers, MA). Culture supplies were purchased from Invitrogen Life Technologies (Carlsbad, CA). Prototypic *P. aeruginosa* strains used in this study are PAO1, clinical isolates PA103 and PA14 (kindly provided by Dr. Dara Frank, University of Wisconsin, Madison), and *P. aeruginosa* strain PA103ΔUAΔT, expressing pUCP plasmid-encoded ExoS tagged with a hemagglutinin epitope (ExoS-HA) (kindly provided by Dr. Joan C. Olson, West Virginia University). In addition, *Staphylococcus aureus* (ATCC 12600) was used in the LasA assay. Cells were maintained in Luria Broth (LB) (Life Technologies, Carlsbad, CA) or *Agrobacterium* (AB) minimum medium (Bio-World, Visalia, CA) to which glucose and casein amino acids [20%, wt/vol] were added.

2.2. Determination of Minimum Inhibitory Concentration (MIC) and Minimum Bactericidal Concentration (MBC). The minimum inhibitory concentration of DhL was determined by micro dilution broth assay [12] for PAO1, PA103, PA14, and CDNI18 strains of *P. aeruginosa*. Serial doubling dilution of DhL was made, ranging from 2.24 mg/mL to 0.224 μg/mL. Twenty (20) μL of standard inoculums (0.5 McFarland) of all three *P. aeruginosa* strains was introduced to desired volume of growth medium and incubated at 37°C for 18 hr. Controls were set up as follows: (1) sterility control: LB broth only; (2) growth control (negative): LB broth + bacteria; (3) positive control: LB broth with Gentamycin; (4) vehicle control: LB broth + bacteria + DMSO. MIC was interpreted as the least concentration with no observable turbidity. Optical density readings (λ = 600 nm) were taken using microplate reader at 0 and 18 hr. MIC<sub>50</sub> and MIC<sub>90</sub> were determined as the concentration of DhL that inhibited bacterial growth by 90% and 50%, respectively. Results were reported as the MIC, MIC<sub>50</sub>, and MIC<sub>90</sub> for growth at 18 hr after inoculation.

Minimum bactericidal concentration (MBC) was recorded as a lowest extract concentration killing 99.9% of the bacterial inocula after 24 h incubation at 37°C. Each experiment was repeated at least three times. MBC values were determined by removing 100 μL of bacterial suspension from subculture demonstrating no visible growth and inoculating nutrient agar plates. Plates were incubated at 37°C for a total period of 24 h. The MBC is determined with the wells whose the concentrations are ≥ MIC [29]. According to the ratio MBC/MIC, we appreciated antibacterial activity. If the ratio MBC/MIC is 1 or 2, the effect was considered bactericidal but if the ratio MBC/MIC is 4 or 16, the effect was defined as bacteriostatic [30].

For each assay 0.12 mg/mL (MIC<sub>50</sub>) of DhL was added to *P. aeruginosa* culture at early log phase unless otherwise stated. The effect of DhL on bacterial cell proliferation was determined by monitoring the growth curve of *P. aeruginosa* strain PAO1. Briefly, an overnight culture (in LB medium) of PAO1 was diluted to OD<sub>600</sub> 0.05 in LB medium (control) or control and DhL (0.12 mg/mL) and incubated at 37°C while shaking. The OD<sub>600</sub> was monitored at 30 min intervals until OD<sub>600</sub> of approximately 1.7 was obtained (approximately 8 hr). All OD<sub>600</sub> measurements were verified at a 1/10 dilution for greater accuracy.

2.3. Determination of Antibiotic Synergy with DhL by the E-Test Strip. Bacterial suspensions (PAO1) homogenized in sterile saline were prepared from overnight fresh cultures to a McFarland standard of 0.5 and were spread with a sterile cotton swab on 150 mm Mueller-Hinton agar control and containing DhL (MIC<sub>50</sub>) plates. The agar plates were allowed to stand for 15–20 min at room temperature to allow any excess surface moisture to be absorbed before placement of MIC test strips. Antibiotic gradient strips (E-test, Liofilchem, Italy) containing Gentamycin (concentration range 0.016–256 mg/L), Ciprofloxacin (concentration range 0.002–32 mg/L), or Chloramphenicol (concentration range 0.016–256 mg/L) were then used; the MHA plates with the over layered strips were incubated at 37°C or 24 hr, and the growth inhibition zones were measured. Differences in MIC values between the control and test plates were recorded (end points were determined according to the manufacturer’s instructions).

The Muller Hinton agar (MHA) dilution method was used to evaluate the Fractional Inhibitory Concentration Index (FICI) of DhL with Chloramphenicol on PAO1 being
tested following previously established protocol [31, 32]. Eight serial twofold dilutions of DhL were prepared as described before, to obtain final concentration range of 2.24 mg/mL–0.224 μg/mL. A series of twofold serial dilutions of Chloramphenicol was also prepared similar to DhL. All antibacterial standards dilutions were mixed with the appropriate concentration of DhL compounds thus obtaining a series of the combinations of Chloramphenicol and DhL. The concentrations prepared corresponded to 1, 1/2, 1/4, 1/8, 1/16, 1/32, 1/64, 1/128, and 1/256 of MIC values. The 96-well plate containing 100 μL of Mueller Hinton (MH) broth was used. For bacteria strain PAO1, three columns of eight wells of 96-well plate were used. Each well received the culture medium + combination of DhL with Chloramphenicol + inoculum (10 μL of inocula) and INT (sigma-Aldrich, St. Louis, MO) (50 μL; 0.2 mg/mL). The plates were covered and incubated at 37°C for 24 hr. All tests were performed in triplicate and the bacterial activity was expressed as the mean of inhibitions produced. Inhibition of bacterial growth was judged by rose or yellow color. The analysis of the combination of DhL and Chloramphenicol was obtained by calculating the Fractional Inhibitory Concentration Index (FICI) as follows: FICI = (MIC of the combination of DhL and Chloramphenicol/MICa alone) + (MIC of the combination of DhL and Chloramphenicol/MICb alone), where MICa is Minimal Inhibitory Concentration of DhL and MICb is Minimal Inhibitory Concentration Chloramphenicol. The FICI was interpreted as follows: (1) a synergistic effect when FICI < 0.5; (2) an additive or indifferent effect when FICI > 0.5 and <1; and (3) an antagonistic effect when FICI > 1.

2.4. LasA and LasB Activities. Staphyloccytic activity of LasA was determined spectrophotometrically by measuring the decrease in absorbance at 595 nm (OD595) due to lysis of heat inactivated Staphylococcus aureus (S. aureus) cells (0.3 mg/mL; 0.02 M Tris-HCl, pH 8.5) upon addition of PAO1 culture supernatants [34]. One hundred (100) μL aliquot of P. aeruginosa culture supernatant with or without DhL (after normalizing the supernatant total protein concentration) was added to 900 μL of a boiled S. aureus suspension. The OD595 was determined after 0, 5, 10, 20, 30, 45, and 60 min, respectively. Activity was expressed as the difference in absorbance unit/min.

Elastolytic activity of LasB in PAO1 culture fluids was determined by elastin Congo red (ECR) assay [35]. One hundred (100) μL aliquot of the AB medium culture supernatants from mid log phase with or without DhL treatment (concentration was normalized) was added to 900 μL of ECR buffer (100 mM Tris-HCl, 1 mM CaCl2; pH 7.5) containing 20 mg ECR. Tubes were incubated for 18 hr at 37°C with rotation and then were placed on ice after 0.1 mL of 0.12 M EDTA was added. Insoluble ECR was removed by centrifugation, and the OD595 was measured. Absorption due to pigments produced by P. aeruginosa was corrected for by subtracting the OD495 of each sample that had been incubated in the absence of ECR. Cell-free AB medium alone and AB medium with DhL were used as negative controls.

2.5. Relative Gene Expression Analysis of LasR. Total mRNA was purified from mid log phase PAO1 (106 cells/mL) untreated or after DhL treatment using QIAGEN RNaseasy mini kit (QIAGEN, Valencia, CA) and quantified following standard techniques. cDNA was synthesized from 1 μg of mRNA using iScript Supermix (Biorad, Hercules, CA). Real time PCR was performed in triplicate: each sample using Biorad CFX96 Real Time System (Biorad, Hercules, CA) and SsoAdvanced SYBR Green Supermix (Biorad, Hercules, CA) with the primers for LasR (5’-GAAAATGGCTGGTTTCCGGCCACAAC-3’ and 5’-AGGCCATAAGCGCTACGGTTCTTT-3’) and gyrB (DNA-gyrase subunit B: 5’-TGCTGGATGCCGTACGCAAGC-3’ and 5’-TATCCACCGGAAATACCGGCTCATTGTGCC-3’). Relative gene expression was determined using the 2−ΔΔCT method [36]. Mean CT of triplicate measures was calculated for each sample. Sample mean CT of gyrB (internal control) was subtracted from the sample mean CT of the respective gene of interest (ΔCT). The ΔCT of the sample with no treatment was selected as the baseline and subtracted from the mean ΔCT of each experimental sample (ΔΔCT). 2−ΔΔCT yields fold change in gene expression of the gene of interest normalized to the internal control gene expression.

2.6. Polyvinyl Chloride Biofilm Formation. The effect of DhL on the attachment phase of biofilm formation was measured by using the polyvinyl chloride biofilm formation assay [37]. Briefly, overnight cultures of PAO1 were resuspended in fresh AB medium in the presence and the absence DhL. After 24 hr of incubation at 30°C, the biofilms in the polyvinyl chloride microtiter plates were visualized by staining with a crystal violet solution. Plates were rinsed once to remove planktonic cells, and then attached cells to the surface were quantified by solubilizing the dye in ethanol by measuring the absorbance at OD566.

2.7. Type III Secretion Assays. Low calcium fractionation protocol was adopted for the detection of Type III secretion effectors [8]. Briefly, P. aeruginosa PAO1, PAI03AUΔT (control), and PAI03AUΔT expressing HA-ExoS were grown overnight in LB. Bacteria were then subcultured 1:1,000 in LB supplemented with 5 mM EGTA with or without DhL and grown for 6 hr at 37°C with aeration. Bacterial densities were determined at OD600. Bacteria were sedimented by centrifugation at 3,220 ×g for 15 min at 4°C.

Culture supernatant was collected, and proteins were precipitated with 5% trichloroacetic acid and washed once with ice-cold acetone. Proteins were resuspended according to culture density and separated by SDS-PAGE. Proteins derived from precipitated PAO1 supernatant were run on SDS-PAGE and then either stained with Coomassie blue or transferred onto nitrocellulose membranes as described below.
2.8. Immunoblotting Analysis. Samples (treated and non-treated with DhL) were resuspended in sample buffer and then separated by SDS-PAGE, transferred onto nitrocellulose membranes (Biorad Laboratories, Hercules, CA, USA), and incubated with antibodies specific to HA-epitope tag for 2 hr at room temperature. Subsequently, membranes were incubated with the appropriate horseradish peroxidase-conjugated secondary antibodies. A Super Signal West Pico chemiluminescent substrate kit (Pierce/Thermo Fisher Scientific, Inc., Rockford) was used to visualize protein bands. Band densities from Western blots were quantified using the ImageJ64 software at a gray-scale amplification of 600 dpi.

2.9. *P. aeruginosa* Mediated Apoptosis of Macrophage Cells. The effect of DhL treatment on *P. aeruginosa* mediated apoptosis of J774-Eclone mouse macrophage cell was monitored as previously described [38]. J774-Eclone cell monolayer was plated from suspension culture 1 day prior to infection in DMEM supplemented with 5% FBS (DMEM-5%FBS). Cell monolayer (5 × 10^5 cells per well; >80% confluence) was washed with phosphate-buffered saline (PBS), mixed with either DhL treated or DhL-untreated PAO1 bacteria at a multiplicity of infection (MOI) of 20 and incubated for 2 hr at 37°C in a 5% CO₂ incubator. The cells were washed with PBS to remove the nonadhering bacteria. Fresh DMEM containing 5% FBS was supplemented with 400 μg/mL of Gentamycin and then added to cells for an additional 2 hr to kill any unwashed *P. aeruginosa*. As positive control for the apoptosis, J774-Eclone cells were incubated with 0.1μM of Staurosporine (Fischer Scientific, Waltham, MA) for 1 hr. Cells were washed once with PBS and stained with 1 mg/mL Hoechst 33258 (Molecular Probes, Inc., Eugene, OR) for 10 min in the dark as described in Section 2. Chromatin condensation was examined under the fluorescence microscope by using a DAPI (4, 6-diamidino-2-phenylindole) filter after stained cells were mounted onto slides using mounting medium.

2.10. Statistical Analysis. All experiments were performed independently in triplicate and each experiment was repeated three times. Values represent the mean ± SEM of three independent experiments. Data were analyzed by Mann-Whitney *U* test with a significance threshold value of 0.05, by using the SPSS (Chicago, IL) statistical software package.

3. Results

We first examined the antibacterial effects of DhL against several *P. aeruginosa* strains (PAO1, PA103, PA14, and clinical strain CDN118, a multidrug resistant strain) with varying concentrations of DhL ranging from 2.24 mg/mL to 0.224 mg/mL. As displayed in Table 1, DhL inhibited 50% of PAO1 and PA103 population at 0.12 mg/mL whereas 0.48 mg/mL of DhL successfully inhibited 50% of PA14 population. The minimum inhibitory concentration that is the lowest concentration of the DhL solution required to completely inhibit the growth of the *P. aeruginosa* was 0.48 mg/mL for PAO1 and PA103 as compared to 0.96 mg/mL for the more virulent strain PA14 (Table 1). However, for the clinical strain DhL MIC was 0.28 mg/mL (Table 1). The bactericidal and bacteriostatic effect of DhL was determined by MBC/MIC (Table 2). The antimicrobial effect of DhL is prominent against all strains of *P. aeruginosa* tested here, although strains PAO1 and PA103 seemed to be more susceptible to DhL than PA14 and clinical strain CDN118. We then determined whether DhL activity at MIC<sub>50</sub> concentration was effective to slow down the bacterial growth in vitro in a time-dependent manner. We found that the ideal growth phases of PAO1 represented a log phase during the first 150 min and then a stationary phase with OD<sub>600</sub> 1.7 that remained until 360 min (Figure 1). Treatment with DhL at MIC<sub>50</sub> concentration (0.12 mg/mL) declined the slope of log phase that ended at 270 min of culture, which then turned to stationary phase at a very low OD<sub>600</sub> (i.e., 0.7). Noticeable difference in generation time (50±5%) was observed between 1 and 3 hr of growth (mid log phase) between treated and untreated PAO1 (Figure 1). Treatment at MIC<sub>90</sub> failed to portray normal growth curve (data not shown).

Several studies have suggested that combining plant- or animal-derived natural compounds with antibiotics is a new strategy for developing therapies against infections [39–41]. We report that the antimicrobial activities of commercial antibiotics are enhanced by pretreating *P. aeruginosa* with 0.12 mg/mL DhL. MIC values were decreased by the coactions of DhL with gentamicin (aminoglycoside), Chloramphenicol and Ciprofloxacin (fluoroquinolone), Figure 2. To further
Figure 1: DhL inhibits growth of P. aeruginosa. (a) Chemical structure of DhL. (b) P. aeruginosa PAO1 strain was grown in the absence (○) and presence (●) of 0.12 mg/mL DhL from early log phase to stationary phase (1.7 hr) at 37°C with constant shaking. Generation time (between 1 and 3 hr) of PAO1 in presence of DhL (calculated from three independent experiments) was 64 ± 5 min whereas it was 35 ± 5 min in the control PAO1 culture. Data represent the mean of three independent experiments ± SEM.

Figure 2: Synergistic effect of DhL with systemic antibiotics. (a) Table represents synergistic activity of subinhibitory concentration of DhL and antibiotics belonging to various classes determined by the E-test strip/agar dilution method against PAO1. (b) A control plate (MHA) with Chloramphenicol E strip. (c) A Chloramphenicol E-test plate (MHA) with DhL at a dilution of MIC<sub>50</sub> concentration.

confirm the combined effect of DhL and conventional antibiotics we calculated the FICI for DhL and Chloramphenicol combination on PAO1 (Table 3). Overall the observations from both assays demonstrated significant antibacterial synergy activities of DhL on P. aeruginosa.

Elastase A and elastase B (LasB) are effectors of Type II secretion system in P. aeruginosa and are major virulent factors in lung infection, often related to high death rate in acute pneumonia [42]. The elastase properties of LasA and protease activity of LasB play a major role in P. aeruginosa pathogenesis [43,44]. LasB secretion is a prominent virulence factor in cystic fibrosis lung infection [45], which is known to degrade elastin and collagen in host [46]. To investigate the effect of DhL on LasA and LasB activities, P. aeruginosa.
strain PAO1 was incubated with DhL at 0.12 mg/mL (MIC50) as described in Section 2. PAO1 cultural supernatant showed an exponentially increasing staphyloytic effect indicating protease activity when compared to S. aureus concentration in LB as a control (Figure 3(a)). A significant decrease (89 ± 3%) in LasA activity (Figure 3(a)) was observed after 60 min of incubation of S. aureus substrate along with the DhL treated P. aeruginosa strain PAO1. Furthermore, significant decrease of 75 ± 5% in LasB activity was also observed when PAO1 was grown in the presence of DhL (Figure 3(b)). In parallel control studies, DhL along with S. aureus in absence of PAO1 did not show any LasA activity as well as DhL and LB alone did not show elastase activity (data not shown). In both experiments, PAO1 cultures grown in presence or absence of DhL were normalized so that the total number of bacteria remained the same.

LasR is a transcription regulator of LasA and LasB gene [43, 47]. The mRNA expression level of LasR in PAO1 population from mid log phase reduced fivefold after DhL treatment (Figure 3(c)). These results indicated DhL effectively inhibited both LasA and LasB activity in PAO1 population by controlling transcription regulator in live bacteria, and the absence of such virulent activities was not due to loss of bacterial viability.

P. aeruginosa has the ability to form biofilms, in which cells are organized into layers and enmeshed in a matrix of mucoid polysaccharides [48]. P. aeruginosa biofilms are linked to quorum sensing behavior [48, 49] by using two distinct acyl-homoserine lactone [3]. Biofilm-grown bacterial cells show increased resistance to antibiotics [48]. To determine whether DhL could prevent biofilm formation, P. aeruginosa strain PAO1 was incubated in the absence or in the presence of DhL and then the generation of biofilms was quantified as described in Section 2. Results indicated a significant decrease of 55 ± 5% in biofilm formation (Figure 4) in DhL treated PAO1 compared to the control, suggesting an inhibitory effect of DhL on P. aeruginosa biofilm formation.

T3S system is a complex multiprotein apparatus that facilitates the secretion and translocation of effector proteins such as ExoS, ExoT, ExoU, and ExoY from the cytoplasm of bacterial cell to the cytoplasm of mammalian cells. Active T3S system is significantly associated with acute infections, extreme clinical outcomes, and death in patients infected with P. aeruginosa [50]. ExoS and ExoT are bifunctional proteins with Rho-GAP and ADP-ribosylation activity whereas ExoU is a potent phosphor lipase and ExoY is adenylate cyclase [9]. In animal infection models mimicking P. aeruginosa mediated acute human infections, such as burn wounds, acute pneumonia, and corneal infection, it was shown that T3S is an important virulence mechanism [51, 52]. To determine whether DhL inhibits the T3S system-mediated secretion of effector proteins such as ExoS, P. aeruginosa strain PAO1 was incubated in the absence or in the presence of DhL under T3S system-inducing conditions (see Section 2). The secreted effectors were analyzed on SDS-PAGE as described in Section 2. DhL inhibited the secretion of ExoS in PAO1 by at least 95% (Figure 5 (top panel)). To further confirm this result, presence of ExoS was screened in the secretion profile of PA103ΔUΔT: HA-ExoS strain, carrying HA-tagged ExoS, in the absence or in the presence of DhL. The secretion of HA-tagged ExoS was probed with immunoblotting using specific anti-HA antibody. These results indicated that DhL blocked the secretion of HA-ExoS (Figure 5 (bottom panel)).

Several Studies have suggested that T3S system effectors from P. aeruginosa are responsible for inducing rapid apoptosis in macrophage cells and epithelial cells [49]. In an effort to support our previous observation, antimicrobial activity of DhL was tested in a cellular activity assay for T3S system effector translocation into mammalian cells [53]. P. aeruginosa PAO1 strain was added to 774-Eclone cell monolayer at MOI of 20:1 in the absence or in the presence of DhL as described in Section 2. After 2 hr of incubation at 37°C, cells were stained with Hoechst stain and apoptotic nuclei were observed under fluorescent microscope. The total percentage of apoptotic cell counted suggests that DhL treated P. aeruginosa PAO1 strain fails to induce apoptosis significantly when compared to untreated PAO1 induced apoptosis (control). Almost 87 ± 5% inhibition of apoptosis was observed in PAO1 population previously treated with DhL (Figure 6). As a positive control of apoptosis we have treated 774-Eclone cells with Staurosporine (see Section 2).

Together, these results demonstrate that DhL suppresses the T3S system-mediated secretion of effectors from PAO1 as well as the translocation of effectors into the target mammalian cells.

### 4. Discussion

P. aeruginosa represents a wide number of strains with strong pathogenic capacity and has developed a number of strategies to affect and invade the host cell. PAO1 strain of P. aeruginosa is the standard laboratory strain as well as genetic reference strain [33]. PA14, a "multihost" pathogen, is capable of infecting animals (in a burned mouse model), plants, insects, and nematodes [54]. Both strains were able to initiate and maintain chronic infection in rat lung model [55]. Exotoxin-U producing strain, PA103, is cytotoxic strain of P. aeruginosa, which is known to cause severe alveolar epithelial injury during infection [56]. In this study, we have demonstrated that DhL is bacteriostatic for virulent strains of Pseudomonas aeruginosa, PA14, and CDNI18 [57, 58] but bacteriocidal for less virulent strains PAO1 and PA103 of P. aeruginosa.
When PAO1 strain was treated with sub-MIC dose of DhL (MIC<sub>50</sub> = 0.12 mg/mL) and inoculated in growth medium, a significantly reduced (50 ± 5%) generation time was observed. Such treatment also modified the susceptibility of P. aeruginosa toward potent antibiotics and lowered the MIC of systemic antibiotics. A combination of sub-MIC levels of DhL and antibiotics can help reduce undesirable side effects from routine antibiotic dosage. The FICI assay of DhL with conventional antibiotic on PAO1 strain showed significant synergistic effect.
DhL treatment also inhibited several virulence factors in PAO1 at the threshold dose of 0.12 mg/mL. PAO1 cultural supernatant treated with DhL showed 89 ± 3% decrease in LasA activity and 75 ± 5% reduction in LasB activity. Significantly low mRNA expression of transcription regulator LasR corroborates with the activity status as well. It is important to note that the virulence mechanisms in P. aeruginosa are highly controlled by transcription factors and regulators. It is well documented that LasA and LasB transcription activation requires LasR gene products [33].

DhL treated PAO1 culture failed to demonstrate successful initial attachment phase during the course of biofilm formation and prolonged observations revealed disruption in biofilm formation compared to untreated PAO1 culture (data not shown). Inhibitory effects of DhL were also poignantly observed in P. aeruginosa T3S system that successfully restrained secretion of important T3S effectors such as ExoS, ExoT, ExoY, and ExoU. Overall, the results indicated a prominent regulation of P. aeruginosa growth and virulence due to DhL treatment in vitro. Finally, when DhL treated P. aeruginosa was cocultured with mouse macrophage cells, the typical PAO1 induced cellular apoptosis was successfully controlled, reinforcing the active inhibition of T3S system virulence which otherwise leads to cytotoxicity.

Although the exact mechanism of DhL mediated suppression of P. aeruginosa virulence is still under investigation, it is likely that DhL imparts a direct effect within the bacterial cells rather than extracellular substances and mucoid layers of biofilm. Previous studies suggested that the α-methylene-γ-lactone moiety in sesquiterpene lactones like DhL exerts its biological activities by Michael-type additions attacking nucleophiles. The modified nucleophiles react reversibly with sulfhydryl groups in the cell such as transcription factors [59, 60]. To confirm the functional properties of DhL, we utilized a DhL derivative, which is a mixture of two epimers (11S)DH-DhL and (11R)DH-DhL [21]. DH-DhL epimers which are devoid of the highly reactive α-methylene-γ-lactone moiety failed to show any significant antipseudomonal activity at similar concentration to DhL (0.24 mg/mL).

Due to high mutation rate in bacterial genome, P. aeruginosa is extremely difficult to eradicate from mucoid colonies [61]. Therefore, alternatively antivirulence therapy to prevent P. aeruginosa invasion holds strong grounds against development of bacterial resistance [15, 62]. The success of DhL against several virulence effects of P. aeruginosa in this study can lead to new treatment strategies and could also pave the way to the reduction of the amount of antibiotics required.
The presence of DhL. Data represent the mean of three independent treatments. Significant (asterisk indicates *P < 0.05) decrease in apoptotic cells was noticed when infected with PAO1 grown in LB-DhL (MIC<sub>DhL</sub>, 0.12 mg/mL) or only LB, at a multiplicity of infection of 20, and incubated for 2 hr at 37°C in a 5% CO<sub>2</sub> incubator. In a parallel experiment an equal number of J774-Eclone cells was subjected to 1 µM Staurosporine for positive control. Cells were then washed with PBS, stained with Hoechst dye, and subjected to fluorescence microscopy (Section 2). Five fields were randomly sampled from each experimental population, and all of the cells stained with Hoechst dye in each field were counted up to 500 in total. The total number of apoptotic cells with condensed or fragmented nuclei was determined in the five sampled regions and was expressed as follows: percentage of apoptosis per sample: number of apoptotic cells/total number of cells × 100. Each column is the mean of three individual experiments with two replicates per treatment. Significant (asterisk indicates *P < 0.05) decrease in apoptotic cells was noticed when infected with PAO1 grown in presence of DhL. Data represent the mean of three independent experiments ± SEM.

Conflict of Interests

The authors declare that there is no conflict of interests regarding the publication of this paper.

Acknowledgments

The authors acknowledge Florida International University for financial support. They thank Dara Frank and Dr. Joan, C. Olson for reagents and <i>P. aeruginosa</i> strains.
